To explore these issues, we introduce three clients from the range of many that have worked with the School of Geography, University of Leeds and with GMAP (see Section 3.2). Each client had/has very different requirements in terms of store location research. Two of these are drawn from the financial services industry. The first client is the State Bank of South Australia. This is an example of the most straightforward use of spatial interaction modelling: the desire to use the models to evaluate a number of what-if proposals concerning new branch openings. This application is described in Section 3.3. The second client is a leading financial organisation based in the north of England whose spatial analysis requirements were built around two major issues. The first issue was the impact of new branch openings on its existing client base. This involved a much greater consideration of the success of the models for impact assessment. Second, was the desire to locate a network of automatic telling machines (ATMs) in good or 'optimal' locations. There was also a third concern regarding the evaluation of potential mergers and acquisitions from the perspective of the combined branch network that might be inherited: however, this is dealt with in detail elsewhere (Birkin *et al.*, 2002b). These objectives require a much more critical look at the traditional spatial interaction models typically used for such analyses. The issues these applied problems raised are addressed in Section 3.4. Finally, in Section 3.5, we review an area deemed to be extremely difficult to model – namely the petrol market. Here, the client is Exxon/Mobil. The switch from a traditional modelling approach to a multivariate approach is discussed with reference to the very difficult issues that the petrol market brings to spatial interaction modelling.

3.2 Background to Commercial Modelling

For 20 years, GMAP Limited has successfully applied geographical modelling tools within a business planning context. Clients of GMAP include retail organisations in the broadest sense, from supermarkets (Asda-Walmart, Iceland), high street multiples (Dixons, W.H. Smith) and out-of-town retailers (IKEA, MFI), to travel

agents (Thomas Cook), petrol companies (BP, Exxon/Mobil), banks (Halifax, Alliance & Leicester) and automotive manufacturers and distributors (Ford, Toyota, Volvo, Mazda). The intellectual foundations of this applied research programme reside in the 1960s and 1970s, when gravity and spatial interaction models found widespread application in transportation and land-use planning, and in planning assessments of retail impact analysis (e.g., Boyce *et al.*, 1970, for examples of the former; Foot, 1981, for a review of the latter: see also Clarke and Stillwell, this volume). At this time, however, there was little or no commercial awareness or interest in these models.

Interest in commercial applications of spatial interaction models was more obvious in the 1980s and early 1990s for a number of reasons. From a retail point of view, markets were increasingly competitive, and tending towards saturation, making profitable new sites increasingly difficult to find. From a methodological perspective, the increased availability of data (about customers, markets and competitors), of PCs to process and distribute the data, and of geographical information systems (GIS) for the analysis of data, were all factors providing an impetus to market analysis. These factors were supplemented by an economic boom in the 1980s which led many UK companies to want to expand their networks. This increased interest in modelling was manifest in a number of ways:

- provision of spatial interaction modelling capabilities as standard within GIS systems (e.g., ARC/Info);
- development of specialist market analysis software (e.g., InSite, Environ, MicroVision) by business consultants; indeed, some of these business consultants were new to the scene, specialising in spatial modelling (e.g., GMAP, Geobusiness Solutions); and
- creation of dedicated site analysis and modelling departments within major retail organisations (e.g., Tesco, Marks and Spencer, J. Sainsbury, Whitbread).

There is a reasonable amount of evidence to suggest, however, that increased commercial interest in modelling has not been associated with increased technical sophistication. Despite the increasing availability of spatial interaction models, it is clear that proprietary GIS (normally standard buffer and overlay techniques) remain the most common methodology for site location (if organisations use anything over and above gut feeling – see Hernandez and Bennison, 2000). Reynolds (1991) and Elliot (1991) describe the application of such simple catchment area analysis techniques within GIS. There does not seem much evidence to support more sophisticated use of GIS since then (see Jones and Hernandez, this volume). This is somewhat surprising to the extent that our own experience demonstrates unequivocally that substantial development work has been required to transform spatial interaction models from interesting pedagogic and academic tools into valuable commercial weapons. Similarly, it seemed to be the case that, whilst the number of packages including models was increasing, the concept of the gravity model was much misunderstood and mistrusted in the commercial world. In part this was because the models were synonymous with very aggregate versions of the spatial interaction model, and in many instances simply did not work well enough. Similarly, users often did not have

the experience or expertise to be able to build models from scratch and attempt the detailed disaggregation needed to make the models operational. In the next section of this chapter, we set out the classic model before discussing some of the developments and extensions required to answer the applied problems set by the clients.

3.3 Classic Model

The classic retail spatial interaction model has the following structure:

$$S_{ij} = A_i \times O_i \times W_j \times f(c_{ij}) \tag{3.1}$$

and,

S_{ij} is the flow of people or money from residential area i to shopping centre j;
O_i is a measure of demand in area i;
W_j is a measure of the attractiveness of centre j;
c_{ij} is a measure of the cost of travel or distance between i and j; and
A_i is a balancing factor which takes account of the competition and ensures that all demand is allocated to centres in the region. Formally it is written as:

$$A_i = \frac{1}{\sum_j W_j \times f(c_{ij})} \tag{3.2}$$

In summary, the model assumes that in order to forecast the flow of expenditure from an origin zone i to a destination (retail outlet or centre) j, then one begins with a fixed demand pool at i. This demand is shared between retailers in proportion to their relative size (or other measures of attractiveness), and in proportion to their geographical proximity. Individual parameters are added to these variables so that the model can be fitted (or calibrated) to real-world data (see equations below). At the very heart of what makes spatial interaction modelling so appealing as an analysis tool is that predictions are based on the replication of customer trips between individual origin and destination pairs rather than by using statistical or analogous evidence (see Birkin *et al.*, 2002a for more details on alternative methodologies for store location analysis).

For all real-world applications this model is likely to require disaggregation. This might be by demand, i.e., different parameters of the model are appropriate for different income groups, or age groups – or supply based (a new version of the attractiveness term – see below). As we shall argue below, new trends in retail geography have caused other types of refinement to be introduced.

Before we examine these new model developments, it is useful to present an application used in a classic what-if fashion for the first of our clients to be reported here – the State Bank of South Australia (SBSA). The model was of the type shown in equations (3.1) and (3.2) but disaggregated (in standard GMAP fashion) as follows:

$$T_{ij}^{lk} = \sum_{k \in j} A_i^{lk} O_i^l W_j^{lk} \exp^{-\beta_i^{lk} d_{ij}} \tag{3.3}$$

where:

$$A_i^{lk} = \frac{1}{\sum_{jk} W_j^{lk} \exp^{-\beta_i^{lk} d_{ij}}} \tag{3.4}$$

to ensure that:

$$\sum_{jk} T_{ij}^{lk} = O_i^l \tag{3.5}$$

and:

$$W_j^{lk} = R_j^{lk} Z_j^{lk} \gamma_{l(j)}^{lk(j)} \mu_j^{lk} \chi_j^{lk} \tag{3.6}$$

where:

T_{ij}^{lk} = estimated sales of product l, for organisation k in origin zone i at destination j;
O_i^{kl} = demand for product l in origin zone i;
W_j^{kl} = attractiveness of outlet j selling product l, organisation k;
β_i^{kl} = distance decay parameter disaggregated by origin i, product l, and organisation k;
d_{ij} = drive-time from zone i to outlet j;
R_j^{lk} = attractiveness of outlet j, belonging to organisation k, selling product l;
Z_j^{lk} = size of outlet j (i.e. square feet) belonging to organisation k, for product l;
μ_j^{kl} = parameter reflecting proximity of outlet j belonging to organisation k to surrounding outlets for product l;
χ_j^{kl} = parameter reflecting operating period (i.e. months open/12) for outlet j belonging to organisation k, selling product l; and
$\gamma_{l(j)}^{lk(j)}$ = brand attractiveness of organisation k, selling product l, to customers resident in i.

Figure 3.1 shows the predicted market share of SBSA across the Adelaide Metropolitan Region. It shows that generally SBSA did have a very high market share, but as with most organisations that deliver services from fixed points, that market share varied significantly across the region. The areas of low market share clearly provide an immediate snapshot of market potential. The models were then used in a systematic fashion to explore the impacts of adding a new SBSA branch in all of these market gaps. Figure 3.2 shows the market share before and after the opening of a new branch at St Agnes. It can be immediately seen that market share improved significantly. However, as important is the total revenue predicted for the new branch, and where those sales are likely to come from (including cannibalisation from the

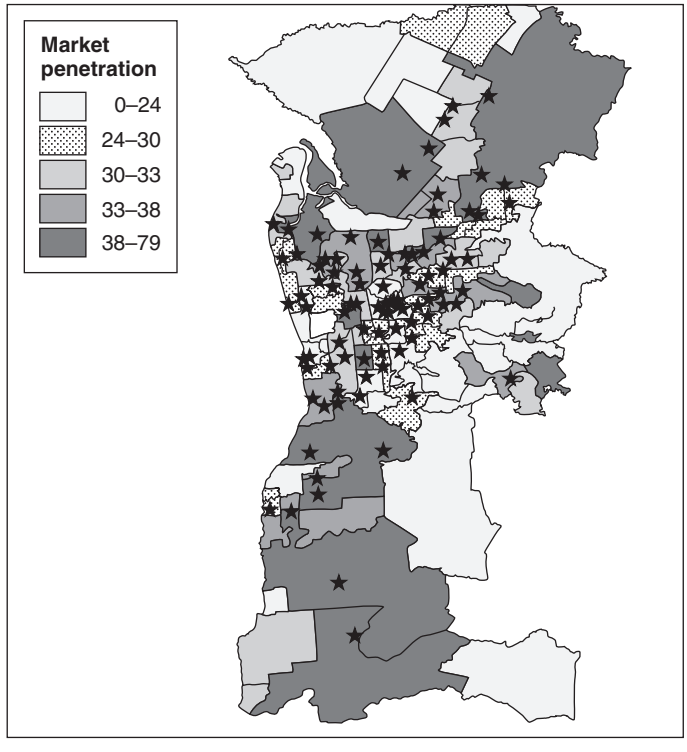

Figure 3.1 *SBSA market share in Adelaide metropolitan market in mid-1990s*

SBSA existing branches). Table 3.1 shows the net change in sales. It can be seen that the impacts on existing SBSA branches are not high and hence this looks like a good new location.

As we noted above, this kind of application was typical of GMAP applications in the 1980s and early 1990s. However, a more sophisticated approach to the art of store location research was required from the mid-1990s onwards. We shall explore the implications of this change in the next section.

3.4 Model Extensions

3.4.1 Introduction

The aim in this section is to explore new challenges in spatial interaction modelling, and store location research more generally, brought about by new types of application and client requirements. First, there has been an increasing concern to explore the predictive power of the models in terms of their ability to represent real deflection rates accurately. Second, there are those applications that have challenged the nature of demand: where does this come from and how can this be incorporated into

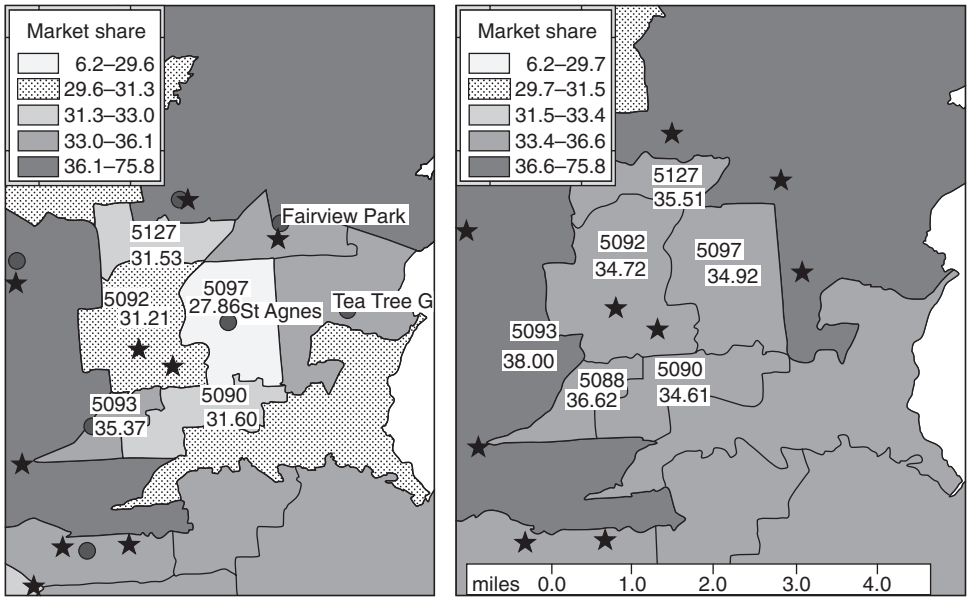

Figure 3.2 *Market shares before and after new branch opening in St Agnes*

the spatial models? Third, there are those applications which seem to challenge the very principles of spatial interaction modelling. We shall look at each in turn.

3.4.2 Modelling Centre Deflections

One of the most interesting retail location issues over the last 20 years or so has been the decline in the number of stand-alone large stores. Although many early

retail warehouses and grocery superstores occupied single-store sites the pattern since the early 1980s has been to locate within centres (warehouse parks and shopping centres often anchored by a major superstore). Similar developments are observable in non-food retail sectors: for example, the trend towards agglomerations of activity in automotive distribution – the so-called auto-mall – and the proliferation of multi-franchised outlets is transforming choosing a new car into something more akin to comparison shopping. For the retailers, whenever outlets are grouped together within city centres or retail parks, then there are potential scale economies to be obtained. In effect, these benefits may be closely related to multi-purpose trip-making, so that customers can also see benefits in visiting more than one destination within a centre or cluster. Alternatively, this may be viewed as a hierarchical choice process in which customers first choose a centre in which to shop, and only then select an outlet within that centre. This structure has been exploited and developed in the creation of the 'competing destinations' model (Fotheringham, 1983, 1986), in which a new variable is included that measures accessibility to other retail outlets. This structure is reproduced within GMAP's generic model, which is explicitly hierarchical in character, so that individual customer flows are modelled to groups of retail outlets (but the attractiveness of the group is related to the attractiveness of its component parts). Individual outlets within each group then compete for market share within the cluster. In a sense, there is also a special case of the model, in which the clusters are constituted from single outlets. This is then the traditional model, which might still be most appropriate for single-purpose trip patterns, say to stand-alone hypermarkets or schools and hospitals in the non-retail sectors.

The increasing use of centres has produced another issue of importance when dealing with classic gravity or spatial interaction models: namely, the way in which the models handle customer deflections when new stores are opened. This discovery was made through working with client B, a northern bank. For this client, financial centres were used instead of individual bank branches. That is, interactions were predicted between residential areas and financial centres (such as town centres containing four or five branches). Revenues to individual branches within the centres was then allocated according to the fascia and its store attractiveness (age of store, size, etc.). The traditional interaction model worked well for predicting revenues and catchment areas for the existing set of stores. However, for new store openings the patterns of deflections seemed intuitively wrong. Let us take the common scenario of client B wishing to open an additional branch in a large town centre where it is already present (along with a number of competitors). All things being equal, we would expect total centre sales to undergo a marginal increase in sales, but we would not expect 400 or 500 new customers suddenly to come in from surrounding towns to go to that new branch. In other words, we would expect sales for the new branch to be generated mainly from the centre's existing branches, deflecting most heavily perhaps from the existing client B branch. What we actually see from the standard model is an increase in centre sales, near incremental sales for the new branch and minimal deflections from the other client B branch in that centre.

In the 'standard' model (Table 3.2, Column 3), the introduction of a new branch has a proportionate effect on the attractiveness of the centre (via an increase in

Table 3.2 *Open a financial service branch in a large centre*

	Baseline	Standard model	GMAP model
Centre sales	18 332	18 782	18 353
Change		450	21
Percentage change		2.4	0.1
Open branch		727	707
Existing branches	5 663	5 578	5 288
Change		85	275
Percentage deflection		1.5	4.8

floorspace – F_j). The extent of the associated sales increase depends on the relative balance between attractiveness and accessibility. In this example the new branch generates 727 new sales, and about two-thirds of these (450) are sales which were previously made in competing centres (for higher values of beta, then we would expect to see less diversion of sales between centres as the respective catchments are more or less fixed; for lower values of beta then sales will follow floorspace, and we would expect more new centre sales). Thus, our new branch takes 450 sales away from branches in neighbouring centres, and the remainder (277) from existing branches within the same centre. The deflections within the existing centre are proportionate to the floorspace of competing financial services organisations. In the baseline, client B has a share of 5663/18 332 = 31%. Therefore client B loses 31% of 277 = 85 sales within the standard model scenario.

In the revised model (Table 3.2, Column 4), the effects are explicitly hierarchical. In the first stage, the flow to centres is modelled as a function of a basket of centre characteristics (quality of access and parking, presence of key retailers and anchor stores, pubs, restaurants and other attractors) in addition to financial services branches. Opening a new financial services branch has only a marginal effect on the character of the centre; hence the vast majority of new sales are at the expense of existing branches within the same centre. A second layer of distinction concerns the loyalty of customers to each financial services brand. Although client B can attract new customers by the addition of new branches, there are diminishing returns to scale – doubling the number of branches will not double sales, for example, because existing customer niches may become saturated. Thus, the deflections from existing branches within the estate of client B are proportionately higher than from its competitors.

In Table 3.3, we can see the same processes for a branch closure within a small centre. In this case, client B does better than expected because many of its customers choose to switch their loyalty to the remaining branches rather than defecting to an entirely new competitor.

Table 3.3 *Close a financial service branch in a small centre*

	Baseline	Standard model	GMAP model
Centre sales	4657	4157	4588
Change		500	69
Percentage change		10.7	1.5
Closed branch	558	0	0
Remaining branches	733	751	837
Change		18	104
Percentage retention		3.2	18.6

The centre effects can be expressed through a revised set of model equations:

$$T_{ij}^k = A_i^k O_i^k \theta_j^k W_j \exp^{-\beta_i^k d_{ij}} \tag{3.7}$$

where:

$$A_i^k = \frac{1}{\sum_j W_j \exp^{-\beta_i^k d_{ij}}} \tag{3.8}$$

to ensure that:

$$\sum_{jk} T_{ij}^k = O_i \tag{3.9}$$

where W_j is now a measure of the attractiveness of centre j:

$$W_j = f\left(X_j^1, X_j^2, \ldots, X_j^n\right) \tag{3.10}$$

X_j^k, $k = 1, \ldots, n$ are variables which contribute to centre attractiveness.

Flows are allocated in proportion to market share within a centre:

$$\theta_j^k = f\left(V_j^{k1}, V_j^{k2}, \ldots, V_j^{km}; W_j\right) \tag{3.11}$$

where V_j^{kl}, $l = 1, \ldots, m$ are attributes for retailer k in centre j.

Ongoing research is also examining other issues to do with impact assessment. Using a set of traditional retail models for the identification of areas poorly served by the major food retailers (so-called 'food deserts') produced a standard set of deflection rates when a new Tesco store was opened in East Leeds (Clarke *et al.*, 2002). The model predicted deflection rates of up to 60% for those stores in close

proximity. However, this case study was unusual in that actual consumer deflections were collected as part of the overall food deserts project. The results of this major household survey (1000 households in the vicinity of the new store) showed more complex deflection patterns than predicted in the model (Wrigley *et al.*, 2003). Two trends were particularly noticeable. First, there was more loyalty to the discount sector than predicted by the models. It seems that some consumers felt uncomfortable in the new Tesco store – they felt more at home remaining in the discount store. Second, there was a greater switching from Tesco's other store in the region. That is, the models under-predicted the amount of switching from the rather distant centre at Crossgates (home of the other Tesco store). These issues are driving the examination of new consumer behaviour variables in the retail grocery model (Clarke *et al.*, 2003). This is another good example of the importance of applied research in terms of driving theoretical extensions of our models.

3.4.3 Incorporating Elastic Demand

A second major issue to emerge from working with client B was the concept of elastic demand. In practice, the assumption of a fixed demand pool (O_i) is not always a sufficient one. This is particularly the case when the levels of demand and supply for a product or service are interrelated. In the case of groceries, for example, it is safe to assume that customers have a reasonably fixed requirement for fruit and vegetables, meat, dairy products and so forth. These requirements are unlikely to be altered by the decision of Safeway to build a new supermarket on the doorstep. That is, although consumers may switch allegiance and frequent the new store, their average weekly budget for food is unlikely to increase significantly. On the other hand, providers of leisure services such as cinemas, sports clubs or restaurants would do well to recognise that these facilities will to some extent generate their own demand. People lacking access to a cinema, for example, will tend simply to substitute other activities, and will have a lower demand for cinema tickets than similar people who have easy access to cinemas.

Modelling frameworks for the treatment of elastic demand have been proposed by Pooler (1994) and Ottensmann (1997). The principle of these applications is that the level of demand in an area is not fixed, but is related to some measure of service provision in that area. The relationship may be regulated through the introduction of a new parameter, which can adopt some very low or zero value for activities such as the sale of retail groceries, to much larger values for a restaurant or cashpoint machine. The latter is the example emanating from client B. Figure 3.3 plots the relationship between ATM location and consumer residence in Leeds.

There are many approaches to the problem of coping with a demand base which is not fixed. One strategy is to develop a hybrid model, since the flows can no longer be strictly considered as origin-constrained. An alternative is to specify the model via a two-stage process: first, estimate the demand; second, allocate the flows. So we might start with:

$$O_i = e_i P_i w_i^{\phi} \Big/ \hat{w}_I^{\phi} \tag{3.12}$$

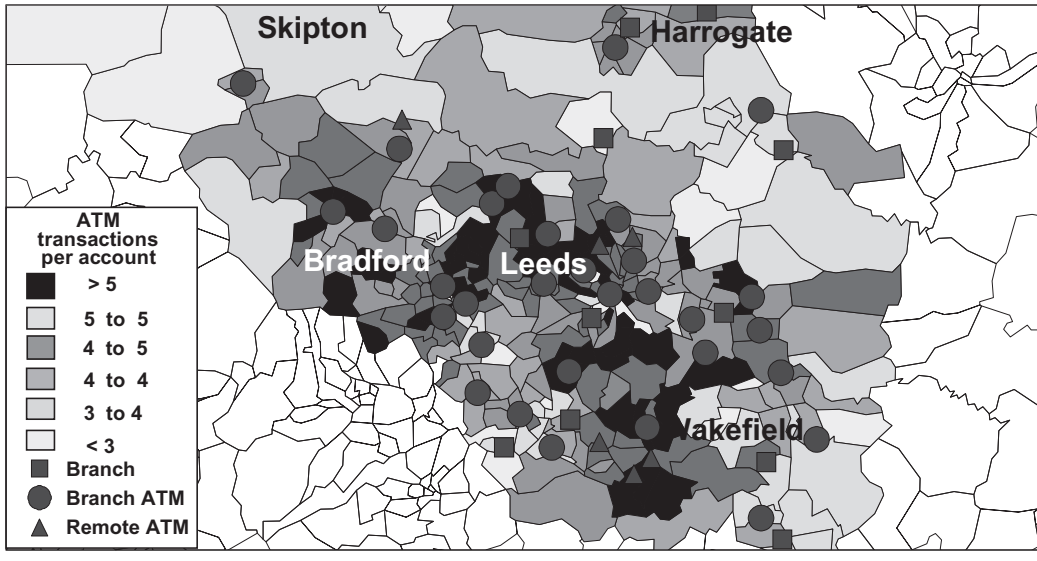

Figure 3.3 *Variations in ATM usage by Leeds residents*

where:

e_i = estimated sales of product l, for organisation k in origin zone i at destination j;
P_i = demand for product l in origin zone i; and
w_i = measure of access to services for residents of zone i, such as the Hansen accessibility:

$$w_i = \sum_{jk} W_j^k \exp^{-\beta_i^k c_{ij}} \tag{3.13}$$

and where:

$\hat{w}_l$ = average accessibility across the whole region; and
ϕ = is a parameter.

Having estimated the demand, we may then continue as previously with the traditional spatial model.

3.4.4 Trips from Work

Even if it is safe to assume that the demand for products and services is relatively fixed, the assumption of a simple flow from the point of consumption (residence) to the point of sale (outlet or retail centre) is an increasingly unsophisticated representation of the consumption process. To an increasing extent, retail consumption is

satisfied through a complex web of multi-purpose trips, including trips to or from places of work, education or leisure.

One implication is that the demand pool needs to be segmented, at least into a portion which may be satisfied from the home, and another portion which is satisfied from the workplace. A journey to work model may be the most appropriate way of assigning customers to workplace locations since the buoyancy of retail sales within a typical city centre owes as much to the proximity of workers as to its attractiveness to suburban neighbourhoods. Our experience suggests that when analysing model outputs in the case of W.H. Smith town or city centre branches, somewhere between a quarter and a third of retail expenditure for these products was being released through the workplace rather than the residence. However, such work-based trips are also highly constrained in the geographical sense, so there will not be many trips of four or five miles undertaken within the lunch hour. There may also be an element of elasticity here between the demand components, so that householders employed within city centres may tend to spend heavily through the working week; others may be restricted to the usual evenings and weekends. This is one of the features which makes petrol forecourts so difficult to model, as we will see in the next section below. Rather than drawing from a 'captive' local market, customers will typically be intercepted at the mid-point on trips which might connect the home, workplace, shop, cinema, nightclub, holiday resort, or any other of a myriad of possible locations.

3.4.5 Conclusions

The implementation of these various model enhancements has been facilitated by the production of a combined software module incorporating a range of application building blocks. This is somewhat more complex than the basic spatial interaction model which was introduced in Section 3.2 above. Thus while a basic spatial interaction model simulation might be effected through less than a page of FORTRAN code, the 'generic model' is composed of several thousand lines of C++ code, because the model is designed to deal with many different data structures and model specifications within different markets. This latter point is illustrated in Table 3.4, which makes explicit some of the issues which we have already discussed above, i.e., that different approaches are more relevant in some circumstances than others. For example, as we saw earlier, elasticity of demand is far more important in the provision of financial services than motor vehicles.

3.5 Approaches to Modelling Difficult Markets

Some retail markets are evidently more difficult to model than others. This idea is summarised in Figure 3.4. Excellent results have been achieved in forecasting outlet revenues for retailers such as supermarkets and DIY retailers. For example, Birkin *et al.* (1996) report on an application to the DIY sector in which average forecasting errors of around 5% were consistently achieved. Of equal importance is the ability

Table 3.4 *Importance of model drivers by retail market*

of the models to produce accurate forecasts of the impact of new store developments on an existing portfolio of stores, and to identify the geographic extent and composition of the store catchment for advertising and promotion. Certain other markets are less tractable. A notorious example is the car market. Here the issue is not so much about the ability of the models to generate accurate estimates of 'market potential', but the fact that the actual performance of dealers varies quite strongly from place to place (not least because of the persuasiveness of individual salespersons!).

In this section we draw upon experience built up from client C – Exxon/Mobil. In the petrol sector, the issues of complexity are more fundamental. Here the normal linkage between an outlet and its local market is less strong, and the range of factors which influence revenue generation is very large. That said, using standard modelling procedures had produced some impressive results in the petrol sector. Table 3.5 shows the results from a model run in Sicily. However, as can be seen, the error margins are much higher than we would expect in other sectors, and there tends to be more outliers. Those petrol stations with particularly poor model predictions turned out to be in key transient locations. To build a model which captures transient demand as well as local demand would need a full transport network model. The daily effects of price changes are also a difficult marketing activity to capture within the models. The petrol

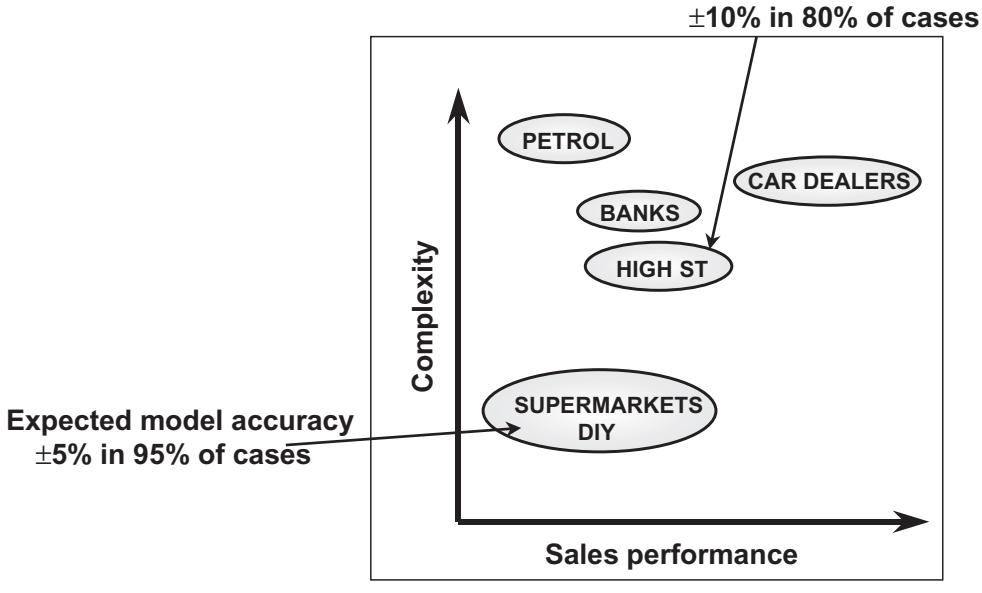

Figure 3.4 *Effectiveness of forecasts by market*

Table 3.5 *Observed versus predicted sales volumes at selected petrol stations in Sicily*

Petrol station location	Actual volume	Predicted volume	Performance index
Corso Tukory	1510	1663	0.91

Niscemi	1250	1350	0.93

market is one of the most susceptible to small variations in price. Although it is relatively simple to build in a price variable to standard models (cf. Wilson, 1985), modelling the impacts of daily price changes on both local and transient demand is a more difficult issue.

In these circumstances, we have experimented with the development of multivariate statistical approaches to revenue modelling. The core of our approach is to prepare 'site ratings' for each location. There are two steps to this process: first, to identify the most important factors and to calibrate their relative importance; second, to construct individual scores for different attributes or outlet configurations. Note that while there are some similarities to straightforward regression analysis in this

Table 3.6 *Components of a site rating system*

Factor	Maximum score
Quantity	45
Quality	35
Competition	15
Concentration	5
Total	100

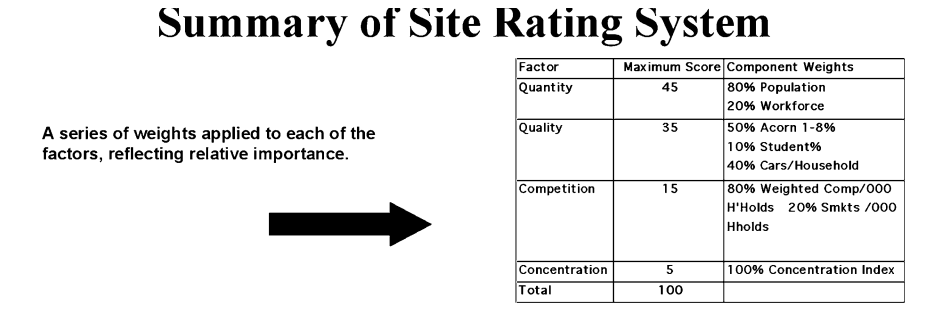

Figure 3.5 *Rating summary*

approach, and that indeed multiple regression may be used in the process of deriving the individual scores, the approach is more closely related to credit scoring (Leyshon and Thrift, 1999), and indeed to business scorecards (Ahn, 2001) in which the performance of an organisation might be evaluated against a whole raft of criteria.

Consider the example shown in Table 3.6. Here four sets of factors which drive convenience store ('C-Store') performance on petrol forecourts have been identified. Note that despite our comments above, the local trade area (or quantity of demand) is still the most important factor (generating both drive-in and walk-in traffic to forecourt shops) but accounts for less than 50% of the overall site score.

Further description of these components is provided in Figure 3.5. For example, the competitiveness of markets is assessed according to the presence of retailers of different types. Each type is in turn weighted according to its relative impact, with supermarkets having the most effect, and other forecourts the least. Summary results are shown in Figure 3.6. A typical application of this type of model would be

Figure 3.6 *Sample results for a site rating system*

expected to explain between 75 and 80% of the variance in C-Store performance. The tools are being extensively used to prioritise investment from a local to a global scale (i.e., not just Otley versus Ilkley, but Mexico versus Thailand!).

It may of course be possible to look for new quantitative methods to solve these difficult problems. The authors have experienced some success with genetic algorithms. These evolutionary algorithms are particularly suitable for network optimisation problems: for example, how to configure a new network of 50 car dealers or supermarkets in an Eastern European country (such problems are being faced with increasing frequency by growing retail groups in the UK and the USA). A conventional solution to problems of this type is described by Birkin, Clarke and George (1995), and a GA version by Birkin and Culf (2001). Unsupervised neural networks are also thought to be useful for problems of pattern recognition. In an abstract sense, the problem of rating sites is of this type, in which one needs to find the pattern of factors and attributes which determines outlet performance. The application of self-organising maps in the style of Kohonen (1984) (cf. Openshaw and Openshaw, 1997) has been used by GMAP to generate more effective solutions to the site rating problem described above. The weakness of this approach is that the ratings tend to be less 'clean' than those prepared through desktop analysis. In practice, a hybrid approach in which the results from some neural network-based approach are then manually tidied up has been found to be most effective (see Birkin, Boden and Williams, 2003).

Consider a simple example. We wish to rate sites according to the number of petrol pumps (two, four or six) and their accessibility (on an integer scale from one to five). The parameters to be optimised via the neural network are the importance of accessibility (relative to number of pumps), and the relative weightings between each pump size. Thus the model would be:

$$R_i = \sum_k \delta(1)_i^k a^k + \gamma \sum_m \delta(2)_i^m b^m \tag{3.14}$$

where

R_i is the 'rating' of petrol station i;
a^k is a size parameter;
b^m is an accessibility parameter;
$\delta(1)_i^k$ is a zero-one variable, one if site i has k pumps, zero otherwise;
$\delta(2)_i^m$ is a zero-one variable, one if site i has an accessibility score of m, zero otherwise; and
γ is a scalar.

An ideal solution might look like this:

$a_1 = 0.77$
$a_2 = 1.02$
$a_3 = 1.48$
$\gamma = 0.43$
$b_m = 0.48, 0.56, 0.84, 1.19, 1.21.$

Whilst this set of scores represent the best available fit to the data, it will often make sense to smooth them into a form which is slightly less accurate but intuitively pleasing and simpler to describe, for example:

Pumps – max 20 points
  2 pumps – 8 points
  4 pumps – 12 points
  6 pumps – 20 points
Accessibility – max 10 points
  1 – 3 points
  2 – 4 points
  3 – 6 points
  4 – 9 points
  5 – 10 points

In this example, if there are an equal number of sites in each category then the simple model retains 99% of the variance in the precise estimates, but involves no decimal points!

3.6 Conclusions

The application of theoretical models within an applied commercial environment has generated many extensions and enhancements. It has also posed challenging problems. To solve these problems may require imaginative extensions of an existing

framework, the introduction of completely new techniques, or a recourse to old-fashioned but robust methods. A distinguishing feature of business is that novelty counts for less than performance. As the geomodelling industry continues to mature we should expect to see a greater plurality of approaches, providing demonstrable benefits to an increasingly wide portfolio of business customers.

Location-Based Services for WAP Phone Users in a Shopping Centre

António S. Câmara and António Eduardo Dias

Abstract

Advances in mobile Internet devices together with the recent availability of location awareness for mobile phones represent new opportunities for the implementation of location-based services (LBS). In the commerce arena, LBS can have a crucial role in combining virtual and real infrastructures, thus improving the experience of visiting a commercial area like a large shopping centre. To support these synergies between real spaces and their symbolic representations, a new personal navigation technology has been developed based on mobile phones named DiWay. DiWay facilitates user navigation and bridges the gap between traditional 'bricks and mortar' commerce and electronic or mobile commerce by the use of anchor points. The most relevant of these can be memorised using the phone, a concept called Phonemarks. Furthermore it also provides security and community applications. DiWay is built upon the FluidMapping software framework that facilitates the use of heterogeneous databases and displays the results in any presentation device, including 2.5 or 3G mobile phones. The system is being deployed for one of the largest shopping centres in Europe, the Centro Colombo in Lisbon.

4.1 Introduction

Maps are symbolic representations of real spaces. The gap between reality and its symbolic representations has been shortened in recent years with digital multimedia

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

information systems. Such systems have included maps, aerial and ground photos, video and sound. Reviews of available spatial multimedia systems may be found in Câmara and Raper (1999), Gouveia and Câmara (1999) and Câmara *et al.* (2000). Mobile devices and particularly Internet-enabled mobile phones are helping to bridge that gap further by enabling the confrontation of reality with their digital representations in real time.

Such devices are creating opportunities for new LBS that rely on having a spatial background usually in map form with geo-referenced points of interest and other relevant information. LBS also depend on knowing the position of the user in space. LBS applications for the common mobile phone user include personal and car navigation, point-of-interest search, e-commerce, emergency services and entertainment. LBS are supported by context-aware systems relying on the dissemination of contextual information (Dias *et al.*, 1998; Ryan *et al.*, 1998; Ryan, 1998; Abowd *et al.*, 1997a). Their main focus regarding context is on location, thus falling into the field of location-aware computing systems. These systems have been thoroughly discussed in Dias *et al.* (1996, 1997), Davies *et al.* (2001), Beadle *et al.* (1997, 1998), Abowd *et al.* (1997), Frisk (1998) and Pradhan *et al.* (2001). A good review of location systems for location-aware applications can be found in Hightower and Borriello (2001).

The Colombo Centre (http://www.colombo.pt) is the largest shopping centre located in the Iberian Peninsula. It has over 40 million visitors a year, 420 shops, 65 restaurants, 10 movie theatres and many other facilities. The parking lot has capacity for 6000 cars. In such a large shopping centre, guidance is needed to locate shops and products. A system that facilitates car finding in the parking lot may be also helpful. The need for systems, minimising those problems, is well understood by the companies that manage shopping centres. SONAE, the company that runs Colombo Centre, has developed paper-based diagrammatic maps and signs available in several locations to help locate stores. It has also created a system based on the parking cards and fixed machines that stamp the position of a car in the parking lot.

Both systems have shown limitations as follows:

- paper-based representations cannot be queried and are usually thrown away after use. Moreover, any change in the Colombo Centre's structure requires new representations. These two issues bring up both financial and environmental problems;
- diagrammatic maps also represent a level of aggregation not suitable to detailed information needs from the customers, which are often centred on products;
- information structure on diagrammatic maps is static which limits its use by those with specific search needs; and
- the car location system is expensive to maintain and forces the visitor to find the nearest stamping machine.

Our group has developed a navigation technology, called DiWay, based on mobile phones that overcomes these limitations and, at the same time, presents additional advantages. These include the facilitation of mobile commerce, social and entertainment activities and emergency services. DiWay is based on the use of wireless

application protocol (WAP) using images and text, and the short message service (SMS) relying upon on text messages. It will also accommodate multimedia message service (MMS) sending images, sounds and text upon request or permission of the user. DiWay architecture is supported by a view of geographical information systems (GIS) as being composed by a data tier, a logic tier and a presentation tier. The data tier facilitates the access of geo-referenced data. The logic tier incorporates spatial analysis tools to determine shortest paths, near points of interest and shortest circuits. Finally, the presentation tier enables the visualisation of maps, images and text on the Web, mobile Internet, and SMS and MMS systems. DiWay may be seen thus as a gateway for mobile access to a customised GIS of a shopping centre. Early tests at the Colombo Centre, carried out in cooperation with SONAE, have shown that the system may be adapted to other shopping centres of the SONAE group. The success of that adaptation depends on minimising the burden placed on the user in future developments of DiWay.

This chapter discusses the problem underlying the need for DiWay, and the methodological issues behind DiWay such as micro-detailed geo-referencing, database development, algorithms behind navigation and user interface design. The DiWay application to the Colombo Centre is reported for illustrative purposes. Future developments of DiWay are also listed.

4.2 Problem Definition

The geo-referencing of points of interest in urban areas is becoming increasingly detailed to satisfy user needs. Maps of major cities available on the World Wide Web illustrate this trend. Shopping centres provide the setting to go one step further. Geo-referencing points of interest such as shops is not enough; one may be interested in locating shelves or even products in a shop, and certainly one is interested in having the parking places geo-referenced. The definition of spatial location, at this refined level, facilitates navigation, commerce and social activities.

Exploration of a place is usually associated with the use of symbolic representations such as maps that are then matched against the reality they try to synthesise. This matching is facilitated by the use of ‘anchors’: a discrete number of points of interest displayed in maps that are landmark shops or other easily recognisable locations. In a shopping centre, there are certainly shops more easily noticed than others. From the perspective of different visitors, one may conclude that every existing shop may be an anchor for a certain visitor. By the same token, every product in a shop may be a point of interest and, clearly, the same is true of every parking place in the centre.

The Colombo project has shown that the definition of anchors has been limited by the lack of the availability of back-office data to support the potential uses of the system. That data may be only location (such as in the case of the parking places), but it may also include other data such as the Web address, list of products and prices. In the end, anchors have to be defined by the shopping centre operators. Traditional maps and wayfinding signs of shopping centres are thus limited to aid generic navigation:

- they do not help a visitor to find a particular product on a shelf or remind him or her of the place he or she left the car;
- they do not help him or her in obtaining more information on a product or even where and how to buy it; and
- they are of little use in helping the visitor in meeting other visitors at a certain time in a certain place.

Mobile phones, and particularly Internet-enabled mobile phones, provide an alternative platform for navigation in shopping centres: they can display maps showing the visitor's location, offer directions and present product information. They may be used to buy products, locate friends and in emergency situations. However, the development of navigation systems for mobile phones to be used in shopping centres presents key research problems such as:

- indoor positioning, as traditional mobile phone positioning systems (based on the Global Positioning System or other radio-based triangulation systems) are not successful in indoor spaces;
- the selection of anchor point technology to provide information to the mobile phone user;
- the definition of the most appropriate spatial analysis tools to aid the users in navigation;
- the software framework to support heterogeneous data sources and present information in different platforms (Web, WAP, SMS, MMS, UMTS, VoiceXML); and
- user interface issues in the design of the DiWay system for mobile phones.

4.3 DiWay Methodology

4.3.1 Introduction

The DiWay methodology comprises proposals to solve the research problems mentioned above. It is based on the representation of a shopping centre as a set of graphs, each graph representing a floor. In the parking lot floors, each node represents one parking spot and the arcs are the paths to elevators and stairs. In the shopping floors, each node is a shop, restaurant or other facility. The arcs are the shopping centre streets. Each shop's node may have associated secondary nodes representing shelves or products. Links between floors are represented by special arcs, which have specific properties indicating the type of connection (stair, elevator, escalator, ramp) and the floors they link to. Using these properties the system is able to generate paths according to specific user needs. If, for example, a handicapped person wants to visit the centre using a wheelchair, DiWay will only use floor-linking arcs with an elevator or ramp connection thus providing the user with a personalised path.

Each node is represented by an alphanumerical code defined hierarchically (Figure 4.1). Country, city and shopping centre sub-codes are automatically provided by the operator's location technology, so that the user only has to enter between three (shop) and seven characters (shop + object). In the DiWay methodology, these codes are

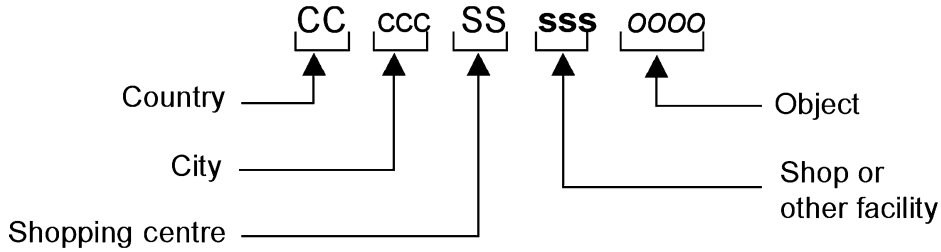

Figure 4.1 *The hierarchical structure of the spatial bar code (SBC)*

named spatial bar codes (SBCs) and identify uniquely an object anywhere in the world. Each node is considered to be an anchor point. It is possible to geo-reference them *a priori*, thus establishing a correspondence between their coordinates and the SBCs, by digitising the plans of the shopping centre.

4.3.2 Indoor Positioning

Anchors may be tags or emitters with associated SBCs. The SBCs may be presented together with the corresponding WAP address or SMS number (Figure 4.2). This concept solves the positioning problems in indoor spaces where both satellite and radio frequency triangulation systems are often inadequate.

4.3.3 Anchor Point Technology

For the time being the best option is to use plastic tags as in Figure 4.2. The user can then use this code to locate him or herself to the system, writing it on a WML form or in the text of an SMS. For the third-generation mobile phones, and even for some 2.5G smart phones, a Bluetooth-based emitter will probably be the best solution (Held, 2000). Using Bluetooth emitters as anchors will allow users to pinpoint their location automatically without having to read or write any SBC. Whenever they ask for some information, DiWay will tell the phone to read the nearest SBC and display the adequate contextual information. Tests with Bluetooth-based anchors are already being conducted using a PDA to simulate a 3G phone.

The anchors may be used to support navigation, as a reference for meetings and emergency services and to facilitate mobile commerce as discussed for the Colombo Centre case study.

4.3.4 Spatial Analysis Tools

The spatial analysis problems involved in shopping centre navigation are essentially the definition of the shortest path between an origin and a destination. Typically, the

Figure 4.2 *Use of a tag to anchor a shop in the Colombo Centre*

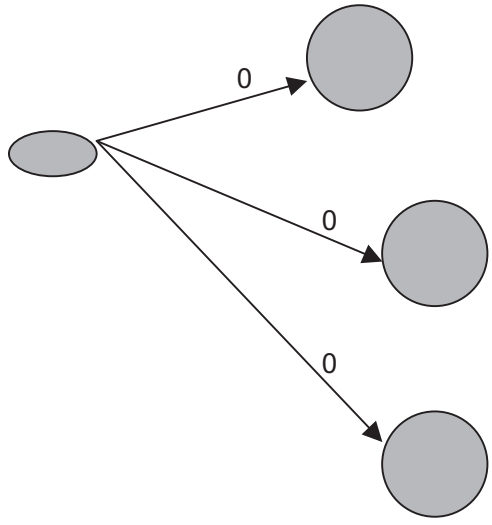

Figure 4.3 *Adaptation of Dijkstra algorithm to solve the problem of having alternative origin points: the distance between the virtual origin point and the potential departing points is 0*

visitor wants to find the route between an entrance of the shopping centre and a shop or a product. Conversely, he or she may be interested in finding the way between the exit and the car in the parking lot. For both problems, DiWay applies the Dijsktra algorithm (see the description in Cormen *et al.*, 1990). The Dijsktra algorithm requires that weights are assigned to each arc (or shopping street). Those weights represent distances. The algorithm then proceeds to determine the shortest distances from the origin to all other points in the network. It also provides the sequences of arcs that are associated with those distances.

DiWay applies a modification of the Dijkstra algorithm to solve two other problems: finding the shortest path between a destination and several possible origin points; and determining the nearest point of interest. The former problem is of interest when one wants to select which entrance to use to be closer to a certain shop. The latter occurs when someone wants to look, for example, for the nearest bookshop to his or her current location.

To solve both problems, artificial nodes and arcs with null weights are considered. When there are several origin points and one destination, an artificial node is inserted as a virtual origin point. The distances between the virtual and the real origin points are zero (Figure 4.3). The Dijsktra algorithm is then applied with the virtual origin point as the starting node. The origin point that is part of the shortest path is the entrance that the user should select.

In the nearest-point problem, several destination points may be considered (i.e., all the bookshops in the centre). In this case, the arcs from the real destination points (the available bookshops) to a virtual destination point have weights equal to zero. The Dijsktra algorithm is applied considering the virtual destination point. The bookshop that is part of the shortest path is the nearest bookshop to the user.

Other analytic problems of interest are node-covering algorithms (see Princeton's Department of Mathematics website on the travelling salesperson problem). One may be interested in defining shortest circuits or paths covering a predefined number of shops. The solution to these problems is not included yet in the DiWay methodology. Examples may include the planning of a visit to a number of predefined shops (i.e., to a bookstore, sports store, furniture shop and clothes store), trying to spend the minimum amount of time departing and arriving at the parking place. Inside a supermarket, one may want to define the minimum path from the entrance to the exit booth while picking up predefined items, provided that these are geo-referenced.

4.3.5 Software Framework

The software platform developed by YDreams to support LBS is called FluidMapping. It was developed on Microsoft.NET, taking advantage of the flexibility, security and performance of this platform. FluidMapping is structured into three tiers: the data tier, the logic tier and the presentation tier (Figure 4.4). These tiers have been designed to:

- handle heterogeneous sources of information therefore allowing the integration with already deployed database services. This is important for a system like DiWay where data are provided by several different entities using different information systems;

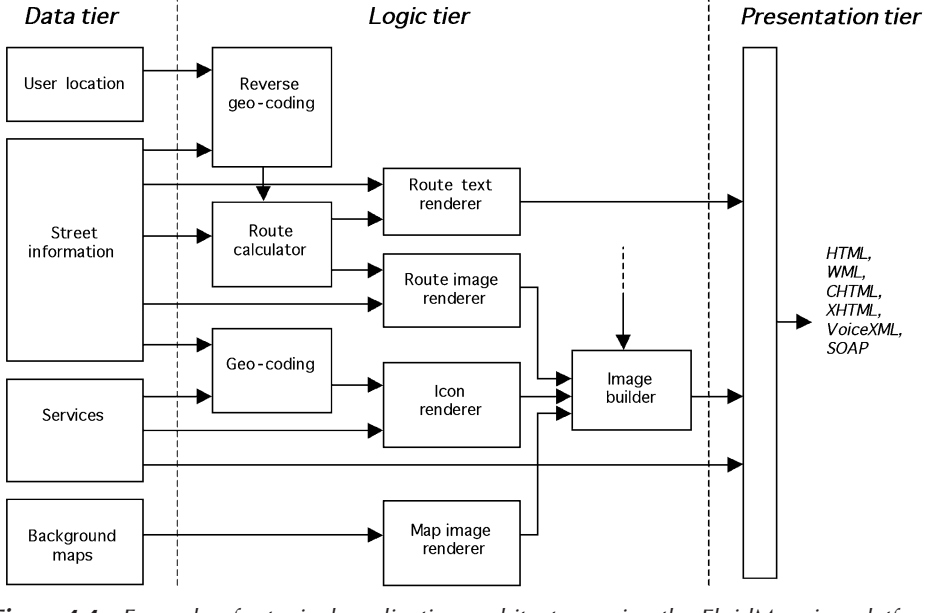

Figure 4.4 *Example of a typical application architecture using the FluidMapping platform*

- be incorporated into locally executed applications (classic architecture), client/server environments (three-tier architecture), or distributed environments (distributed three-tier, or *n*-tier). This is therefore a flexible solution allowing the same service to run locally (e.g., on a kiosk or a PDA) or remotely (e.g., on a mobile phone, Internet-enabled PDA or interactive television) or even as a web-service;
- allow the stratification of products using different combinations of modules. In this way, the same framework can be used to deploy different products or services. Using FluidMapping, DiWay can easily be converted to a museum navigation service; and
- allow the presentation of the services in all wired and wireless devices (SMS, MMS, HTML, WML, CHTML, XHTML, VoiceXML and SOAP).

4.3.6 Data Tier

There are four types of information that are essential for location-based services: user location, street information, background maps and the services (or contents) themselves.

User Location

The user location is what differentiates the LBS from the traditional wired services. The location can be found by automatic technologies such as enhanced observed time difference (E-OTD), time of arrival (TOA), cell ID and assisted-GPS (A-GPS) or simply supplied by the end user. The existing automatic methods can only give the area where the user is located; they still cannot provide the store or object location. If the service needs a more accurate position, the user still has to type it or say it, depending on the device he or she is using. Future outdoors solutions will minimise this problem. DiWay type propositions, based on Bluetooth code emitters, will solve the indoor positioning problem.

Street Information

The street information database includes all the information for the streets. It is used for the calculation of the route between two points, the determination of the nearest point and to find the geographic position of a point given its address (geocoding). This information is created using the FluidMapping Graph Editor.

Background Maps

The background maps are used for the graphical visualisation of the route and position of a point. These maps are related to the street information but are handled separately. For example, WAP uses black and white maps, while the Web may use coloured maps. However, the road information can be exactly the same. The FluidMapping platform has editors for raster and vector maps. When using raster

maps, the adequate maps are automatically tiled to form the background map. Vector maps can either be constructed using the appropriate editor or imported from other applications like MapInfo.

Services

The services databases include the contents that will be geocoded and made available to the end user. The FluidMapping framework only needs the address of the points of interest to handle the contents automatically. The operator usually controls the user location, and the shopping centre's administration, the street information and background maps databases. Third-party companies usually supply the services databases through syndication. This means that the operator may not have control over how the data is supplied. As a result, there can be a great variety of transportation protocols, query methods and data structures involved. The conversion and integration problems are usually significant.

To minimise these problems, FluidMapping adopted the Microsoft BizTalk server solution (http://www.microsoft.com/biztalk/). BizTalk provides powerful and easy-to-use tools to control the flow of information and its conversion into formats that the YDreams platform can interpret. The use of this product considerably reduces the time necessary to integrate a new third-party data provider.

The data tier framework of FluidMapping is developed on top of the latest generation of Microsoft database-access components called ADO.NET. These are very generic components allowing a common data retrieval method for all types of databases, static files or data generated dynamically by other components, simplifying the code of each component.

4.3.7 Logic Tier

The logic tier framework consists of several modules. Key modules were shown in Figure 4.4 and are discussed below. These components use XML to communicate between them thus providing total control over the data flow. This data can also be redirected, at any place, to third-party components.

Geocoding: this module uses the street information database to convert an address into geographical coordinates.

Reverse geocoding: uses the street information database to convert geographical coordinates into addresses.

Map image renderer: generates the background map image given the geographic coordinates, image size and source.

Route calculator: calculates the route between two geographical points. The different methods of calculating routes (shortest, fastest, cheapest) are implemented in different modules so that they can be used separately, depending on the product.

These modules share the same interfaces so their interchange is straightforward.

Route text renderer: processes the route calculation result so that the name of the streets, shops, direction changes and other useful information are added to it.

As for all the other components the output of this module is in XML. For example, the direction changes are coded as tags, instead of text, so that they can later be translated into any language using a simple XSLT rule.

Route image renderer: draws the route so that it can be superimposed on the background map. It provides total control over the line colour, style and width.

Icon renderer: calculates the relative position of the icons to be superimposed on the background map image. It gives total control over the icon design.

Image builder: allows the combination of several layers of images. It gives total control over the layer order, position, size and opacity. This module also enables the addition of other elements to the image such as legend, copyright notice and watermark. The image can be saved in any of the Web file formats (PNG, JPG, WBMP and GIF) and other graphical formats.

4.3.8 Integration

The logic tier framework is currently implemented on the Microsoft.NET framework (http://msdn.microsoft.com/net/) and can take advantage of all the related technologies on the Windows 2000, Windows XT and Windows CE platforms. On client/server architectures, the end user does not need to have any of these platforms to be able to access the services. The framework is located on the server and only the output is sent to the client, meaning that it is independent of the client's platform.

In case the framework is run locally on devices with Windows CE platform, like pocket PCs and auto PCs (http://msdn.microsoft.com/library/default.asp?URL=/library/wcedoc/apcintro/apcintro.htm), it can take advantage of the CE edition of the Microsoft SQL Server database (http://msdn.microsoft.com/library/default.asp?URL=/library/wcedoc/sqlce/portal_6ol0.htm) to store the data on a local database. To keep memory usage down, this database can store just the data related to the services close to the user location. This database can be automatically updated through wired or wireless synchronisation. The framework can also be wrapped in a SOAP compatible Web-service that allows its access to third parties through a custom API.

4.3.9 Presentation Tier

The use of XML on the framework allows the customisation of its output to virtually any device, from regular HTML for web browsers, passing by several wireless types such as WML, CHTML and XHTML, to VoiceXML, that allows the use of voice on a regular cellular phone.

The DiWay interface consists of the display of maps and associated geo-referenced content by request on WAP enabled mobile phones. Typical queries include point-of-interest search (which may comprise nearest point-of-interest search), information on anchor points, directions for personal navigation and emergency services.

The display of maps is limited by:

- the size of most WAP-enabled phone screens; as a result, display clutter usually occurs; and
- the monochromatic nature of those screens; colour cannot be use to differentiate floors, shops or products.

Interaction with WAP phones is further hampered by the multidimensionality of the keyboard (Matilla and Ruuska, 2000): most keys stand for one number and three letters. To minimise these problems, DiWay has incorporated the following principles.

- Minimise display clutter. Two levels are provided: the overall view of the floor and the local area where the visitor is at a certain moment. Both are represented diagrammatically. Text labelling is done for major anchors at the global level. At the local level, text is only used to label the anchor of interest; numerical labelling, complemented by text, is used for adjacent anchors and streets.
- Minimise text input. Menu options are offered for point-of-interest search. Users only need to type three letters to obtain a list of matching names for streets and points of interest.

An additional feature of the interface is the Phonemarks (Figure 4.5). By using the Phonemarks feature the user stores anchor points for later exploration in the fixed or mobile Internet platforms. If those anchor points reflect commercial items this

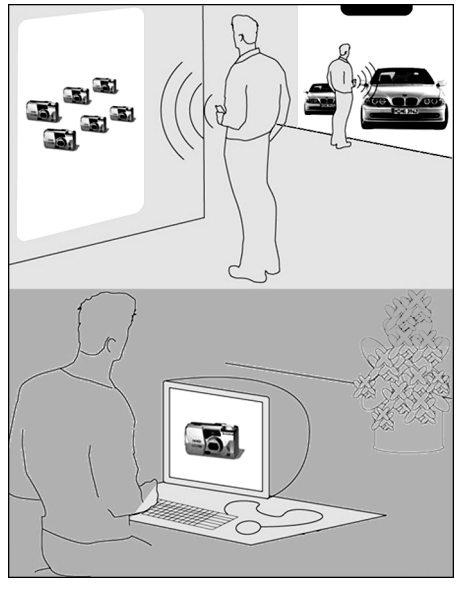

Figure 4.5 *Phonemarks – whilst visiting, users can send codes of preferred objects or shops to a descriptive file. This will allow the user to visit, at a later date, Web sites or WML decks that are associated to these codes*

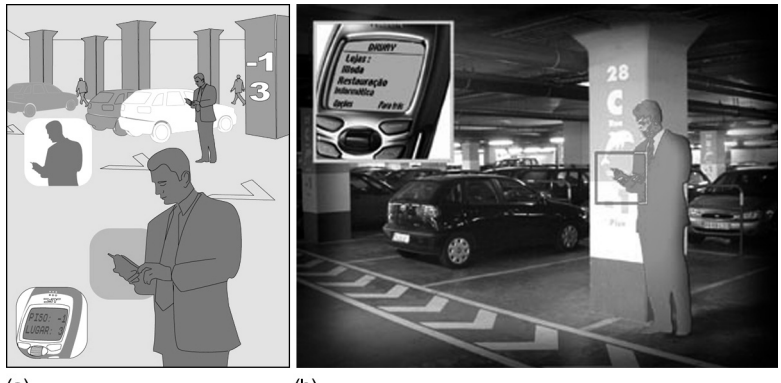
feature may be used for mobile commerce. Phonemarks are also used to store the location of cars in the parking lot.

The DiWay system may also use text messages (SMS) and, in the recently released phones, text, image and sound messages based on MMS. At this point, it is not yet clear if navigation systems based on MMS, that place less of a burden on the user, may overcome mobile Internet alternatives. If flat rates are adopted as in Japan, mobile Internet will become less expensive, and allow for a thorough use of mobile applications.

4.4 Application

DiWay is being implemented for the Colombo Centre in a demonstration project that includes the following features.

- Store and product finders, to find stores that sell a particular product. These are displayed on diagrammatic maps of the shopping centres. Paths from origin to destination are provided on those maps and by textual directions using key anchor points.
- Parking place finder. Using the Phonemarks feature, the visitor stores the spatial code of the place where he or she parked the car. The parking place finder will later help him or her in finding the way back to the car (Figure 4.6).
- Product interaction, to enable the visualisation of detailed product information and facilitate its mobile purchase (Figure 4.7). The user types in the code for the product (or receives its code via a Bluetooth anchor) and accesses all the corresponding stored information. Furthermore, if the store is closed the user can buy the product through DiWay or use the Phonemarks feature to store the product's code for a later review.



(a) (b)

Figure 4.6 *Using Phonemarks to (a) store the position of the car and (b) locate the car in Colombo Centre's parking lot*

Figure 4.7 *Interaction with a product using the mobile phone*

- Casual encounters, to facilitate the meeting of people with identical profiles. This is a community-building feature that uses the centre as a link from the cyberspace to the real world, allowing people to establish virtual communication and eventually meet using the directions provided by DiWay. This works like a treasure-hunting game where the treasures are real people. Profiles are filled on the Web prior to the visit, or through DiWay upon entrance to the shopping centre. In order to stimulate sponsorship of the system, directions will be given using shops as points of interest and the meeting points will be established at main sponsor stores.
- Emergency alerts are possible by pressing e after entering the nearest spatial code (or in the future receiving it by activating its emission from the nearest Bluetooth anchor).
- Information on transportation to and from the centre. This feature includes an automated service to request taxis, without forcing the user to make any phone call. DiWay will both inform the user and the taxi of the most adequate meeting point.

The experience so far has shown that frequent WAP users find the system useful. However, such users total less than 10% of the Colombo Centre visitors that have mobile phones. A much higher percentage regularly use SMS and is expected to adopt MMS. Thus, it is clear that unless third-generation devices enable an easier use of the mobile Internet, DiWay and other navigation systems will be based on MMS systems that will enable the display of maps, sounds, images and even 360 degree views.

4.5 Conclusions and Further Developments

The emergence of mobile computing has opened new opportunities for LBS. Indoor applications of LBS in shopping centres are most relevant to facilitate navigation, mobile commerce and community activities. This chapter has described a methodology developed with those goals in mind for mobile phones that are mobile Internet,

SMS and MMS enabled. The approach, named DiWay, includes detailed geo-referencing of anchor points and other relevant objects, spatial analysis tools and an appropriate interface for mobile phones. DiWay is based on a software platform called FluidMapping. It relies on a view of GIS as composed of modular components. FluidMapping is designed to handle heterogeneous databases and multiple presentation devices such as personal computers, personal digital assistants and mobile phones. It also includes modular spatial analysis components. In this chapter, FluidMappping was applied to a shopping centre represented as a graph where nodes were shops and parking places and the arcs were the shopping streets. The spatial analysis component used in DiWay was based on the Dijkstra algorithm. This algorithm was applied to determine the shortest path and the nearest point of interest. The potential application of node-covering algorithms to determine optimal circuits was also discussed.

The DiWay approach was illustrated with the development of a system for the Colombo Centre in Lisbon. This system has been developed in cooperation with SONAE, the operator of the centre. It was designed to replace the existing methods of assisting visitors in their shopping experience. The experience so far has shown that the system is only beneficial for seasoned WAP users. These make up less than 10% of the total number of visitors to the Colombo Centre. MMS, which enables the visualisation of maps, sounds, images and 360 degree views, may be an alternative for future implementations. DiWay will benefit also from the development of the third-generation mobile phones and the increasing use of Bluetooth chips. Third-generation phones will offer a larger bandwidth and colour. Bluetooth chips will provide an infrastructure to facilitate indoor positioning and avoid dialling codes which is the current positioning solution.

Mass Appraisal and Noise: the use of Lifestyle Segmentation Profiles to Define Neighbourhoods for Hedonic Housing Price Mass Appraisal Models

Steven Laposa and Grant Thrall

Abstract

This chapter presents a case study on the application of geographic information systems (GIS) with the mass appraisal of 1400 residential properties located in an urban area. The objective of the case study is to estimate the total value of the residential portfolio using 850 sales from the multiple listing service. The residential properties are in an urban area subject to extensive vandalism, crime and vacant homes. The authors contend that the use of GIS, and special three-dimensional (3D) modelling and visualisation of sale prices, provides a higher explanatory power than typical hedonic residential price models. The study shows how the application of lifestyle segmentation profiles (LSPs) such as ESRI Bis (formerly CACIs Coder/Plus) ACORN geodemographic database can support valuation modelling.

5.1 Introduction

The practice and implementation of mass appraisal models are widespread in the real estate industry. Local tax assessors use a form of mass appraisal modelling to

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

estimate residential property values for property tax assessments (for a discussion and overview, see International Association of Assessment Officers (IAAO), 1999). Implementations of computer-assisted mass appraisal (CAMA) applications are widespread throughout the assessment industry. Mass appraisal models have been used in litigation cases and portfolio investment analysis for similar properties, such as fast food or convenience stores. Mass appraisal is a statistical procedure of defining a representative sample of a larger population with the purpose of estimating the aggregate value of the overall population. According to the Appraisal Institute Foundation, a mass appraisal includes:

- identifying properties to be appraised; defining market area of consistent behaviour that applies to properties;
- identifying characteristics (supply and demand) that affect the creation of value in that market area;
- developing a model structure that reflects the relationship among the characteristics affecting value in the market area;
- calibrating the model structure to determine the contribution of the individual characteristics affecting value;
- applying the conclusion reflected in the model to the characteristics of the property(ies) being appraised; and
- reviewing the mass appraisal results.

Lead author, Steve Laposa, is global Director of Real Estate Research for PricewaterhouseCoopers (PwC). In that capacity, he was responsible for supporting a team assigned to appraise approximately 1400 residential properties in a major midwestern city. Grant Thrall, was invited to contribute his GIS and business geography expertise to the team. The properties were located in an older, downtown neighbourhood. The properties were owned by a client of PwC; the client requested a total value of those properties in order to establish a market value which would be used to contribute those properties for the creation of a new public–private joint venture. Mass appraisal therefore derives a reasonable estimate of the aggregate value of the properties. Individual property appraisal would instead estimate the value of each individual property, which could be aggregated for an estimate of total value. However, the cost and time involved in executing 1400 individual appraisals would be too great and would not therefore meet the clients objective. Mass appraisal generates comparable results at a much lower cost and in a much shorter time horizon. Hedonic mass appraisal models assume there to be a high level of homogeneity in the population. Hedonic mass appraisal models are a special case of the more general hedonic model. Hedonic models rely upon various forms of regression analysis, where a dependent variable is hypothesised to be explained or described by a set of independent variables (for discussion, see Thrall, 2002, Chapter 4).

Residential home values within small local neighbourhoods are generally homogeneous in terms of size, number of bedrooms, lot size, age and other commonly used descriptive characteristics. Large variances between adjoining homes are usually not found. However, large variances between adjoining homes can be found in older urban neighbourhoods. In the United States older urban neighbourhoods often

exhibit great structural and value differences from street to street, and even within a block. So, the assumption of homogeneity in the population breaks down. Older urban, downtown residential neighbourhoods, often contain deteriorating homes due to abandonment, vandalism, fire, crime and lack of standard maintenance. Thus, the average price per square foot over a large sub-market does not necessarily reflect the value of an individual home. This provides a problem for the usual procedures for mass appraisal.

A key ingredient to mass appraisal models is the assumption that variance is small between residential home values within a neighbourhood; the smaller the geographic delineation of the neighbourhood, the smaller would be the expected housing price variance. The assumption of small variance excludes the existence of large price per square foot variance between nearby homes. In other words, the land price surface is expected to be smoothly unfolding across space, and not discontinuous (see Thrall, 1998a, for a discussion on the error of this assumption).

Geographic surface interpolation procedures assume that space is smooth and continuous. These procedures assume that values between locations do not change abruptly, allowing local values to be accurately represented by a larger spatial trend. In many instances, these assumptions accurately represent physical phenomena. However, real estate is more problematic. Ownership and build characteristics change from parcel to parcel. So, spatial trend models may be used to represent general trends, but not individual parcel values. When the variation between parcels is very large, as in our study, large area spatial trends have considerable error.

In this chapter, we deal with two issues of mass appraisal: first, how can one specify an appropriately small geographic neighbourhood in a manner that is both defensible and repeatable between neighbourhoods, and even between cities? Within the resulting small geographic neighbourhood, land prices would be expected to have a small (minimum) variance between dwellings; second, when large per square foot variances between nearby homes do occur, what can explain the variance and how can that explanation be incorporated into a mass appraisal model? This chapter addresses the use of mass appraisal modelling incorporated with GIS and databases. Our contribution to the literature is the use of lifestyle segmentation and 3D GIS applications in addition to standard housing hedonic models. First, we provide a discussion of the explanatory variables we use in our mass appraisal, including lifestyle segmentation profiles which are particularly important for neighbourhood delineation. We then present a discussion of our methodology and our conclusions.

5.2 Explanatory Variables and Lifestyle Segmentation Profiles

It has long been recognised that house prices are highly dependent upon neighbourhood. Homer Hoyt in his renowned study demonstrated that like-kind neighbourhoods were so spatially interdependent that they formed geographic clusters giving rise to Hoyt's classic hypothesis of the sectoral nature of cities (Hoyt, 1933, 1939, 1966). Within a sector, a variety of measurements are correlated with housing prices; the most commonly used in hedonic housing price models are listed in Table 5.1. The first column of Table 5.1, AM, are measurements of access to place specific

Table 5.1 *Independent variables by geographic scale*

Accessibility measures (AM)	House features (HF)	Neighbourhood attributes (NA)
Highway	Living area	Average house size
Central business district	Bathrooms	Size of neighbourhood/subdivision
Major retail	Pool	Floodplain
Minor retail	Fireplace	Census tract land characteristics
Major employment centres	Foundation type	% land area in single-family dwellings
University/colleges	Age	% land area in multi-family dwellings
Hospitals	Heating type	% land area in offices
	Air-conditioning	% land area in industry
	Roof type	% land area in parks
	Wall type	Census tract population characteristics
	Garage type	% non-white
	Lot size	Median income
		School district

phenomena that are often cited as being important in households' decisions to locate which translates into a housing price effect. Features of a house (HF) affect the market value of a dwelling; the larger the square footage, and the more bathrooms, the greater will be the market value of the house. Fireplaces and pools are expensive to build (often, dwellings with greater construction costs will have greater market value) and neighbourhood attributes (NA) generally affect housing prices. Neighbourhoods dominated with large houses are generally expected to have greater housing values than neighbourhoods with smaller houses. Hedonic housing models will have house price or square footage price as the dependent variable, and sets of variables from the three columns of Table 5.1 as independent variables (see Thrall, 2002, Chapter 5 for further discussion, and Thrall, 1998b, 2002, Chapter 3, on how land prices are related to the leading independent variables).

A typical hedonic housing price model (see also Case *et al.*, 1991; Clapp *et al.*, 1995) might be expressed, using terms from Table 5.1, as

$$P = P(AM, HF, NA) \tag{5.1}$$

where AM are a representative set of accessibility measures, HF is a representative set of housing features, and NA is a representative set of variables that characterise a neighbourhood. Regression coefficients are estimated for a hedonic expression based upon equation (5.1). Dummy variables might be added to the hedonic expression of functional (5.1) to capture the difference in how the independent variables affect the dependent variable between the various neighbourhoods. The mechanics of appropriate estimation of functional expression (5.1) are well known and successfully applied in CAMA (computer assisted mass appraisal) for the determination of estimates of market value of individual dwellings. However, two problems can arise that can make for unreliable estimates of a hedonic expression based upon

functional form (5.1): spatial autocorrelation and biased data sets, and appropriate geographic delineation of the neighbourhoods.

Spatial autocorrelation is a measurement of how closely correlated near neighbours are. If near neighbours are highly correlated with one another, then there is said to be a high level of spatial autocorrelation. From the above discussion, housing prices are generally expected to be highly correlated with prices of neighbouring dwellings. After all, it is said that real estate is 'location, location, location', and indeed if that is true, then real estate prices will be dependent upon the spatial association with neighbouring properties. Spatial autocorrelation in hedonic housing models arises because an observation's price highly depends upon the price of a near neighbour, and that dependence declines the further apart are the observations in geographic space. The degree of spatial autocorrelation may be measured. If there are high levels of spatial autocorrelation, then regression coefficients will be biased in an unknown direction and thereby make for unreliable housing forecasts. An accepted and most frequently used method for correcting for spatial autocorrelation is by way of appropriate independent variable choice, where the independent variables capture the spatial trend. The problem has been, however, the identification of independent variables that can capture the uniqueness of the neighbourhood. A neighbourhood can be a geographically contiguous area, or noncontiguous, where similar physical characteristics of the properties may or may not be important. However, usually, similarity among the inhabitants is important when defining a neighbourhood.

Data observations that form the basis of the calibration of a hedonic housing price model are assumed to be unbiased representations of the population that the model is intended to represent. Constraints on experimental design might not allow the data observations to represent the population adequately. Constraints on the experimental design might give rise to small variations among the observations in the traditional independent variables listed in Table 5.1 – namely the experimental design might have constrained the observations to have been selected from a region where the properties were physically similar. In addition, house prices within the region might have substantial sub-market variation.

In this chapter we propose a solution for when housing observations are taken from a housing stock that is highly homogeneous in physical characteristics, taken from the same region of the city, while at the same time whose prices are observed to be highly variable though spatially autocorrelated. The experiment reported on here is to estimate housing prices of 1400 properties that are overall of the same age and physical characteristics, and taken from what colloquially would generally be accepted as the same sector of the city. Yet, the sales of the subject properties revealed that there was a wide variation in actual prices paid for these properties. The traditional hedonic housing price approach, following accepted practices and including those physical variables listed in Table 5.1, did not yield acceptable results. The researchers then were confronted with discovering the underlying cause of housing price differentiation, where those housing prices are not a function of traditionally measured physical characteristics.

Since the observations were taken from a small geographic area, and since the experiments revealed that whatever physical variation there was that existed between

the dwellings were not determinants to revealed house prices, the researchers then hypothesised that some underlying social forces were the cause of variation in housing prices. The problem was how to measure those small geographic-scale neighbourhood-specific social forces in a repeatable unbiased manner? In other words, we preferred to use some automated procedure to define a neighbourhood versus relying upon our own prejudices, biases and limited information to define a neighbourhood. Therefore, we turned to methods and procedures of social area analysis.

While lifestyle segmentation profiles (LSPs) have their roots in academia, they recently have received more attention by practitioners with requirements to use consistent criteria to define neighbourhoods on the basis of the type of people that live there. LSPs provide a multidimensional view of people, in contrast to conventional univariate census variables such as census tract median income. LSPs allow for a differentiation between neighbourhoods on the basis of the social makeup of the inhabitants of those neighbourhoods. If neighbourhoods are defined on the basis of dominant LSPs, then within a geographic region of a city, a neighbourhood need not be spatially contiguous as has been the convention in hedonic modelling with dummy variables representing neighbourhoods. LSPs are used to define a social neighbourhood. It is our contention that LSPs can identify geographically small sub-markets, and thereby capture the small-scale component that gives rise to near neighbour spatial autocorrelation for some properties, and discontinuities for other properties. In our study, we used ESRI Bis (formerly CACI) ACORN LSPs because they have a geographic resolution of a ZIP + 4 code that we considered a necessary and sufficient level of geographic resolution. Other LSPs such as Mosaic (Thrall *et al.*, 2001) have the geographic resolution of the census block or block group, and are appropriate for other forms of analysis. For a discussion of LSPs from Claritas Corporation, see Hartshorn (1992, p. 255) and Weiss (1988).

Social area analysis was developed in the post World War II era, by sociologists interested in the social structure of urban sub-markets (see Shevky and Williams, 1949; Shevky and Bell, 1955; as quoted in Hartshorn, 1992, p. 248). Geographers, adopted the social area analysis work of sociologists (see for example Berry, 1964, 1969, 1970) and used factor analytic methods to classify neighbourhoods. CACI Marketing Systems commercialised the concept through the sale of neighbourhood classification data, which CACI referred to as ACORNs, an acronym for 'A Classification of Residential Neighbourhoods'. CACI Marketing Systems became well known to the business community for its ACORN LSPs. CACI Coder/Plus, the product used in this research, integrates the assignment of geographic coordinates, ACORN LSPs, and ZIP + 4 codes to each record observation based upon its street address. Recently, ESRI (www.esri.com) purchased CACI Marketing Systems and markets the same product under the name ESRI Bis. ACORN categories are accurate and differentiated at the geographic scale of the ZIP + 4 code (for further discussion on the derivation and use of LSPs, see Thrall *et al.*, 2001; and Thrall, 2002).

5.3 Data and Methodology

In order to estimate the values of 1400 homes, the authors collected 850 actual home sales from a local Multiple Listing Service (MLS). They selected actual

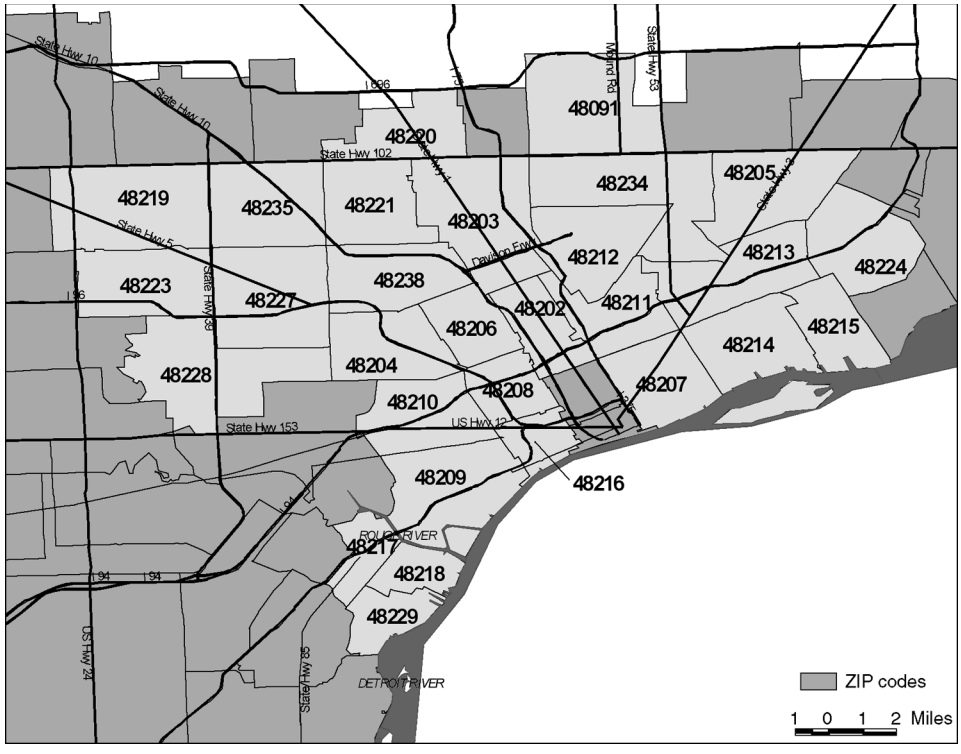

Figure 5.1 *Targeted geographic area by zipcode*

home sales for the prior year and limited their sample to (1) homes sold under $80 000 based on discussions with field inspectors, and (2) geographic proximity to the 1400 homes. Figure 5.1 illustrates the zipcodes selected for the MLS home sale database.

Plate 4 is a geographic visualisation of the MLS properties selected for use as comparables. Addresses of the properties were used to geocode. ESRI Bis (Thrall, 1998b) was used to assign geographic coordinates. ESRI Bis assigns geographic coordinates on the basis of the most accurate coordinate that can be derived between each data record's street address, ZIP + 4, or ZIP code; ESRI Bis is an 'intelligent' geocoder in that addresses will be corrected and standardised using current US postal records. Among the corrections are street address format, name spelling and the addition of ZIP and ZIP + 4 codes. Standardised FIPS codes are also added for documenting the census polygon (block, block group, tract) in which the address is located. Because the neighbourhood is 'older urban inner core', ESRI Bis intelligent use of the US Census TIGER/Line files results in street address assignment of the geographic coordinates (Thrall and Thrall, 1993). ESRI Bis also assigned its ACORN LifeStyle Segmentation Profiles (LSPs) to the data observations; all properties within the same ZIP + 4 are assigned the same ACORN LSP classification. ArcView (www.esri.com) software was used to visualise the geographic data. ArcView was commanded to

display the MLS parcels as a point data file, and to shade those points thematically by three categories of range: \$0 to \$20 K, \$20 K to \$60 K, >\$60 K. Qualitative interpretation of the map includes that there are clusters of observations within each price category; however, observations from all price categories can be observed throughout the map.

There were several steps in our methodology:

- review client-supplied data on the 1400 homes and ensure that critical data fields are populated, i.e., age, size of home, number of bedrooms and condition of the home. Field inspectors coded each property for fire damage, vandalism and whether the property was abandoned (dummy variables);
- geocode the 1400 homes, identify zipcodes, and integrate ACORNs for each property;
- select MLS actual home sales from the zipcodes identified in step 2. Obtain similar data fields as found in step 1 and code with ACORNs;
- run standard pricing models on MLS database, including transformations and stratified models based on price ranges. Test for differences across zipcodes and LSPs; and
- use 3D GIS applications on MLS data.

5.4 Analysis

Figure 5.2 shows the distribution of MLS home prices and correlation between home price and size in square footage. Table 5.2 confirms the lack of correlations between home price to number of baths, number of bedrooms and square footage.

Figure 5.3 is a boxplot of house prices by ACORN categories and the number of MLS home sales by each ACORN (see Table 5.3 for a complete listing of ACORN LSPs). Only eight LSPs were represented in our data set. ANOVA tests confirm significant differences between ACORN categories.

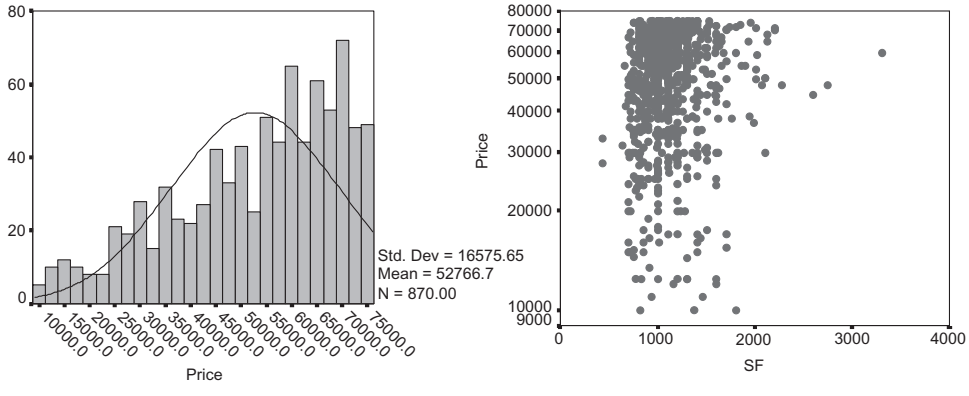

Figure 5.2 *MLS home price distribution and size correlation*

Table 5.2 *Correlation matrix*

		Price	Baths	Bedrooms	SF

**Correlation is significant at the 0.01 level (2-tailed)

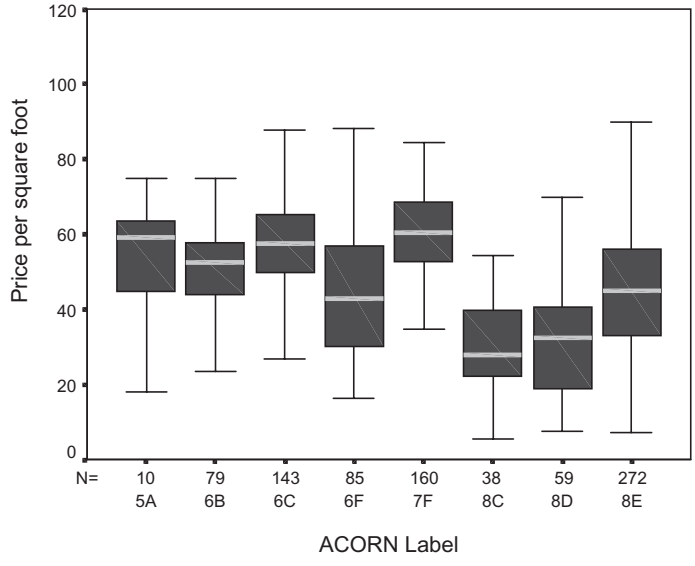

Figure 5.3 *Sale price per square foot by ACORN category*

Table 5.4 presents results from a multiple regression model with price as the dependant variable, and square footage, number of baths and number of bedrooms as independent variables. The regression model's explanatory power is around 1%.[1]

So what is the implication of the model of Table 5.4 having only an R^2 of 1%? First, the traditional hedonic mass appraisal model as described above is inappropriate for neighbourhoods such as that represented in our data set. The traditional hedonic

[1] The authors attempted several other regression models with similar results.

Table 5.3 *ACORN lifestyle segmentation profiles*

ACORN	Description
1A	1A Top One Percent
1B	1B Wealthy Seaboard Suburbs
1C	1C Upper Income Empty Nesters

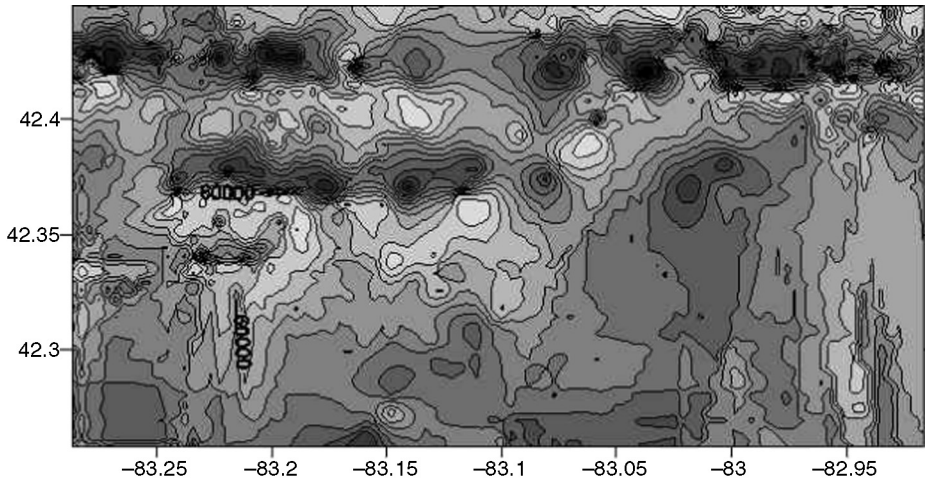

Figure 5.4 *Map of estimated home prices*

Figure 5.4 is a geographic visualisation of the total price surface. The darker shades are isoline peaks, while the lighter shades are isoline valleys. Hence, the higher the price of the MLS comparable property, the darker the area; the lower the price, the lighter the area. Thrall (1998) argued that isoline maps cannot be used to derive estimates of properties within a contour; however, he reasoned that their use was appropriate for qualitative analysis to generate hypotheses about the underlying geographic nature and regularity of the phenomena being studied (in this instance, neighbourhood variation prices of homogeneous properties). Visual analysis of Figure 5.4 reveals a clear east–west street trend, with adjacent streets having abrupt and discontinuous (versus a gradual smooth) change in housing prices. Figure 5.4 was constructed using the same data set as elsewhere in the paper; SURFER (www.goldensoftware.com) was used to derive the isolines. Qualitative analysis of Figure 5.4 gave rise to the hypothesis that prices were highly dependent upon neighbourhood, where neighbourhood was defined as a street face.

The US Postal Service defines unique ZIP + 4 codes along a street face. A second hypothesis arose from the qualitative analysis as well: that since various and nonspatially contiguous ZIP + 4 codes shared the same price isoline, and since the properties were highly homogeneous between neighbourhoods, then the underlying geodemographic characteristics might explain the variation in prices between ZIP + 4 neighbourhoods, and commonality of prices between various ZIP + 4 neighbourhoods.

Figure 5.5 corroborates the qualitative analysis of Figure 5.4. The spatial trend is strongly east–west, with abrupt changes along parallel lines (streets) from north to south,[2] particularly in the northern study area. So, even though the physical

[2] Field inspectors confirmed that houses on main neighbourhood arteries were generally in acceptable quality condition whereas similar sized homes on adjacent streets were of lower quality.

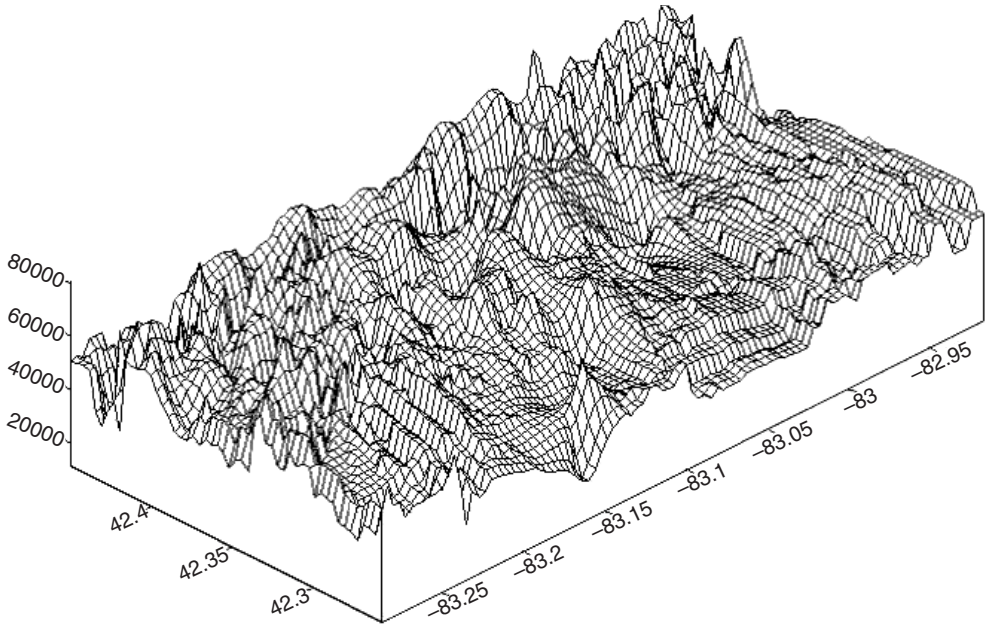

Figure 5.5 *3D map of home prices in study area*

properties were highly homogeneous, there is a strong geographic trend among the properties within what would be considered a sub-market. Therefore, any global averaging of housing values following conventional appraisal techniques would result in an underestimate of properties on some streets in the north, an overestimate of some properties on other streets in the north, and a highly mixed quality of assessment in the southern area of the sub-market.

Plate 5 provides the necessary geographic documentation (Thrall, 1998a) showing the location of the point observations along with the neighbourhoods generated by the isolines. Spatial smoothing can create surfaces even when no observations are present, as evident in the southeastern quadrant of the study area. In other words, the estimate of the surface in the southeast is not reliable. However, because of the apparent geographic regularity and the high density of the observations that give rise to the east–west trend and the abrupt changes from north to south, qualitative analysis here may be considered as reliable. This corroborates our hypothesis that LSPs at the ZIP + 4 scale might capture the underlying cause of spatial variation in prices of the dwellings. In other words, we hypothesise that the variation in prices within LSP categories is less than the variation in prices between LSP categories. Consumers are responding to very small-scale neighbourhood specific geodemographic characteristics, and that response creates a price effect. If so, then neighbourhoods within the study sub-market can be geographically discontinuous, while at the same time sharing LSP characteristic. Plate 5 was created in the same way as the other surface maps, but with optional parameters set differently in SURFER software.

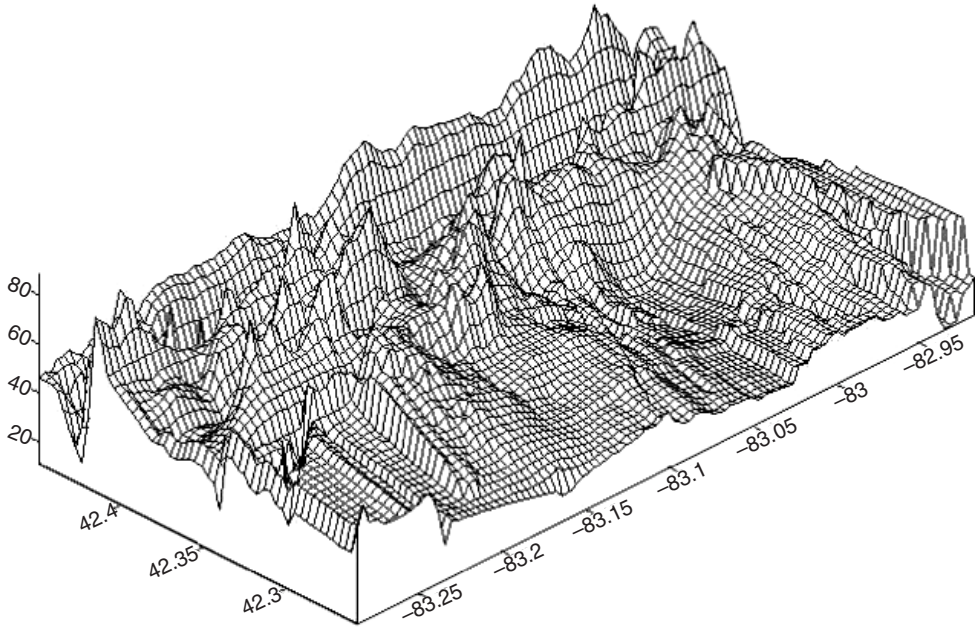

Figure 5.6 *3D model of price per square foot*

Figure 5.6 increases the vertical scale of price thereby allowing the analyst to observe and confirm the qualitative analysis presented in the other figures.

5.5 Conclusion

Practitioner applications often challenge the envelope of tidy academic solutions. Certainly as academics we would not have designed an experiment with an inherently problemsome design as this. However, practitioners are often called upon to provide acceptable solutions to real-world problems that are not as tidy as that derived from an ideal laboratory situation.

The authors support the inclusion of LSPs, such as ESRI's ACORN, in hedonic mass appraisal models. Visualisation with 3D maps assists in improving one's intuition about the geographic problems inherent in hedonic mass appraisal of urban residential neighbourhoods. A long-standing issue in mass appraisal has been how to define appropriately a neighbourhood and sub-market. Here we have demonstrated that LSPs can effectively define neighbourhoods, including neighbourhoods within a larger sub-market, that are not spatially contiguous. That is, within a sub-market, ZIP + 4s with the same or similar LSP can be grouped together to define a neighbourhood. Average square footage prices of houses can be effectively derived from those dwellings within a neighbourhood so defined. Future applications of this procedure might improve suburban residential hedonic mass appraisal that have proved

problemsome because of their heterogeneity. The client accepted the value of our mass appraisal, and used that as a basis to improve their judgement and complete negotiations for the successful transaction.

Targeting Clusters of Deprivation within Cities

Richard Harris and Paul Longley

Abstract

This chapter considers the relative merits of census-based and lifestyles approaches to identify and represent spatially concentrated areas of urban deprivation (and affluence). Using census-based geodemographic indicators and lifestyles data supplied by a UK-based data warehouse company, we appraise three broad approaches: conventional deprivation indicators based on census information; hybrid approaches that link census data to more specific social survey information; and, finally, approaches that make use of private sector lifestyles surveys that can be combined with high resolution imagery of the built environment to more precisely determine social and built conditions. We argue that appraisal of these different methodologies and of the representations of socioeconomic geography they create enhances our understanding of uncertainty in GIS and other geographic modelling. It also casts light on the role and substance of generalisation in urban analysis. We explore these issues in relation to the practice of marketeers working within the geodemographic and lifestyles industries.

6.1 Introduction

Urban geography seeks to identify and understand the geographical patterning of urban landscapes and urban populations in relation to the processes that give rise to those patterns. By forming general understandings of such processes and of the inter-relationships between processes, people and places there is a possibility both to compare the socioeconomic, demographic or environmental structures of different places at particular points in time, and to predict and simulate how settlements might

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

evolve in the future. These understandings are essential to the governance and management of urban environments and systems. However, the detailed richness of any (specific) representation is always depleted by the process of generalisation when hard decisions are made regarding what to deem as irrelevant detail in order to establish baselines of comparability. Rarely is all of what is discarded wholly irrelevant to the process of building representations (Longley *et al*., 2001, Chapter 3).

Donnay *et al.* (2001) make this clear in the context of urban remote sensing and image classification. They see advantages of a generic model in the power of constructing a relatively simple (and understandable) representation of the properties of a large number of objects and in the portability of that general model from one location to another, permitting comparison between places. Yet, the match between a generalised model and the specific patterns observed in any scene normally will not be exact; there is inevitable uncertainty associated with the application of a generic model to a particular setting. Such uncertainty is likely to be greater than that associated with more specific, finely focused case studies. But if the merits of generalisation are accepted as worthwhile, then attention focuses upon how to minimise the uncertainty associated with the practice of abstraction and generalisation; how to ensure general models are 'fit for purpose' and usable.

In the past, outdated, imprecise, coarsely aggregated and indirect data sources have done urban geographers few favours in their search for empirical regularities and general understandings of urban growth, structure and morphology. Given those circumstances it is unsurprising that many geographers have become disenchanted with working with inert spatial mosaics and sometimes absurdly surrogate data, instead channelling their efforts to detailed, qualitative and ideographic approaches. At its best, urban geography continues to generate valuable insights into urban lifestyles and landscapes. However, there is also a gathering sense that the subject has become overly preoccupied with introspective and individualistic case studies and anecdote at the expense of more system-wide understandings of urban environments and systems. It is ironic (or perverse) that the relative abandonment of systematic, quantitative approaches in much of urban geography has come at a time when the data infrastructure for representation building has improved enormously, offering more direct and meaningful sources of information and analysis. In the UK, for example, Ordnance Survey (OS) recently has launched MasterMap, an ambitious project to provide a consistent, national framework for referencing geographic information. The foundation of MasterMap is a database containing information about polygons that together represent 400 million man-made and natural features (for example, individual fields, lakes or pillar boxes) and includes National Grid, GPS and detailed topographic information for all features (see www.ordsvy.gov.uk).

We are not suggesting that only that (large, and increasing) subset of phenomena that can be incorporated in quantitative representation should be deemed worthy of academic study; nor are we implying that better data and better data-handling technologies are a panacea to the limits of GIS-based representation. However, it is increasingly apparent that the worlds of business and commerce, with their pragmatic tactical and strategic concerns, better understand the importance and power of generalisation than much of academia. We view this as an odd, undesirable and some-

what self-defeating state of affairs when policy-makers at many levels of governance (in both the private and public sectors) are increasingly becoming minded to ask geographical questions, and look to geographical data and analysis for the answers. Consider, for example, the UK Government's Policy Action Team (PAT) 18 report on better information which states that 'comprehensive and up-to-date [geographical] information about deprived neighbourhoods is crucial to the National Strategy for Neighbourhood Renewal [. . .] Far too often information is seen as an additional and peripheral issue in regeneration activities, rather than as central to them. In reality, information is one of the key tools in the drive towards a more inclusive society' (PAT 18, 2000, p. 5).

One outcome of the Action Team's report was the setting up of a Neighbourhood Statistics Service (NSS) for the UK (see www.statistics.gov.uk). Yet, despite this important initiative we are actually little closer to answering one of the main questions that acted as a catalyst to creating PAT 18 and the NSS in the first instance. Specifically, at what scale does deprivation and social exclusion exist and persist? That is a question that the information currently provided by the NSS cannot answer because it is constrained to a particular, possibly inappropriate, zonal geography prior to dissemination (namely, to the 1991 UK Census ward geography). Use of the information presumes the census geography is suited to the task of targeting deprivation and measuring variation in socioeconomic conditions – a presumption that we have challenged (Harris and Longley, 2002).

Elsewhere we have followed the lead of business and commerce and looked to the datasets they are using to try and produce more finely attuned and targeted measures of deprivation (Harris and Frost, 2003; Harris and Longley, 2002). We have sought to navigate a path between the polarities of 'scientific but outdated and dull' academic research, and 'unscientific but rich and timely' analysis of private sector databases (Longley and Harris, 1999). In this chapter we continue along that path in the context of studies of deprivation in urban areas. We argue that clearer thinking about the conception, measurement and analysis of deprivation has far-reaching implications for anyone with interests in social exclusion. We focus on establishing the scale at which private sector sources of income information can be utilised to provide robust and comparable estimates of geographical concentrations of deprived (or, conversely affluent) income groups.

6.2 Geographies of Deprivation

The conception of deprivation is very much a contested domain: different conceptions lead to different geographical representations of physical and social conditions. Any representation can come to reflect the priorities of those who do the representing. The nomenclature of deprivation is often linked to notions of poverty, inequality and social exclusion. It can also have an absolute or relative meaning. Few could argue that the estimated average 24 000 people who die each day worldwide from hunger – 75% of whom are children aged under five – are not deprived (The Hunger Site: www.thehungersite.com). However, it is a moot point whether those who (are

said to) wear new clothes, own a microwave and also a VCR can honestly be described as living in poverty (*Daily Telegraph*, 2000 responding critically to a report by the Joseph Rowntree Foundation: Gordon *et al.*, 2000).

In generally affluent societies such as the UK's, few people are deprived of access to food, clean water, health, shelter and education (the UN's definition of absolute poverty). However, that does not mean that levels of wealth, well-being and social opportunity are harmonious across society – they are not. Hall and Pfeiffer (2000, p. 81) write that 'the optimistic high-growth period after World War II saw poverty in retreat; even experts could not imagine that inequality would increase again – yet in many countries, and cities, it has' (they cite London, New York and Los Angeles as examples). The emphasis on inequality is indicative of much deprivation-related research in the UK. For example, Shaw *et al.* (1999) and Dorling *et al.* (2000) focus upon inequalities in health outcomes in Britain. Measures of deprivation assume relative connotations, often defined against mean or median household. But this raises the question of what constitutes an inequality? The answer is necessarily subjective. Ultimately, the way in which deprivation is conceived conditions the way that it is measured (Yapa, 1998).

Even if there was consensus about the physical and social measures and manifestations of deprivation, to identify, measure and target geographical clusters of the deprived 'on the ground' requires consistent and task-relevant geographical information to be available to the analyst or policy maker. The usual areal 'containers' of deprivation in the UK – that is the zones to which social and physical characteristics are ascribed – are (1991) Census wards, containing on average a household population of 2081 but varying from a minimum of 153 households to a maximum of 9591 (Openshaw, 1995b). Are these geographical zones really the best suited for measuring and monitoring deprivation? The decision is not neutral in its effects: the choice of geography can alter the apparent intensity and extent of deprived conditions in various locations (Openshaw, 1984). Scale and aggregation effects have profound impacts upon the representation of measured attributes.

Differences of conception compounded with vagaries of measurement have far-reaching consequences for the identification and representation of deprived areas. Harris and Longley (2002) contrast the outcome of Lee's (1999, p. 178) study of local conditions with those of Gordon and Forrest (1995). The former, calculated using a central government measure (Department of the Environment, 1981), suggested that 40% of the most deprived wards in England and Wales are located in Greater London and South East England. The latter (the 'Breadline Index', described below) suggests that the same two regions actually account for 24% of the most deprived wards.

Harris and Longley (2002) also consider Lee *et al.*'s (1995) review of areal measures of deprivation, including the (then) Department of the Environment's 1981 and 1991 Indices (Department of the Environment, 1981, 1994), Jarman Scores (Jarman, 1983), the Townsend Index (Townsend *et al.*, 1988) and an index developed from the Breadline Britain poverty study (Gordon and Forrest, 1995; Gordon and Pantazis, 1995). Lee *et al.*'s study emphasises how apparent similarities or differences between various indices are a function of the variables that make up a particular index and also the scale at which the comparison is made. Lee *et al.* conclude that the various indices for measuring and mapping deprivation differ in terms of how they are

constructed, what their constituent variables purportedly represent and how they are weighted. Despite this, at the coarse Census district scale of analysis, the different indices produce similar deprivation profiles and identify similar lists of the most deprived areas. However, at the ward level and below, the opposite is true – different indices produce quite different results. Multivariate indices produce better representation of the multifaceted nature of deprivation than univariate measures and can identify different populations and areas as being deprived. Yet, a large proportion of the households identified using univariate measures such as unemployment or overcrowding will also be flagged in multivariate indices.

6.3 Census-based and Hybrid Measures of Deprivation

The indices that Lee *et al.* (1995) review are typical of those that are reliant (either directly or indirectly) upon data collected in the UK Census of Population – the only comprehensive data source for mapping the widely recognised indicators of deprivation or poverty within small areas (Lee, 1999, p. 172). The 'preferred status' of the Census arises from the high proportion of the population that it enumerates and the high public sector quality control standards that govern its collection. Nevertheless, its reputation was tarnished in 1991 because of the 'missing millions' omitted (following the debacle of the Poll Tax: see Openshaw, 1995a, p. 14) and the confusions surrounding whether students should be enumerated at home or at their term-time address (Mitchell *et al.*, 2002). The overall response rate for the 1991 Census was about 97% of Britain's 55.94 million residents (Champion, 1995), but with increased under-enumeration of particular sub-groups of the population, notably city dwelling, young males. The response rate for the 2001 UK Census is estimated at about 98% but with an increased non-response rate for some questions. Questions that in 1991 met with a non-response of less than 1% tended to have, in 2001, a non-response of 1–5%. Questions with a non-response rate of 1–5% in 1991 had a rate of 5–10% in 2001. Almost one in five individuals did not complete the 2001 census question enquiring about their professional qualifications (http://www.statistics.gov.uk/census200/pdfs/dataquality.pdf). The trend to increased under-enumeration is worrying, though in an international context it is worth mentioning that the overall response rate achieved by the 2000 US Census was only 67%. Nevertheless, it is clear that modern lifestyles and attitudes make it increasingly difficult for even compulsory public sector surveys to achieve complete enumeration of the population. Ironically, the rather narrow range of questions which the UK Census asks sheds little light on those modern lifestyles and attitudes (Longley and Harris, 1999).

A particular problem in the context of deprivation analysis is that UK Census data contain no direct indicators of income, which most would agree to be a direct and relevant measure of deprivation. Analysis is also constrained by the 10-yearly interval of Census data collection and the resulting problem of data ageing. In the UK there is still no strategy for either enriching the Census using a wider range of pertinent indicators or improving temporal frequency at the neighbourhood scale. In the US and UK alike there is, however, an open discussion of replacing census

collection with a fusion of other public or private sector databases to obtain the same sorts of information collected by the Census (and more). At their best, the data arising out of such approaches would be more wide-ranging and more frequently updated than conventional censuses. However, the vagaries of data fusion raise important issues of measurement error in the source data and of tracking and quantifying error propagation as the different datasets are merged.

The limitations of the Census for socioeconomic research apply equally to business and service planning applications using geodemographic classifications, such as ACORN, Super Profiles or other census-based typologies (Longley and Clarke, 1995; Birkin *et al.*, 2002). Sleight (1997) describes geodemographics as the 'analysis of people by where they live' – an apt description for area-driven deprivation research also. Indeed, Voas and Williamson (2001) describe geodemographic classifications as no more than 'dressed-up measures of affluence' (conversely, measures of deprivation). Further similarity is found in the efforts of practitioners from both research fields to 'freshen-up' census data by linking them to more up-to-date and relevant but less geographically replete samples of survey data. Batey and Brown (1995), for example, describe how the Census core of the Super Profiles classification is 'cocooned' by an updateable layer of non-census data.

In the context of deprivation measures, the 'Breadline Britain' index is an interesting hybrid measure that has been described by Lee *et al.* (1999) as the best index for identifying the most deprived wards (in Britain) at a national level. Full details of the design and implementation of this index are given by Gordon and Forrest (1995), Lee *et al.* (1995), Gordon and Pantazis (1997a, 1997b), Gordon *et al.* (2000) and also Harris and Longley (2002). In brief, it is based on a quota sample of 1319 individuals aged 16 or above supplemented by an additional 512 quota interviews carried out in low income areas: areas identified as Group G ('Council Estates') of the 1981 ACORN geodemographic system (Gordon and Pantazis, 1997a). Interviewees were asked to identify from a list of 44 items (that covered a range of activities and possessions) those that were felt necessary and important to everyday living (Lee *et al.*, 1995). Items attracting a total of 50% or more support were deemed as socially perceived necessities by 'a democratic majority' (Gordon *et al.*, 2000, p. 13). A poverty line was then set at households lacking three or more necessities. On this basis the sample was classified according to an 'in poverty' (1) versus 'not in poverty' (0) dichotomy. It was assumed that few differences exist between different sections of the population as to what is regarded as a necessary item.

The results of the Breadline Britain sample survey were then generalised to the population at large. The survey data were limited to 1831 individuals. Because no similar information existed for the rest of the population it was not known (at a national level) who else in the population owned fewer than three of the necessities. To resolve this problem a link was created between the sample data and the more restricted range of variables available in the 1991 Census small area statistics by identifying variables common to both. A logit analysis was undertaken at the household scale, with deprived/not deprived as the response variable. The explanatory variables were the socioeconomic indicators of the survey that could be paired with like variables in the census (Gordon and Forrest, 1995). The regression parameters arising

from the analysis were subsequently transferred from the household scale to weight corresponding census variables at both the ward and census district scales (Lee *et al.*, 1995). The resulting Breadline Britain Index is used to estimate the percentage of 'poor households' using the following regression relation:

$$y' = 0.2025x_1 + 0.2174x_2 + 0.1597x_3 + 0.1585x_4 + 0.0943x_5 + 0.1079x_6 \qquad (6.1)$$

where y' is the estimated percentage of poor households (per census ward or district) and x_1 to x_6 refer to the following 1991 census variables respectively: % households not owner-occupied; % households with no car; % lone parent households; % households where household head is of partly-skilled or unskilled occupation; % economically active population unemployed; and % households containing a person with a limiting long-term illness. Each percentage figure pertains to a census ward or a census district, depending on the chosen scale of analysis – the parameter estimates are (wrongly) taken to be independent of the scale of analysis and hence remain constant.

Although the method of the Breadline Index is an innovative means to break out of the straightjacket of conventional, census-based deprivation measurement, the user remains constrained by two main shortcomings. First, the Index is based on a small sample and generalised to the whole UK in a geographically invariant way. A single, national set of parameter estimates is created by the linkage mechanism although it is likely that the weight given to each census variable will be more appropriate in some locations and some scales of analysis than others. Second, the Index is used (and is relatively robust) only at the census ward and district scales. There is increasing evidence that even small areas conceal diversity in population characteristics and social conditions (e.g., Longley and Harris, 1999).

6.4 'Small' Areas and the Problem of Diversity

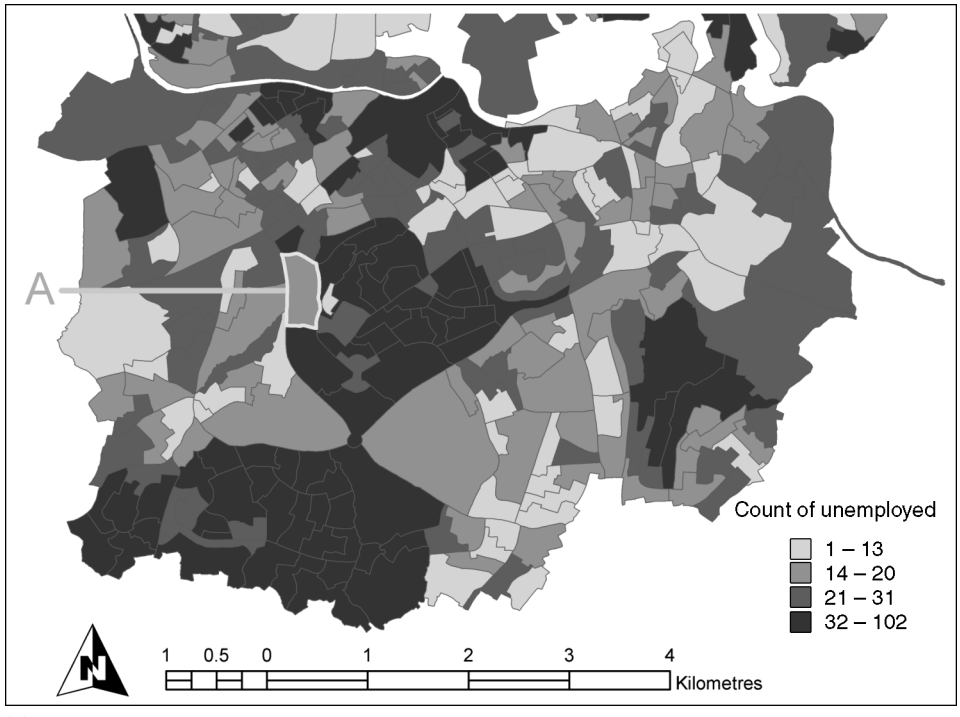
> *'And cities? They are diverse'* (Amin *et al.*, 2000, p. 22).

A significant weakness with the use of census data for deprivation and other area-based analysis is the forced assumption that populations within 'small' areas – meaning census enumeration districts (EDs) or wards – are homogeneous in terms of the socioeconomic conditions in which they live; or, at least, that suppression of within-area diversity is a sacrifice worth making in order to forward the cause of generalisation. Much of our research has contested that assumption (or suppression), focusing on diversity *within* administrative areas. That is not to say that geographical trends and patterns do not exist *between* administrative areas; on the contrary, our argument has been that they do (Harris, 2001; see also Voas and Williamson, 2001). But what of trends and patterns that transcend administrative areas, or are hidden within them? The principal issue is not whether there is a geographical patterning imprinted on the socioeconomic landscape around us – undoubtedly there is – but, instead, the extent to which such trends and patterns are obscured or clarified

by the nature of areal aggregations, including those of the census, or by sources of geographical information that are hardly fit for purpose.

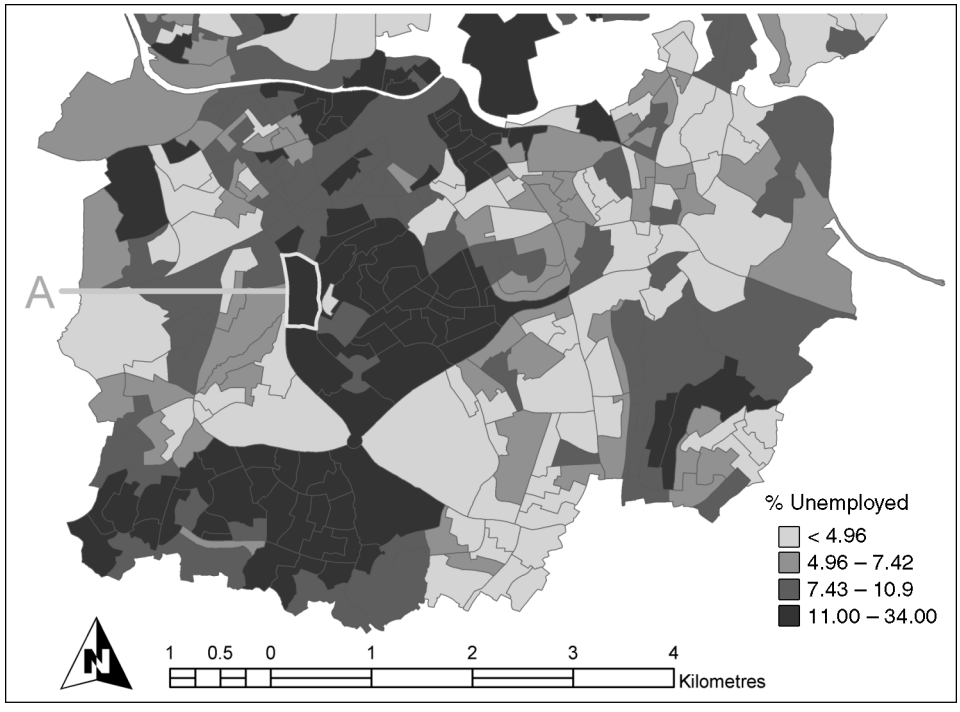
If imperfections and mismatches between spatial distributions are likely to exist, a role for GIS is in quantifying the sources and operation of uncertainties through internal and external validation. Internal validation might, for example, entail experimentation with the scale and aggregation effects arising from different combinations of the smallest available areal units of analysis (e.g., Openshaw, 1984; Alvanides *et al*., 2002). Such experimentation can generate a large range of outcomes but, at the end of the day, there is no incontestable 'optimal' solution. Worse, the results must still take the within-area distributions of the elemental units of analysis as uniform. External validation entails use of ancillary sources that are not constrained by the same (or, ideally, any) zonal geography to reveal more about small area diversity.

A simple example is given by Figures 6.1a and 6.1b, showing the southern half of a map of unemployment in Bristol, for which the unemployment attribute is divided into quartiles. Note that the spatial distribution appears different whether a count of unemployment (Figure 6.1a) or a rate of unemployment (Figure 6.1b) is derived. Consequently it is unclear whether the zone labelled A belongs in a functional sense to the zones to its east or to its west. There is little way of resolving this issue using



(a)

Figure 6.1 *Measures of unemployment in South Bristol, UK*



(b)

Figure 6.1 *Continued*

census data alone. Yet if the area is viewed using high resolution aerial photography, it becomes clear that the area is of mixed land-use: part residential; part industrial; part open space (Figure 6.2). The (small) population of the zone is concentrated to the north-west. Within GIS, a procedure known as dasymetric mapping (Donnay and Unwin, 2001) could be used to mask out unpopulated areas partially in order that census enumeration district (zone) counts might be averaged only over the built-up portion of the zone. In the same spirit, Longley and Mesev (2002) integrate remotely sensed and census data to produce a hybrid representation of the spatial distribution of occupied built structures, and thence create fine-scale density profiles of a city (see also Harris, 2003).

In each of the examples, the ancillary source (aerial photography or satellite imagery) does not identify unique geographical individuals: the element of analysis is determined by the granularity of the image; each individual, pixelated element might enumerate more than one, zero or indeed fractions of human individuals. A different approach is to use ancillary sources that contain individual population records. In this we have taken our cue from the marketing industry, where the era of information commerce and 'one-to-one' marketing has given rise to detailed, disaggregate datasets, commonly about people, their 'lifestyle preferences' and their shopping habits (Longley and Harris, 1999).

Figure 6.2 *High resolution aerial photograph showing land use in zone A. Source: Cities Revealed (1996)*

With the variety of analytical tools now commonplace in GIS software, there exists potential to adopt more flexible and geographically sensitive approaches to classification and modelling of socioeconomic conditions. This provides some defence against the charge that today's planners and policy makers have much better information about the attributes of the built environment from the greatly increased resolutions offered by remotely sensed (RS) imagery (Donnay *et al*., 2001) than they do about the most important part of an urban settlement: the people who live and work there (Harris, 2003).

6.5 Refocusing on Income

To summarise, the lack of conventional survey alternatives has forced reliance on the census as the only viable source of fine-scale socioeconomic data (Green, 1997). Where alternative public sector data do exist they tend to be *ad hoc* and geographically limited, generated in response to the specific needs of individual councils, planning departments and research projects (e.g., Longley *et al*., 1989) and thus not well suited for more general model building or comparative analysis. However, the data blockages to less ambiguous measures of poverty are not insurmountable. Official

(governmental) datasets do not provide the only useful sources of usable information in today's information commerce, although academics and marketeers do appear to have differing perspectives on what is attainable. In the academic domain, for example, Green (1997, p. 181) laments the '. . . dearth of spatially disaggregated [income] data at the local (particularly sub-county) scale'. In a similar vein, Lee (1999, p. 175) notes that the use of unemployment rate as a principal indicator of poverty is largely a response to the lack of household income data. By contrast, private sector companies such as EuroDirect offer commercial products which allow unit postcodes to be selected on the basis of the household income levels found within them (EuroDirect, 1999). A recent study by the market research group CACI also focused upon household income and claimed to give a truer picture of wealth differentials at disaggregate scales than measures provided by the unemployment register (Baldwin, 1999).

There are a number of advantages to the use of private sector 'lifestyles' datasets that can be defined as composite databases created and updated from sources of individual and household data including shopping surveys, loyalty card information, credit ratings and the guarantee returns from consumer products. The advantages include the fact that lifestyles data can be made available to describe households at the scale of the unit postcode. This frees analysis of heterogeneity in social conditions from the out-dated 'mosaic metaphor' which underpins much census-based urban geography (Johnston, 1999; Raper, 2000). The data are also more up to date (shopping surveys of this nature typically are conducted annually) and thus present a more relevant picture of conditions in fast-changing urban systems. Most importantly of all, lifestyles datasets often do have an income question, the nature of which we consider below. This obviates the need to fall back on the indirect surrogate measures that characterise census-based deprivation studies. It is disingenuous to overlook these advantages, even if the quality of the data is at times considered uncertain or unknown (Goodchild and Longley, 1999; Harris and Longley, 2002).

Harris and Frost (2003) argue that despite the uncertain quality of lifestyles data, they can still be used to identify, at the unit postcode level, the location of every survey respondent (in the Borough of Brent, London, in their case study) who indicated their annual family income to be less than £10 000. The respondents to lifestyles surveys are self-selecting from the mailing lists and other sample frames used by lifestyles companies (there is no compunction upon households to complete and return the survey). Nevertheless, if low income respondents are shown to be clustered spatially, then there is cause to believe that there is a clear areal basis to income deprivation, particularly if a reasonable number of the clusters are shown to be within, or in proximity to wards identified as deprived according to more orthodox measures. Lifestyles data and more conventional sources can be used to cross-validate each other, or be combined to produce more data-rich models of the urban fabric (Harris and Longley, 2001).

To map or to create spatial statistics describing any of the data stored in a data warehouse necessarily requires a way of assigning location to each individual or household record. One way of doing this is to use (GB) Ordnance Survey's (OS) Address-Point product to ascribe a UK National Grid reference of up to 0.1 metre precision to the full property address. An alternative is to use OS Code-Point data

which are cheaper for commercial organisations to purchase and are less voluminous to process. Whereas Address-Point assigns (in principle) a georeference to each residential and commercial address in Britain, Code-Point is intended for analysis at the slightly coarser, unit postcode scale (with an average of 12–16 residential delivery points per postcode). The Code-Point file lists, for each postcode in Britain, the grid reference of a point that is located within the footprint of the property closest to the population-weighted centre of the postcode. A Code-Point is defined by first calculating the average Easting and Northing location for all Address-Points within a postcode, and then by identifying the Address-Point closest to that location. The closest Address-Point defines the Code-Point for the postcode (although the grid reference is degraded to a maximum of 1 metre precision). Further comparison between the Address-Point and Code-Point products is made by Harris and Longley (2000).

Code-Point, Address-Point and the MasterMap products each offer ways of ascribing point locations to new souces of attribute data at ever finer levels of granularity. A problem, however, is that points are, by definition, dimensionless and, in a strict sense, occupy zero area on a map. This is clearly a problem if the intention is to use such data to explore and represent socioeconomic distributions! Commonly the problem is 'resolved' by representing a point using a circular symbol, the radius, circumference, area or shading of which can be arbitrary, tailored to enhance the aesthetics of the map or proportional to the value of the phenomenon at the point. Alternative, space-filling methodologies are less cosmetic and may cause permanent changes either to the source data structure or to the attribute table. A variety of kernel, neighbourhood, density and other estimation techniques exist that convert vector points to a near-continuous surface of raster cells, or append a measure of the local intensity of a given phenomenon to the dataset, on a point-by-point basis.

In the context of modelling lifestyles data to produce local indicators of socioeconomic conditions, the advantages of kernel or neighbourhood estimators have been documented by Harris (2003). By analysing each record – each individual or household – as part of a larger and geographically clustered group the sample size is increased and the error component is (in principle) reduced. This approach helps counter the problems of sample and response bias that affect lifestyles datasets to varying degrees (for example, there is evidence that postal shopping surveys tend to miss young, male adults: Longley and Harris, 1999). However, it also raises questions concerning the most appropriate scale at which the geographical clusters should be defined; what is 'the' correct level of aggregation? What neighbourhood, kernel or search window size should be used? This is an important consideration, since the choice has a considerable effect on the amount of smoothing applied to the data. Local estimation techniques are inherently spatial statistics in that the results (the output) are by no means independent of the geographical scale of the analysis (the size of the search window).

In their study of small area income differences within Brent, London, Harris and Frost (2003) choose a circular search window of radius 500 m. But their choice was essentially arbitrary, based only on experience of 'what seems to work'. Even assuming that the chosen scale was indeed appropriate to the analysis, a second question is immediately raised: is the search window size equally appropriate across the entire study region or should it vary geographically in order to adapt to local conditions?

An example of the latter, adaptive approach is Bracken and Martin's population surface algorithm (see Martin, 2002) designed for remodelling census population data into more realistic portrayals of population distributions. The algorithm incorporates a kernel, the size of which is sensitive to local population densities: the kernel is smallest where densities are highest; widest where densities are lowest.

An analogy to fixed versus adaptive search windows is provided by the histogram. A histogram can be plotted using equal class intervals (fixed bin widths) but unless the observations are uniformly distributed between the classes, differing numbers of observations in each class will result. The alternative is to adopt a quantile classification – as in Figure 6.1 – for which the numbers in each class are harmonised by using unequal bin widths (class intervals). The relatively simple procedure outlined by Harris (2003) uses the 'quantile approach', finding the n_i points from a total set of N that are calculated as being at least distance from a single point i (which is also drawn from the set of N). These n_i points, together with point i itself, are then taken to form a 'cluster' or cloud of $n_i + 1$ points and a total population size of m:

$$m = p_{0i} + p_{1i} + p_{2i} + \ldots + p_{ni} \tag{6.2}$$

where p_{0i} is the population at point i, p_{1i} is the population at the (first) nearest neighbourhood point to i, p_{2i} is the population at the second nearest neighbour, and so forth to the nth neighbour. Each of the points is a residential (unit postcode) CodePoint, and the straight-line distance measure does not attempt to accommodate explicitly the effects of built form or spatial structure (e.g., where actual travelled routes differ significantly from the straight-line crow's distance between points or where, in reality, a physical barrier exists that clearly separates two or more points, all be they in seeming close proximity).

The procedure is then repeated for each of the remaining $(N - 1)$ points in turn. The method therefore creates as many clusters as there are points (N). Most households will be allocated to more than one cluster because any individual point can be a nearest neighbour of more than one other. The value of n_i, the number of CodePoints in each group, will vary from cluster to cluster as it is m (the total population size) that is held constant. The value of n_i is governed by both the variable size of postcode populations and the local sample/response rates for the lifestyles survey data that Harris (2003) analysed. Having grouped the households, Harris was able to identify the most frequently occurring (modal) property type within each cluster and also the proportion of households residing in that type. If there are three property classes and the number of households belonging to each class is z_1, z_2 and z_3 respectively, then, assuming z_1 is the modal type:

$$z_1 > z_2 \quad \text{and} \quad z_1 > z_3 \tag{6.3}$$

and

$$p_{z1} = z_1/m \tag{6.4}$$

where

$$m = z_1 + z_2 + z_3 \tag{6.5}$$

or

$$m = p_{0i} + p_{1i} + p_{2i} + \ldots + p_{ni} \tag{6.6}$$

where p_{z1} is the proportion of all households belonging to the modal type.

The proportion – a simple measure of within-cluster homogeneity – was assigned back to the point (i) at the centre of each cluster and this information was used to guide the selection of training samples to classify a remotely sensed image into classes of residential building densities. Training samples were drawn from a Bristol study area where it was most certain that a particular property type existed: areas with the greatest local homogeneity of a dominant property type (Figure 6.3).

If the procedure described by Harris (2003) circumnavigates the issue of what is the correct search window size to aggregate the lifestyles data, it immediately encounters a related problem instead: what is the correct class membership size, m? The Bristol study took a value of $m = 50$ but this was largely chosen to illustrate the analytical methodology rather than for any more considered reason. For the rest of this chapter we therefore consider the effects of changing the value of m on small area measures of modal income and of income homogeneity in London.

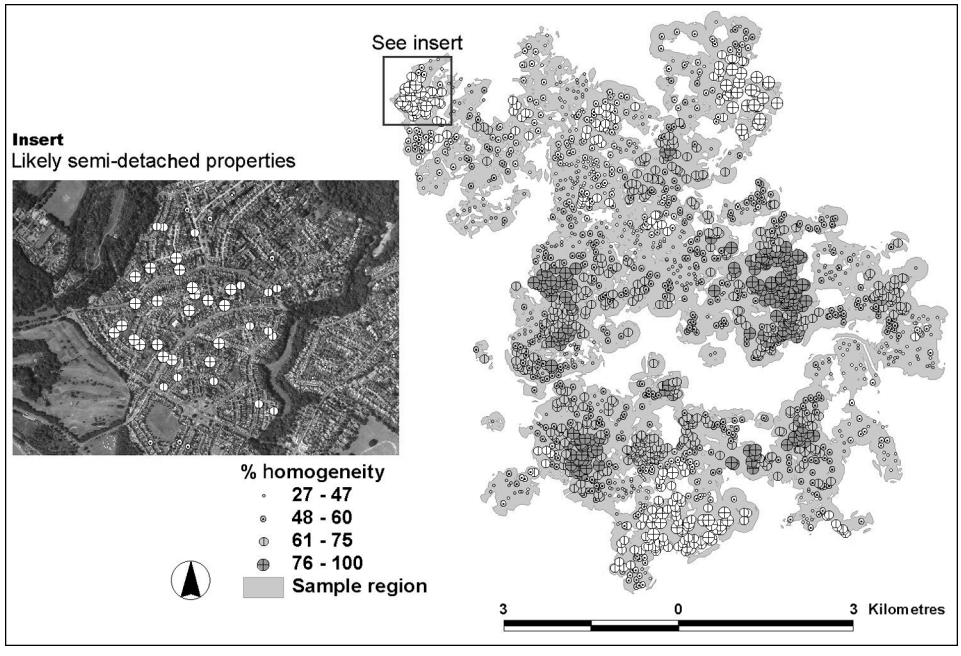


Figure 6.3 *Combining lifestyles and CodePoint population maps to select, from a Cities Revealed image, training samples with high likelihood of being semi-detached properties. Source: Harris (2001)*

6.6 Modelling Income Concentrations in London

Figure 6.4 shows a map of low income clusters in Inner London derived using the methodology described by Harris (2003) but with a value of $m = 75$ and actually undertaken for the whole Greater London region (only Inner London is shown to retain visual clarity of the income distributions). The source data is a commercial lifestyles database compiled from replies to a national consumer survey. That survey was postal, undertaken in England, Wales and Scotland during the spring of 1999, and sent out to a high proportion of households for whom at least one member was listed on the UK electoral register for the three countries. The full lifestyles database contains a wide range of socioeconomic, behavioural and consumer information that describe approximately one million households. We have selected from that dataset those households that gave an indication of their gross household income and have then georeferenced those records, by residential postcode, to an OS CodePoint. This leaves us with a sample of 65 685 households in 42 883 unit postcodes, all of whom

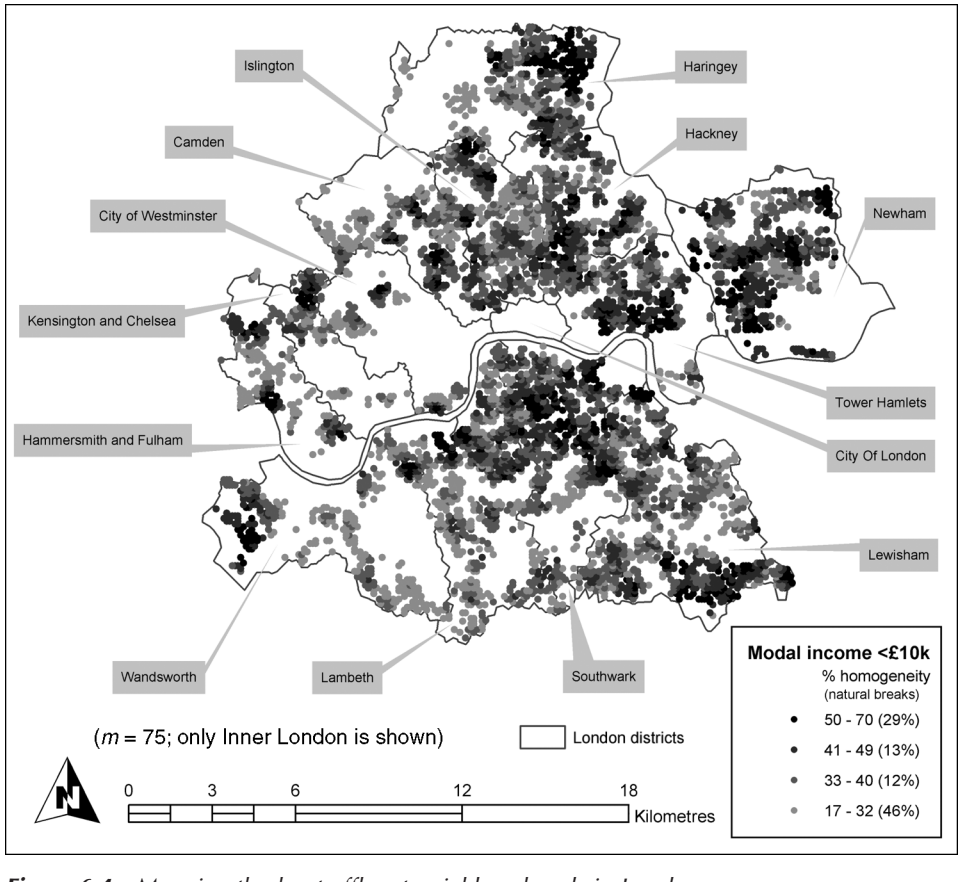

Figure 6.4 *Mapping the least affluent neighbourhoods in London*

have a household income estimated to be in one of six income bands: <£10000; £10000–£19999; £20000–£29999; £30000–£39999; £40000–£49999; £50000 and above. According to Department of Transport, Local Government and the Regions' projections from 1996 household numbers, there are 3.13 million households living in Greater London (http://www.statistics.gov.uk/statbase/Expodata/Spreadsheets/D4524.xls). Hence, the lifestyles income sample is of a size equivalent to 2.1% of households (consistent with Harris and Frost (2003) who estimated the sample size to be just under 2% for the Borough of Brent within London).

Applying the modelling procedure described in Section 6.5 permits the determination of which one of the six income types is dominant in each small area cluster (formed around each of the 42883 CodePoints) and also what proportion of sampled households are of the modal type per cluster. In Figure 6.4 we have grouped the classes to emphasise areas (in Inner London only) where the lowest incomes (<£10000) dominate, and in Figure 6.5 the highest (£50000 or above). The average circular search window required to find the n_i neighbours that give a total population of $m = 75$

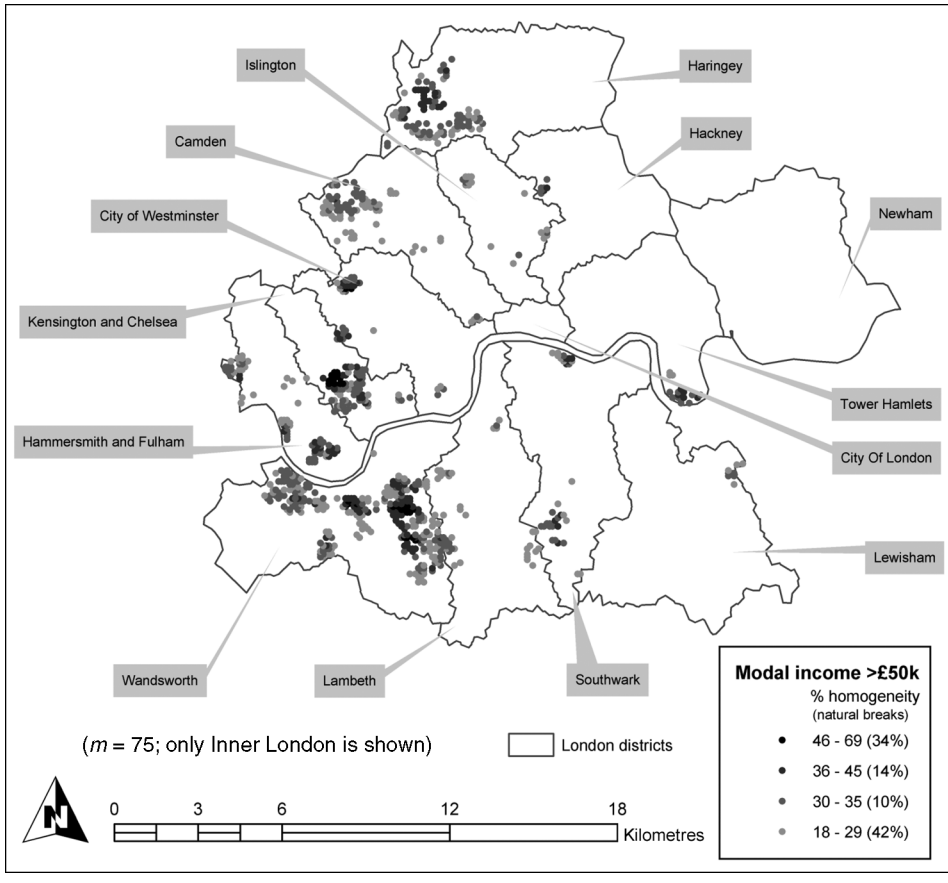

Figure 6.5 *Mapping the most affluent neighbourhoods in London*

per cluster has a radius of 452 metres. We have already noted that there is no reason to suppose that the distribution of lifestyles respondents is evenly distributed across the study region and, accordingly, the radius varies from a minimum of 141 metres to 3999 metres for the set of 42 883 points. The interquartile range is much smaller, however: from 361 metres to 510 metres. Both Figure 6.4 and Figure 6.5 show the proportion of households within the neighbourhood that belong to the modal class: higher proportions suggest spatially concentrated areas of deprivation or affluence.

With respect to our earlier discussion (Section 6.5), why did we choose a value of $m = 75$? In fact, a number of values for m were considered ($m = 25, 50, 75, 100, 200$). The results of the analyses with each of these values are summarised in Table 6.1. The top seven rows of the table (excluding the headers) give summary measures of the search window radii (in metres) required to cluster a total population of m by summation of the n_i records nearest to each of the 42 883 target points. For example, when m is set at 200, the mean average search window size required to gather the n_i points together to meet that population threshold is 768 metres but ranges from 361 metres to 4000 metres. The interquartile range is much smaller: from 608 metres to 854 metres. The general trend, to be expected, is that as the total population size required m decreases, so a smaller search window is required to find the n_i points that will meet the population threshold. Taking the mean, the third quartile (Q3) or the first quartile (Q1) as a measure of the level of aggregation required to meet each

Table 6.1 *Summary of analysis for various values of m*

m	200	100	75	50	25
Mean radius (m)	768	528	452	364	252
Maximum radius (m)	4000	3999	3999	3966	3820
Minimum radius (m)	361	200	141	100	0
Range	3639	3799	3858	3866	3820
Q3	854	600	510	412	300
Q1	608	412	361	283	200
IQ range	246	212	149	129	100
R ($m = 200$)		0.82	0.74	0.63	0.45
R ($m = 100$)	0.82		0.91	0.77	0.55
R ($m = 75$)	0.74	0.91		0.85	0.61
R ($m = 50$)	0.63	0.77	0.85		0.71
R ($m = 25$)	0.45	0.55	0.61	0.71	
Mode: < £10 k (%)	64	57	55	52	47
Mode: £10 k–£19.9 k	20	23	23	24	25
Mode: £20 k–£29.9 k (%)	9	12	13	14	16
Mode: £30 k–£39.9 k (%)	0	1	2	3	5
Mode: £40 k–£49.9 k (%)	0	0	0	1	1
Mode: £50 k+ (%)	6	6	6	6	6
No change from $m = 200$		74	69	62	54
No change from $m = 100$	74		82	70	58
No change from $m = 75$	69	82		77	61
No change from $m = 50$	62	70	77		68
No change from $m = 25$	54	58	61	68	

value of m, then it can be shown that the increase in resolution is in the order of 9:1 as m is decreased from 200 to 25 (the radius is one-third the length, hence the area is one-ninth), and of the order of 4:1 as m is decreased from 100 to 25.

Notwithstanding the apparent increase in precision, the next five rows of Table 6.1 warn that a low value of m is not necessarily to be preferred. These rows record the Pearson correlation coefficients for each set of 42 883 cluster homogeneity values at the five values of m. The homogeneity values give the proportion of the cloud or cluster of $n_i + 1$ points around each of the N points that are of the modal income type for that group of $n_i + 1$ points (i.e., the value p_{z1} in equation 6.4). The set of N proportions is calculated for each of the five values of m. This gives $(m - 1)! = 10$ pairs of cluster homogeneity values, for which the highest correlation, at $R = 0.91$, is obtained between the sets for $m = 75$ and $m = 100$ (Table 6.1). The lowest correlation is (unsurprisingly) between $m = 25$ and $m = 200$. From the table it appears that the homogeneity values for $m = 75$ and $m = 100$ exhibit greatest correspondence with the sets of values calculated for the remaining values of m.

The next six rows of Table 6.1 show the proportion of the N cluster centroids assigned to each of the six income classes at each value of m. Looking across the <£10k row it can be seen that the results are not spatially invariant: as the search windows reduce in size so the proportion of clusters with a modal income in this low income class decreases from 64% ($m = 200$) to 47% ($m = 25$): a 27% decrease. That the results should change with the geography of the problem is not surprising since what we are undertaking is explicitly spatial analysis in the sense defined by Longley *et al.* (2001, p. 278): 'spatial analysis is a set of methods whose results change when the locations of the objects being analysed change'. Here, whilst the location of the points is not actually changing, the boundary of the object class (or cluster) into which they are placed, is. It is this property of geographical contingency that makes it difficult to prescribe the correct value of m. However, bearing in mind the quest for generalisation discussed in our opening section, this is not to say that some values of m are not better suited to particular applications than others. Our criteria remain to construct small area measures of income that do not mask diversity at finer scales but that do aggregate the lifestyles data into representative clusters. Looking again at Table 6.1, and at the distribution of cluster centroids across the income classes, it is seen that a degree of consistency in the results emerge when $m = 75$ or $m = 100$ (we also saw this with the Pearson correlations). Interestingly, the proportion for the highest income class (£50k or above) is constant at 6% for all the values of m tested.

The final five rows of Table 6.1 indicate the movement across the income classes as m is changed. They record, for example, that of the 42 883 points, 74% remain ascribed to the same income class regardless of whether $m = 200$ or $m = 100$. As m is further reduced from 200 to 75, 69% remain in the same income class, and 54% as m is reduced from 200 to 25. The empirical case study confirms the intuitive expectation: that the results of the analytical method depend on the chosen value of m (and hence the search window size). However, the results are by no means unstable. The greatest invariance to scale appears to be when $m = 75$ or $m = 100$. To recall, we chose the former value for the results displayed by Figures 6.4 and 6.5. With $m = 75$, the average search window size has a radius, r, of 452 m (Table 6.1), giving an average

area of 0.64 km^2 over which the lifestyles data are aggregated (= πr^2). This is certainly greater apparent spatial precision than is offered by census ward estimates and also by most census classifications at ED scale. Most importantly, the method offers a direct way of estimating the concentrations of specific income groups using a 'bottom-up' approach that is not constrained to fit within an externally imposed, administrative geography such as that of the census.

6.7 Conclusion

The scale and pace of change in developed countries today is such that we cannot rely upon census data alone. In the UK, the terms of the 1922 Census Act are not interpreted today as providing a mandate for collecting income data. Yet income data, together with richer information on consumption in its broad senses, are central to creation of indicators that can facilitate sensitive spatial policy and rational resource allocation. Such information is, as the report of PAT 18 suggested, essential if the UK Neighbourhood Renewal Unit is to meet its challenge to ensure that 'within 10–20 years no-one should be seriously disadvantaged by where they live' (http://www.dtlr.gov.uk/neighbourhood/).

Developments in remote sensing now allow deprivation arising out of attributes of the built environment to be made consistent with the scale at which housing is in poor condition, or to the scale at which positive or negative externality effects of infrastructure or services are experienced. Yet much remains to be done in creating relevant, timely small area measures of social conditions. Hybrid approaches such as the Breadline Britain Index seek to lever maximum value from the census, yet ultimately only partly compensate for the absence of income measures and sensitivity to local neighbourhood effects. Lifestyles data include an income question, yet the validity of income measures at fine spatial scales can be hampered by the small and geographically variable number of responses received. In our view, it is necessary to undertake some level of aggregation when analysing the lifestyles data, yet to do so in such a way as to be sensitive to local patterns within the data. Aggregating the income information into artificial census units does not meet this challenge so here we have outlined a 'bottom-up' approach to representing income clusters at more precise scales than those offered by more orthodox measures.

The apparent 'Hobson's choice' either of using overly aggregated, surrogate and outdated data on social conditions or abandoning generality and quantitative analysis altogether seems to us a peculiarly academic construct that could be dismantled by an increased, and mutually beneficial, dialogue with business users of geographical information, even withstanding concerns about privacy and ethical issues of data usage (Curry, 1998; Longley *et al.*, 2001, Chapter 19).

Assessing Deprivation in English Inner City Areas: Making the Case for EC Funding for Leeds City

Paul Boyle and Seraphim Alvanides

Abstract

One of the key roles of the European Commission (EC) is to encourage a redistribution of wealth throughout the Community to reduce inequalities, both between and within countries. One mechanism for achieving this is the release of Structural Funds to those places that have particularly serious social and economic problems. This chapter reports on the attempt by Leeds City Council to secure Objective 2 status funding from the Commission, as part of a wider bid submitted by the Yorkshire and Humberside region. To be successful, Leeds needed to prove that the socioeconomic situation in its inner city was at least as bad as that in other cities in England. However, to achieve this required some computationally advanced methods beyond the scope of the Council's researchers. In collaboration, a methodology was devised which used some in-house software, embedded within a geographical information system (GIS), to show that Leeds did indeed have a strong case for support from the EC. Here we describe the methods used and the results for Leeds compared with the other cities in England. The chapter ends by commenting briefly on the positionality of researchers who undertake consultancy work of this type and suggests that we rarely spend enough time considering the interesting ethical dilemmas that work of this nature raises.

7.1 Introduction

One of the roles of the European Commission is to stimulate economic growth and encourage a redistribution of wealth that reflects the fact that some parts of the

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

European Union (EU) are relatively better off than other parts. Rather than simply redistributing funds at the national level, there is increasing recognition of the significant imbalances within countries between cities and towns that need to be addressed. This is particularly so as cities and towns are critical to regional development. In identifying an urban agenda, the Commission states that 'the starting point for future urban development must be to recognise the role of the cities as motors for regional, national and European economic progress' (European Commission, 1998a). In many European cities, however, severe social and economic problems hinder economic development and there is a growing realisation that these need to be addressed before economic growth can be achieved: 'The future of the towns and cities in the EU depends on fighting growing poverty, social exclusion and stemming the loss of certain urban functions' (Committee on Spatial Development, 1999). The EC response has been to distribute central funds to cities across the EU based on uniform criteria designed to identify those most in need of support. The Structural Funds Programmes therefore require that cities and towns with significant social and economic problems can be identified and that 'given the crucial role of towns for regional development and EU regional disparities, it is important for the effectiveness of regional policy that this funding be more explicitly related to urban needs and potential in the regions' (European Commission, 1998b).

The research reported in this chapter was undertaken as part of Leeds City Council's (LCC) attempt to secure Structural Funds from the EU by applying for Objective 2 status funding within a broader bid made by the Yorkshire and Humberside region. For LCC, there was a certain irony in making an Objective 2 application, as in recent times the city has been heralded as one of the fastest growing and most economically successful in the United Kingdom (UK). Thus, on the one hand, the LCC was producing documents aimed at persuading companies to move to what was fast becoming one of the most successful manufacturing, financial and legal services centres in the UK while, on the other, it was attempting to justify the case for significant EU funding, based on small areas within the city that were experiencing severe social hardship. The research described here was undertaken on behalf of LCC with the aim of demonstrating that the problems in Leeds were as significant as those of other competing UK cities that already received EU funding, or were themselves making the case for consideration for funding.

The remainder of the chapter is divided into four sections. In Section 7.2, we describe the nature of the problem and the requirements of LCC. We outline the measures used to identify areas with significant socioeconomic problems and explain that while LCC could speak authoritatively about the most deprived areas in Leeds, it was much more difficult to identify similarly deprived parts of other English cities. In particular, identifying small areas that met certain selection criteria, such as level of deprivation, population size and contiguity, all required a relatively complex methodological approach. Section 7.3 therefore explains the potential measures in more detail and the GIS-based methodology that was developed to solve these problems. Section 7.4 presents the results and compares the area chosen to represent the deprived inner city of Leeds with similarly defined areas for the remaining cities in England. Comparisons are made based on a series of different population cut-offs and using different measures of deprivation. Finally, Section 7.5 concludes by arguing

that LCC did indeed have a strong case for Objective 2 status. The Local Authority District of Leeds includes some particularly rich and poor people and, compared with many English cities, ignoring this would be misleading. The geographically refined analysis of socioeconomic conditions in the city that we provided helped to highlight this fact. However, the chapter ends by reminding us that we need to give serious thought to our positionality as researchers when conducting work of this type.

7.2 The Applied Problem and Client Needs

The EC has a series of programmes designed to redistribute resources to those parts of the EU that are most deserving. For example, Objective 1 status areas were defined as those whose per capita gross domestic product (GDP) was less than 75% of the Community average; consequently these were relatively large areas in severe hardship (South Yorkshire was one of the English Objective 1 areas, for example). Objective 3 was available nationally, rather than to geographically targeted areas, and was designed to support education, training and employment policies. Previously, Leeds had been successful in attracting considerable funds under this scheme. Objective 2, which was relevant to this research in Leeds, sought to address the needs of areas experiencing structural difficulties, whether industrial, rural, urban or fisheries-dependent areas, or to promote the restructuring of services (Department of Trade and Industry, 1999). This definition combined Objectives 2 and 5b from previous funding rounds. Leeds did not submit itself for consideration in the previous 1997 round, but was hoping to be considered in the 1999 round.

Before the EC can identify cities, or parts of cities, as deserving of Objective 2 status, a system of measuring the socioeconomic conditions within each is required, such that their relative situations can be compared. Some standard criteria were set out in a lengthy legal document (European Commission, 1999), although these were designed to be indicative rather than a strict list which each application needed to address. Thus, 'urban areas in difficulty' were expected to be densely populated and of a 'reasonable size' (probably over 100 000 population). The application areas were expected to meet at least one of the following criteria:

- a rate of unemployment higher than the Community average;
- a high level of poverty, including precarious housing conditions;
- a particularly degraded environment;
- a high crime rate;
- a low level of education among the population.

Constraints were also imposed by the EC on how the funds would be distributed:

- a ceiling for all types of Objective 2 areas of 18% of the EU population;
- a UK share of that ceiling determined by the population of its industrial and rural areas which qualify as of right and the extent of its structural problems, subject to a maximum of one-third in population coverage at the time;
- a limit of 2% of the EU population to be covered by Urban Areas (the UK hoped to get a larger than average share of this).

It was assumed that applications would be made at NUTS level III (counties or groups of unitary authorities in the UK), but that separate applications should be made by local areas within these broad areas. Thus, Leeds was aiming to be one of a number of areas that was included in a broader submission made by the Government Office for Yorkshire and Humberside.

The criteria identified above that were of particular relevance to this study are those relating to the geographical scale at which areas for support should be identified and the indicators that should be used to identify the level of need. These two criteria are closely related as the choice of geographical units will constrain the data that are available for analysis. Geographically, the two most important criteria were, firstly, that the areas of greatest need should be 'targeted', and secondly, that these areas should be large enough to allow credible and integrated programmes to be mounted. It had been suggested that the most appropriate zones that could be used as building blocks to identify the areas of greatest need across the EU would be NUTS 5 regions or, in UK terms, wards. Whilst the EC did not specify a population size constraint, it was clear that very small areas would not be considered in isolation, and a population of approximately 100 000 was commonly quoted as an appropriate cut-off.

A wide range of indicators, including social, economic, crime and housing measures, were suggested as appropriate for identifying areas of greatest need in the UK, although the manner in which these indicators should be used was not prescribed. Clearly, to be successful, any application for Objective 2 status required that the chosen areas performed badly across a wide range of socioeconomic criteria. Previously within the UK, one of the standard tools that had been used by the Government for identifying need for Objective 2 status was the Index of Local Deprivation (ILD) (Department of Environment, 1995; Department of Environment, Transport and the Regions, 1998). This has been calculated for local authority districts (LADs), of which there were 366 that encompassed the whole of England at the time of the 1991 Census. Through use of the ILD, each district can be ranked according to a standard measure of the material deprivation in that district. The ILD is a useful summary measure that is used in many applied and academic studies to give a feel for the social standing of a particular place. For LCC, the focus of attention was on identifying how Leeds compared with other LADs in England, against whom it was competing for the limited amount of funds.

However, the assumption that LADs are homogeneous areas that can be summarised using a single deprivation measure ignores the diversity of social conditions that exist throughout a city and it is especially biased for cities that are geographically large, encompassing a range of better-off and worse-off areas. The diversity of social deprivation that exists in cities also varies so that an 'average' measure of deprivation will be more biased in some cities than in others. In this round, it was expected that applications would use ward-level deprivation scores as one way of summarising the socioeconomic situation of the local area, partly because this was a useful way of being able to compare submissions from different parts of the country.

Therefore, applicants were encouraged to identify a group of contiguous wards (which aggregate neatly into districts) that was relatively large and that was also an

area of great need. LCC believed that the scale of analysis was particularly crucial in Leeds as LAD-level measures masked the reality of inner area deprivation in the city. Two points are relevant here. Firstly, because Leeds LAD is such a large geographical area, it inevitably encompasses a range of places with different levels of deprivation. Other cities like Manchester or Liverpool are defined more tightly with their LAD boundaries encompassing the inner city, but few of the surrounding, often more wealthy, suburban and extra-urban areas. On the other hand, cities like London include a number of LADs within their boundary, each of which is relatively more homogeneous than the LADs that include entire cities. Secondly, it has been argued for some time that the city of Leeds is unusual because it encompasses a heterogeneous mixture of residential environments compared with other UK cities. Put simply, there is considerable variation in the levels of deprivation within the inner city area such that Leeds has been described as 'two cities', one 'working hard to position itself as the capital of the north', and the other 'where unemployment is high, educational attainment is low and where dependency on benefits is almost universal' (Leeds City Council, 1998).

To address this problem, LCC required an analysis of deprivation conducted at a more detailed spatial scale that would reflect these extremes – an analysis of deprivation *within* the city, rather than a summary deprivation score for the city as a whole. The aim, therefore, was to identify a contiguous set of wards within the Leeds LAD which, when aggregated together, represented a relatively large homogeneous population with a high deprivation score. The EC required that areas with relatively large populations be submitted for consideration, as the aim of the Objective 2 status programme is to target relatively large areas of concentrated deprivation that require aid. However, it was not stipulated that this should necessarily include the entire city. By selecting appropriate wards from within the district boundary, it removes the problem that using the entire LAD includes a mixture of richer and poorer areas that, on average, suggest that the city is not particularly deprived.

LCC was therefore keen that an analysis be conducted that compared such a choice of wards in Leeds with similarly defined groups of highly deprived wards in other English cities. As most city councils purchase census and other data that can be used to construct deprivation indices for the wards within their own cities, LCC was able to carry out such an analysis for Leeds. In fact, they also had deprivation scores for the wards across all of England apparently allowing them to compare Leeds with other cities. However, as we demonstrate below, relatively complex methods were required to make sure that the selection of wards in other cities was as equitable as possible.

There were two problems with this approach which were the reasons behind LCC's request for some external consultancy work. First, LCC did not have the digital boundaries required to identify which wards in other 'competing' cities were *neighbouring*. This was important since a requirement of the EC exercise was that the areas submitted for consideration should be compact. Before LCC could argue that their preferred selection of wards was a better reflection of concentrated deprivation within the city, it was necessary to compare the results of their analysis with a similar analysis in other English cities. LCC were convinced that there was a large area of inner city Leeds that was significantly more deprived than most equivalent areas in other English cities, but an analysis was required actually to prove this. The second

problem was that, even if contiguous wards could be identified, a strategy for optimising the choice of which wards should be aggregated together was potentially onerous. Given that there are 10 000 wards in England and Wales, deciding how to group wards in every city so that the largest and most deprived combination was achieved was not simple. In Leeds, the planners could do this by hand, knowing well the worst areas of their own city, but they did not have such insights into other English cities. The method we adopted for solving this problem is described below.

7.3 Methods of Identification of Deprived Urban Areas in British cities

The first strategy was to investigate how Leeds LAD compared with other English LADs in terms of the 1998 ILD. This index is based on 12 variables, three of which are derived from the 1991 Census, with the remainder coming from other updateable sources, such as unemployment, mortality and insurance company data. Consequently, this index was relatively up to date and, although we may debate the validity of the index itself, it does at least provide a consistent means of comparing all LADs in England. The ILD can be used as the basis of a number of different comparative measures, including:

- the degree of deprivation, or the overall district level score;
- the intensity of deprivation, or the severity of deprivation in the LAD taken as the average score of the worst three wards in the LAD;
- the ward level extent, or the proportion of the LAD population living in wards that are within the 10% most deprived in England; and
- the ED level extent, or the proportion of the EDs in the LA that fall within the most deprived 7% of EDs in England.

Here we focused mainly on the first of these measures. Of course, as argued above, this method of identifying deprived inner city areas is spatially crude. There is no logical reason why the LAD scale is the most appropriate for analysis and, given the considerable variation in the size and homogeneity of LADs, there is a strong argument that a more considered definition of deprived inner city areas should be sought. In particular, the aim here is to identify *concentrated areas of deprivation*, as these are likely to be especially deprived places.

This objective required analyses that build deprived areas from smaller geographical units. LCC therefore required a series of analyses using aggregations of small areas (wards) for Leeds and other competing LADs in England, which would show that Leeds has a significant area within the city with a higher level of material deprivation compared with other places. These groups of wards would include large populations in most LADs, but in most cases their populations would obviously be smaller than the populations of the entire LADs. Fortunately, a ward-level version of the ILD has been constructed which is based on six variables from the 1991 Census. These six variables were: unemployment, children in low-earning households, households with no car, households lacking basic amenities, overcrowded households, and 17 year olds no longer in full-time education. Although this version of the ILD

is not regularly updateable, as it relies on census information which is only collected every 10 years, it does provide an indication of deprivation for small geographical areas.

In consultation with LCC, inner city Leeds was defined based on informed views of the most deprived parts of the city. Of the 12 chosen wards, the least deprived was Armley, with an ILD score of 7.97, which ranked 1062 out of 8620 wards in England. There were 14 wards in Leeds that were at least as deprived as this ward, using the ward-level ILD, although two (Beeston with ILD = 9.60 and Bramley with ILD = 9.50) were excluded from the definition of inner city Leeds used below (Figure 7.1).

Using the deprivation score of 7.97 for Armley as a cut-off, all wards across England with a similarly high level of deprivation could be identified and relevant groups were then aggregated for each city. As can be seen in Figure 7.2, many districts had few wards that reached this level of deprivation. However, it was not a simple matter of aggregating all these wards for each city, as a strategy was required for deciding which to include. Simply using a deprivation score as a cut-off means that isolated wards within LADs would have been included in the list and their

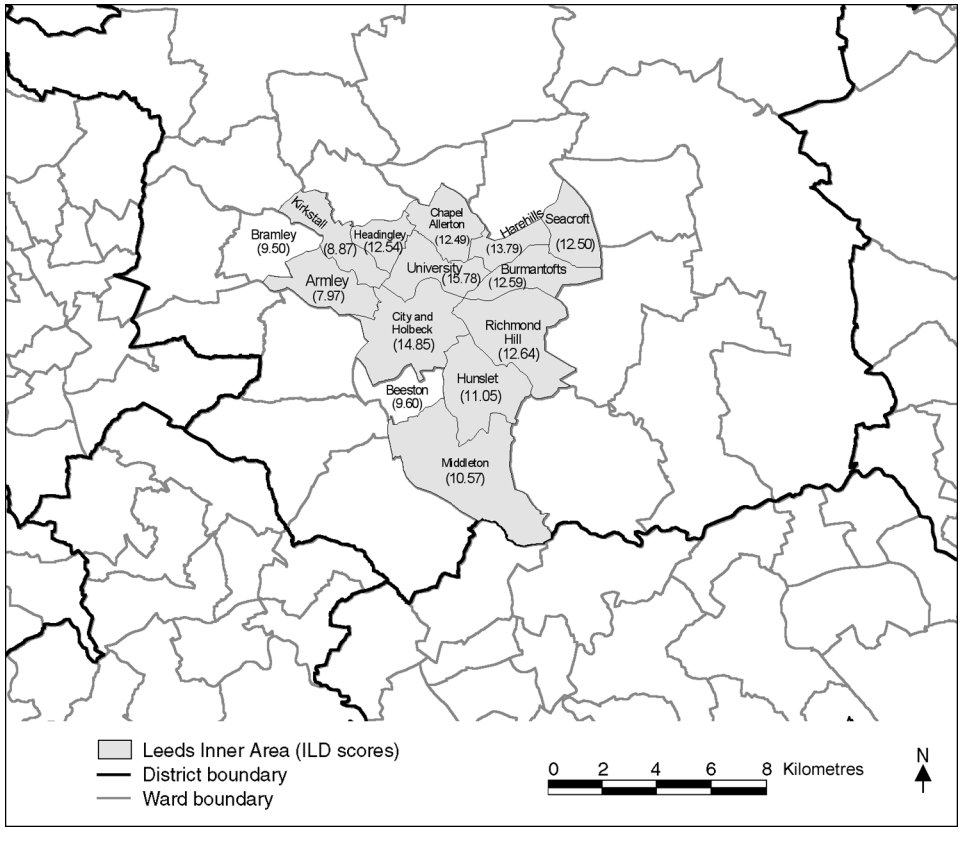

Figure 7.1 *Deprived wards in inner city Leeds © Crown Copyright. Reproduced with permission*

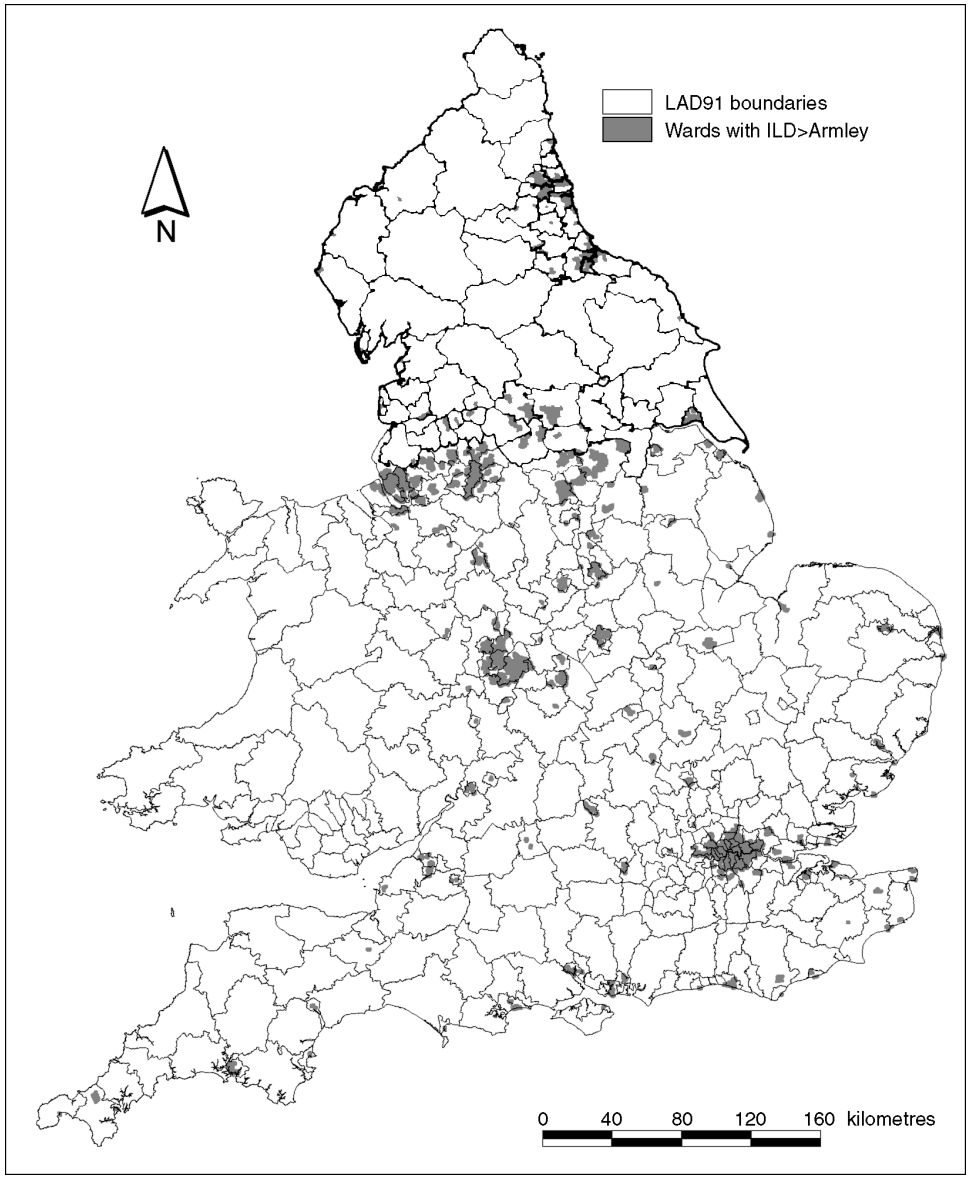

Figure 7.2 *Wards in England that were at least as deprived as Armley ward © Crown Copyright. Reproduced with permission*

inclusion was not acceptable according to the EC guidelines; the group of wards that were chosen needed to be contiguous.

To illustrate this, the districts in West Yorkshire with ILD scores above Armley are mapped in Figure 7.3. Leeds has 14 contiguous wards in total with ILD scores at least as deprived as Armley, including Beeston and Bramley. These 14 wards are clustered to form the contiguous inner area, without any holes or deprived wards outside

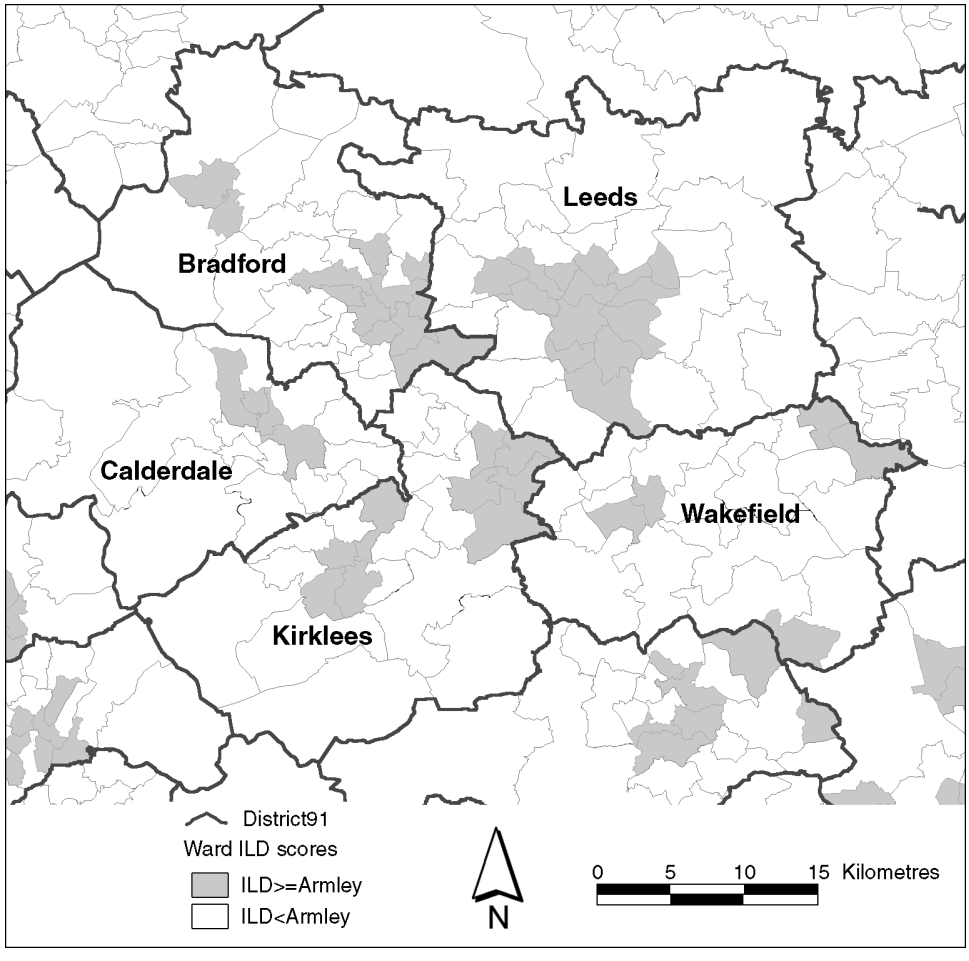

Figure 7.3 *Deprived wards in selected districts in West Yorkshire © Crown Copyright. Reproduced with permission*

this area. This is also the case in Calderdale, where four contiguous wards with ILD scores at least as deprived as Armley cluster to form a deprived area. However, this is not the case in either Bradford or Kirklees, where the deprived wards cluster in two areas, nor in Wakefield where there are three pockets of deprivation. In order to check the contiguity of the selected wards shown in Figure 7.2, our research therefore exploited GIS and some in-house software designed to optimise the selection of contiguous groups of geographical wards based on some pre-determined criteria (maximising deprivation in this case).

The analysis was carried out using semi-automated methods in ArcInfo GIS, utilising the Arc Macro Language (AML) capabilities for topology building, spatial queries and calculations. First, all the wards with ILD scores greater than Armley were selected, as shown in Figure 7.2. Subsequently, the adjacent boundaries of the selected wards were dissolved in order to identify the number of deprived areas within

each LAD. In cases like Leeds and Calderdale, the selected wards would only form a single deprived area, with no internal islands and the selection was acceptable. However, in cases like Bradford, Kirklees and Wakefield, the selected wards would form two or more separate areas, within the same district. These districts were automatically identified within ArcInfo GIS and a number of measures were calculated for each deprived area, such as the total population and the degree of deprivation. If the population within one of the sub-district areas was adequate (as described below), then this area was taken as a representative deprived area for the district, otherwise, further GIS analysis was necessary to secure an acceptable population size. Further analysis was undertaken in the form of aggregations, so that wards with relatively low scores were added to the contiguous set if the ward neighboured another ward with a particularly high deprivation score. These 'lower-than-Armley' wards were known as 'bridging wards'. Thus, the addition of both wards to a cluster increased the average deprivation in that cluster, even though the score for the bridging ward may have been lower than the arbitrary cut-off that had been chosen. This procedure therefore identified 187 large aggregations of contiguous wards, in cities across England.

In the analysis, we also introduced a series of population cut-offs enabling us to identify clusters of wards that were above or below certain thresholds. The deprivation cut-off was agreed with LCC as those wards that were at least as deprived as Armley ward (see above). The population cut-offs were also a subjective choice, but one that was guided by the knowledge that the EC was only interested in funding relatively large areas; deprived pockets were not to be targeted. The software allowed us to identify clusters of wards that were above or below certain populations. While there is a strong case that deprived areas with large populations should be targeted for aid, there are also concentrated areas of deprivation that should not be ignored simply because they have a smaller population than other inner cities. The LCC definition of inner city Leeds had a population of approximately 228 000 but, as suggested above, while 100 000 was an oft-quoted figure for an appropriate size of a deprived place, no guidelines specified that smaller areas would not be considered. Four levels of analysis were therefore conducted to reflect the size of the deprivation problem in the various LADs. Initially, we retained only those sets of contiguous wards that had a combined population of at least 200 000. This is useful as it draws attention to the largest areas of concentrated deprivation in England – places that should certainly be considered as worthy of consideration in attempts to redistribute resources. The second and third definitions used clusters of wards with populations of at least 100 000 and 60 000, respectively. Finally, we also considered those clusters with a maximum population of 60 000 as a cut-off, allowing us to identify the most concentrated areas of deprivation in the various inner cities.

The GIS software facilitated the analysis in many ways. Firstly, it was possible to manage the spatial datasets and carry out calculations in a seamless manner. In addition, the AMLs allowed automation of the process, by completing repetitive spatial queries, building the topology, and producing descriptive measures for population and deprivation scores. Finally, the GIS identified the most appropriate bridging wards, restricting the search of appropriate wards considerably. The diagram in Figure 7.4 illustrates the semi-automated process followed in identifying the optimum district ILDs for selected sets of wards.

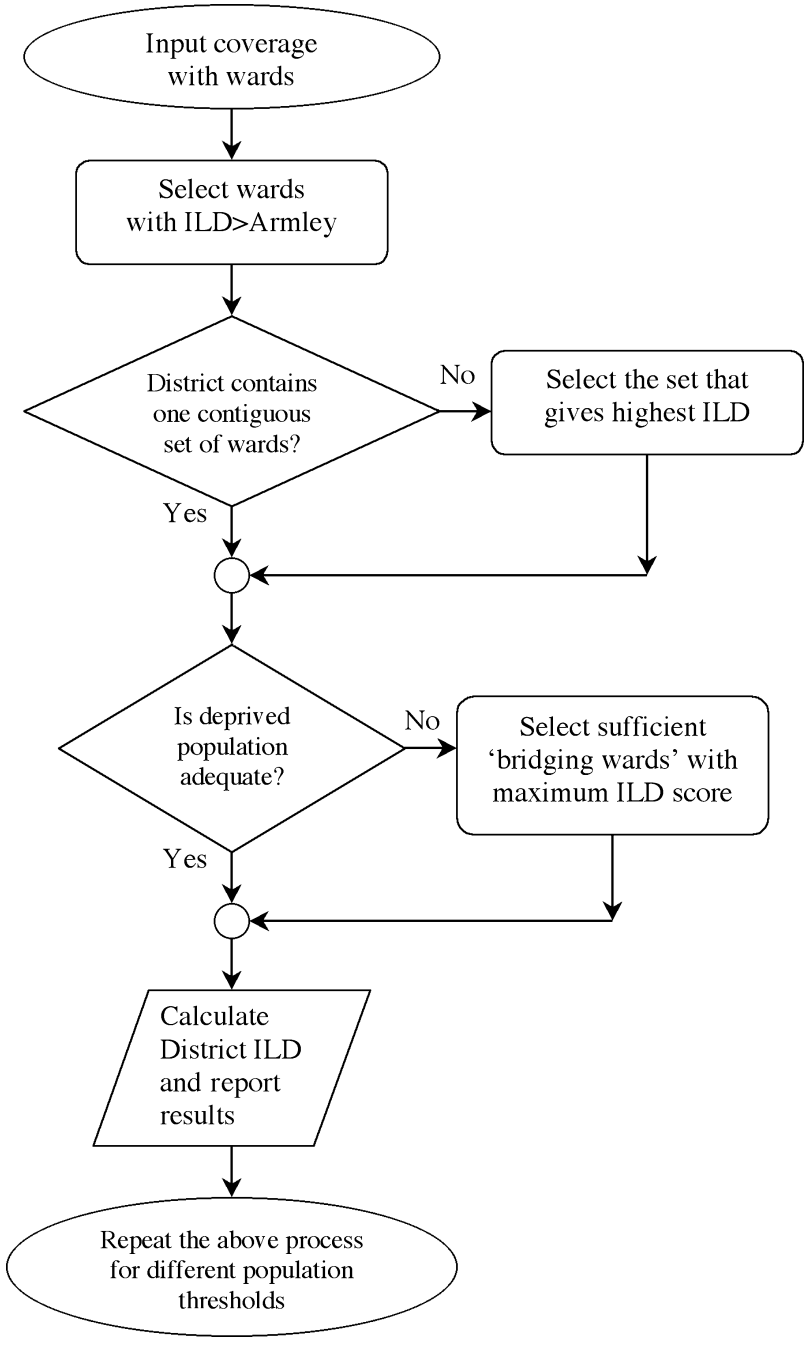

Figure 7.4 *Diagram showing the semi-automated GIS process*

7.4 A Comparison of Concentrations of Deprivation

The results for the *LAD-level* analysis are provided in Table 7.1. The mean deprivation is perhaps the most obvious indicator of overall deprivation. Leeds ranked very low (56th) on this list, demonstrating that it was not among the most deprived LADs in England, using this spatially crude analysis. Note, however, that Leeds ranked seventh in England using the average deprivation in the worst three wards, suggesting that a more sensitive definition of concentrated deprivation may be appropriate for the city.

The next step was to show how Leeds ranked using a simple comparison of *groups of wards* that were included because they had a higher deprivation score than our chosen cut-off value. Table 7.2 provides the cities with the most deprived wards based on this analysis and this is equivalent to the analysis that LCC could have conducted using the information they had to hand. Note, however, that while the wards in Leeds have been chosen because they are contiguous, the wards in the other cities are chosen simply because their deprivation score is higher than a particular cut-off; many of these wards will not have been neighbouring. According to this analysis, Leeds climbed from 56th (Table 7.1) to 11th (Table 7.2). Of particular note is the very large population of the Leeds inner city area compared with other cities. In terms of population size, the group of wards in Leeds was exceeded only by Birmingham, Liverpool, Manchester and Sheffield. Lambeth was the highest-ranking London borough, in sixth position.

The problem with this analysis is that it ignores contiguity for all the cities except Leeds. The aim was to identify a concentrated area of deprivation as the EC had made it known that a smaller number of substantial areas of deprivation were liable to receive funding, rather than a larger number of smaller areas, thus avoiding a 'pepperpotting' of funds. Once a contiguity constraint is introduced it is likely that the deprivation measures will alter for the other cities and, if nothing else, the population of many of the inner city areas will be reduced. For Leeds to make a strong case, it needed to be able to compare its position with that of the other cities in England.

Table 7.3 lists those nine deprived inner city areas with populations of at least 200 000, ranked by the mean deprivation score. In summary, the Leeds inner city area ranked:

- fifth using the ward-level ILD degree score;
- fourth using the ILD ward intensity score;
- third on the maximum index value indicator; and
- fourth on the estimated population size indicator.

Note that the standard deviation of the ILD values is also provided to give an indication of the variation in the deprivation scores for each cluster of wards. Leeds has a fairly high value compared with other clusters (this result is consistent in the following tables).

The second stage of this analysis extended the list of deprived inner city areas to include those that had a population of at least 100 000. These are still large concentrations of deprivation, although many have much smaller populations than the

Leeds inner city area. Table 7.4 provides details of all 27 of these deprived inner city areas. In summary, the Leeds inner city area ranked:

- tenth using the ward-level ILD degree score;
- sixth using an ILD ward intensity score;
- fourth on the maximum index value indicator; and
- fourth on the estimated population size indicator.

The list was then extended to include contiguous sets of wards with a population of at least 60 000 (Table 7.5). Even on this much longer list, Leeds ranked high up the list:

- eleventh using the ward-level ILD degree score;
- sixth using an ILD ward intensity score;
- fifth on the maximum index value indicator; and
- fourth on the estimated population size indicator.

These analyses provide a clear indication that the case for Leeds is strengthened by using definitions of deprived inner city areas based on contiguous sets of wards, rather than LADs. We argue that this geographically sensitive analysis is an improvement on simple studies based on the relatively arbitrary definitions of LADs. However, there is a strong argument that the most concentrated areas of deprivation are much smaller than the areas identified in these analyses. While it is important to identify places with relatively large populations, the decision about where such a population cut-off should be is crucial.

The aim in the final analysis was therefore to identify deprived areas with a maximum population of 60 000 – clearly a considerable number of people, but far short of the populations in many of the 'inner city areas' identified above. This strategy identified the most *concentrated areas of deprivation* in the inner cities as the mean deprivation values in Table 7.6 demonstrate. These values are inevitably much higher than those provided in the previous table. This list indicates that the Leeds inner city area ranked:

- third using the ward-level ILD degree score;
- fourth using an ILD ward intensity score; and
- fifth on the maximum index value indicator.

Indeed, both Birmingham and Bradford, which ranked higher than Leeds, already had Objective 2 status at the time of the study.

The populations in this list of contiguous inner city areas were large and, we suggested, should be given serious consideration as zones that may have been deserving of Objective 2 status. While they were much smaller than the populations of entire LADs, these areas were considerably more deprived. The results for this concentrated area of deprivation certainly supported the wider Leeds case for eligibility and it is noteworthy that Leeds also had a high ranking based on the average of the worst three wards indicator.

Finally, we should not ignore the fact that the geographical size of deprived areas will also influence the relative inequalities experienced by people resident there. Living in a small area of deprivation, where the distance to various resources such as cheap shops, good quality food, parks or medical facilities, may not be as detrimental to well-being as living within a large area of deprivation where the distance to such facilities is greater. Leeds ranked third in geographical area among those clusters of wards with a population larger than 200 000 (Table 7.3) and fifth among those clusters with a maximum population of 60 000 (Table 7.6). Even based on this criterion, Leeds ranked high compared with most other LADs.

7.5 Conclusion: A Tale of Two Cities

The analysis that we were asked to conduct formed part of the LCC application for Objective 2 status (Leeds City Council, 2000). The technique showed that Leeds had a strong case and that a substantial area of the inner city could be described as suffering from severe material deprivation. We believed that the LCC was correct in its assertion that the inner city area was relatively more deprived than would be indicated by a crude analysis based on data collected for LADs. Redefining Leeds based on clusters of wards in the inner city area better reflected the relative needs of Leeds compared with other English cities. Indeed, the final results in Table 7.6 demonstrate that Leeds ranks third among the most deprived inner city areas with populations less than 60 000, while Table 7.3 showed that it ranked fifth among the cities with more than 200 000 people. We concluded that Leeds was indeed a 'two-speed economy' and that despite the strong record of economic growth, the benefits were failing to 'trickle down' to the inner city residents.

The analysis was crude in the sense that it relied on a single measure of deprivation to assess the position of Leeds relative to other English cities. Little attention was given to the extent of relative inequalities that may be relevant to the Leeds inner city case. Leeds can be described as having 'two cities' where the relative inequalities between two broad groups – the rich and poor – are quite extreme. There are good reasons to suppose that people take the standards of others around them as the basis for self-appraisal and evaluation (see, for example, Boyle *et al*., 1999, 2001; Elstad, 1998). Those living in deprived conditions may find it harder to cope if they are surrounded by people that are better off than themselves, rather than being surrounded by people in similar circumstances. This appears to be particularly pertinent to the Leeds case; the analyses presented above demonstrate that there is considerable variation among those living in the Leeds LAD – more so than in most other LADs. There is good reason to suppose, therefore, that this may cause the deprivation in this area to have even worse effects than might otherwise be the case.

Finally, as contracted researchers, we should comment on our own positionality in the context of this research. Obviously, we were employed as neutral researchers who could provide an objective insight into the relative position of the Leeds inner city. It was important for LCC to be able to argue that the research was independent and this was the case. We introduced a methodological approach that was implemented as fairly as possible in every English city, and the results did indeed

demonstrate that Leeds' position was worse than a simple district-level analysis would indicate. However, while our choice of population cut-offs was not influenced by LCC, it is unlikely that the results from each would have been reported by them in their application for funding had the results not supported their general argument. This raises an interesting ethical dilemma. Do we as researchers demand that all of our results are used in any publications associated with the work, or is this an unreasonable expectation given that our services have been paid for? In this case, we felt that the use of our analysis was reasonable and that our conclusions were robust enough for LCC to use them in arguments concerning their claim for Objective 2 status. However, consultancy work of this type does raise questions that are perhaps given little attention in many studies.

Epilogue

Leeds City Council were part of the successful Yorkshire and Humberside application for Objective 2 status following the submission of its report which demonstrated, among other things, that Leeds had a significant cluster of deprived people living in its inner city, compared with other cities and towns in England. As a result, the region has been awarded a total of approximately £320 million from the EC, which when matched with UK and private funds that were also secured as part of the bid, brought the total to £870 million. Leeds, and other areas within Yorkshire and Humberside that were part of the successful bid, are now and have been, competing for these funds between 2000 and 2006 under a series of programmes designed to support business, community regeneration and physical developments.

GIS for Joined-up Government: the Case Study of the Sheffield Children Service Plan

Massimo Craglia and Paola Signoretta

Abstract

This chapter gives a practical example of the use of GIS in supporting public policy at the local level. The issues it raises in respect to the sharing of data among multiple agencies, and the methodology it puts forward to develop a composite indicator able to identify priority areas for intervention will be of interest to many practitioners, particularly because the project it discusses is set in the context of the preparation of the Children and Young People Service Plan, which is a statutory requirement on all local authorities under Section 17(4) of the Children Act 1989. Moreover, the range of agencies involved in this project reflects many of the partnerships being established at the local level to deliver public policy in a range of fields, from urban regeneration to crime reduction. Therefore, much of the discussion will be applicable beyond the specific application discussed here. The chapter is divided into five sections. The first introduces the project and the local setting, the second discusses the use of GIS to identify children's needs using data from different local sources; the third reports on the case study and the methodology used; the fourth introduces the results obtained, and finally the fifth draws some conclusions.

8.1 Introduction

This chapter examines the result of the *Needs Analysis and Mapping Project* supporting the preparation of the Children and Young People Service Plan (CSP)

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

2000–03 in Sheffield. The formulation of CSPs, and their yearly updates, is a statutory requirement on all local authorities (LAs) established under Section 17(4) of the Children Act 1989. The project was requested in 1998–9 by the Joint Commissioning Group (JCG), a local partnership in Sheffield, to the Sheffield Centre for Geographic Information and Spatial Analysis to support data collection and analysis as input to the preparation of the plan. The Partnership led by the City Council included representatives of South Yorkshire Police, the Department of Social Services (DSS), the Department of Education, the Young Children's Service (YCS), Community Health Sheffield, Sheffield Health Authority, and the City Council's Central Policy Unit and Department of Housing.

The chapter demonstrates the value of GIS in bringing together data coming from different agencies for policy purposes, and puts forward a simple methodology for constructing composite indices that capture different dimensions of need, and enable the identification of key priority areas for intervention. The use of composite indices is now well established for identifying need and targeting resources (see Chapters 6 and 7). These include, for example, the Townsend Index in the health field (Townsend *et al.*, 1988), and the Index of Multiple Deprivation regularly updated by the Department of Transport, Local Government and the Regions (DTLR). However, the methodological approach put forward in this chapter has three advantages. Firstly, that a simple methodology can be more easily understood and adopted by the government agencies themselves. This is important to facilitate the wider use of GIS in practice, and enable regular updates to monitor policy and assess outcomes. Secondly, by using enumeration districts as spatial units instead of the wards, which are used both by the DTLR Index and other recently proposed relevant indices (Prince's Trust, 2000), it is possible to identify some of the pockets of needs that are otherwise masked by the ward frame. Finally, for all its simplicity, we did explore the extent to which the results also stood against other methodologies, which whilst more complex, had the advantage of being grounded on firmer statistical bases. Having carried out the necessary tests, we are satisfied that the proposed methodology yields comparable results, with the bonus of simplicity and adaptability.

This project was carried out in the context of children's welfare but has a number of aspects that make it of wider interest for policy analysis: in the first place, there has been an increasing emphasis in Britain, but also in other countries, on a more integrated approach to policy making, which recognises the increasing complexity of many social issues, and therefore the need for a collaborative multi-agency approach. This often requires the integration of data coming from different agencies on a spatial basis, and the methodology to construct a composite index discussed here has wider applicability. In the second place, whilst inter-agency collaboration is fine in principle, it does not always come easily or naturally to many of those involved. Moreover, there may be just as many difficulties of communication within each agency as there are between agencies. This was well illustrated in the course of this project in relation to the challenges of collecting the data necessary from each agency. These challenges are discussed briefly in Section 8.2 and more fully in Signoretta and Craglia (2002).

The project is set in Sheffield, a city of approximately half a million people located in the north of England. Its economy has been traditionally based on steel

production and cutlery, while its hinterland was also strongly based on coal mining. The restructuring of these industries in the 1980s has had a major impact in the city. Employment in the steel industry alone fell by approximately 90%, from 45 100 in 1971 to 4700 in 1993, while another 10 000 jobs were lost in the mining industry in the surrounding region between 1985 and 1994 (Taylor *et al.*, 1996). These job losses have particularly affected the inner city wards where much of the traditional manual labour was concentrated. According to a study based on the use of a deprivation index similar to Townsend's (Woodhouse, 1999, p. 38), 'the most deprived wards, Manor, Park, Castle and Burngreave, are clearly concentrated in the inner city. They consist of both nineteenth-century industrial housing and post-war local authority estates. The next most deprived category consists of areas that have similar housing stock to the most deprived wards, such as Netherthorpe and Firth Park' (Figure 8.1). Regardless of the period of construction, many of these areas share the common characteristics of having been built when the local authority was under enormous pressure to build fast and re-house population after slum clearance or in the aftermath of World War II. Hence the quality of the construction was often low, and physical decay set in relatively quickly (Crook, 1993). Moreover, parts of these estates have been plagued for more than 30 years by high levels of crime, relative to the otherwise generally lower rates for Sheffield as a whole compared with other conurbations

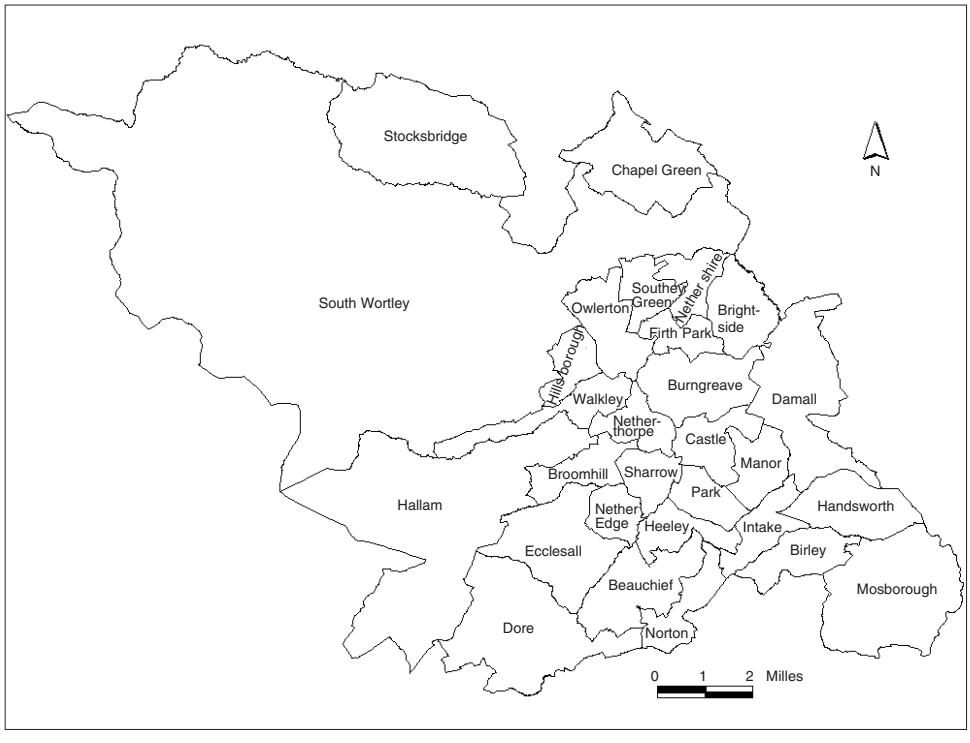

Figure 8.1 *Wards of Sheffield*

in England (Baldwin and Bottoms, 1976). The cumulative impacts of economic restructuring, physical decay and social malaise, including crime, make it all the more important to identify areas where children are most vulnerable, target intervention across many agencies in a coordinated fashion, and monitor outcomes.

With these considerations in mind, the chapter is divided into four further sections. The first sets the project in context and discusses the use of GIS in performing small areas analysis to identify children's needs using data from different local sources to support the Joint Commissioning Group's requirements; the second section reports on the case study and the methodology used; the third introduces the results obtained, finally the fourth draws some conclusions.

8.2 Small Area Analysis for the Identification of Children's Needs

Since New Labour came into power in 1997, there have been numerous policy initiatives aimed at improving children and young people's lives. These policy actions are very important as recent research work points out that experiencing financial disadvantage in childhood has severe implications in adult life (Prince's Trust, 2000). The Children's Services Plans (CSP) which are the focus of this chapter provide the general framework for the strategic planning of children and young people's services. Their importance has therefore increased as a way to help coordinate the many initiatives that are now underway in this field. With this in mind, the Joint Commissioning Group in Sheffield had two aims in setting up the Needs Analysis and Mapping Project with the University. The first was to pool together data about children from the different participating agencies, and set the framework for the yearly updating process; the second was to use the expertise at the University to have a series of analyses made that could inform the preparation of the CSP and in particular help identify areas of priority for intervention. The first aspect of the project highlighted the difficulties that those involved in joined-up initiatives face in trying to build a common base of data to support policy making. These difficulties included organisational issues (such as communication difficulties within agencies, varying organisational priorities among the agencies, and resource constraints), uncertainty on what could be shared in the light of the Data Protection Act, technical difficulties relating to the characteristics of the computer systems (both hardware and software) existing in each agency, and the degree to which they could respond to demands unforeseen at the time of their installation. These problems are discussed more fully in Signoretta and Craglia (2002), whilst the remainder of this chapter focuses on the methodological aspects related to the analysis of the data, and in particular to the development of composite spatial indices that bring together different dimensions of 'need', and help to prioritise areas for investment or additional analysis.

The 1996 Guidance (DfEE, 1996) indicates the content of the CSP for children in need[1] while the latest non-statutory guidance aimed at vulnerable children[2]

[1] Defined as children who will not achieve a reasonable standard of health and development unless they receive services under part III of the Children Act 1989.

[2] Defined as children whose life chances will be jeopardised unless action is taken to meet their needs and reduce the risk of social exclusion.

(http://www.doh.gov.uk/scg/childplan.htm) gives a more strategic role to the plan (defined as the Children and Young People Strategic Plan). The Plan should link vertically to more general plans that set out strategies concerning for instance environment and transport issues, and to more focused centrally prescribed plans such as *Sure Start* aimed at improving the health and well-being of children and their families and area-based programmes such as *Education Action Zones* aimed at raising the achievement of pupils tackling the underlying causes of poor performance and behaviour. Relevant for this work are the latter area-based programmes. These stem from the recognition that areas of deprivation and social exclusion need a multi-agency and cross-sectoral approach for their regeneration and also that the identification of these areas is vital to pursue a programme of local regeneration as proposed in *A New Commitment to Neighbourhood*: *National Strategy Action Plan*, the Government's strategy for the socioeconomic renewal of the most deprived neighbourhoods in England.

The Children and Young People Strategic Plan contains elements such as information about levels and types of needs and gaps between needs and service provision, which allows the preparation and coordination of focused joined-up intervention among the local agencies. A recent report on disadvantaged young people from the Prince's Trust (2000) highlights that mapping is an essential tool for an approach that is based on finding local solutions to local problems. Small area analysis is an important tool to help identify pockets of deprivation. The report looks at a variety of factors to define multiple deprivation for young people and describes several indices to measure disadvantage using broad measures of poverty together with measures more specific to young people. However, the analysis is based on very broad geographical areas (regions, counties, districts and wards) within which severe pockets of deprivations may be overlooked. This aspect severely limits its use for policy intervention at the local level.

The need for small area analysis has also been recognised by the Social Exclusion Unit of the Cabinet Office, and in particular by the Policy Action Team 18 Report on Better Information (PAT 18, 2000). The report recommended that a set of neighbourhood statistics at ward level should be established nationally covering access to services, community well-being, crime, economic and work deprivation, education, health, housing, and the physical environment. Following this recommendation, a new service *Neighbourhood Statistics* was established by the Office for National Statistics in collaboration with central, and local government and other agencies. These small area indicators are used at national level to compare areas targeted by a specific initiative and at local level to evaluate local conditions, to target resources, and to monitor and assess outcomes (http://www.statistics.gov.uk/neighbourhood/patinitiatives.asp). However, the choice of the ward as the basic geographic unit for the dissemination of data about neighbourhoods is problematic. As recognised by a sub-group of PAT18, which focused on Geographic Referencing, wards vary greatly in size and population and their boundaries are continuously modified.

In the UK, the use of deprivation indices is well established and a detailed review was produced by PAT 18 (for more details on indices and associated methodologies, see http://www.cabinet-office.gov.uk/seu/2000/pat18/depindices.htm). For instance, the Townsend Index of Material Deprivation used for health analysis is the sum total

of the standardised Z scores of four census variables. Other indices such as those developed by the former Department of the Environment, now ODPM, for 1991, 1998 and 2000 are based on various approaches. As an example, the latest Index of Multiple Deprivation 2000 (IMD 2000) (DETR, 2000) comprises six ward-level domain indices which were first standardised to indicate the departure of each value from its mean, then transformed to a common distribution and finally weighted. Another example especially relevant for the present work is the already mentioned study by the Prince's Trust (2000) which measures disadvantage for young people using five indices. Each index relates to a different theme (namely population, income and work, care, education and crime) with sub-components each of which is ranked according to a defined classification (for more details, see Prince's Trust, 2000, p. 33). The total score is obtained by adding up the single rankings. The advantage of this methodology is in its simplicity that makes it easier to be employed by government agencies; the downside being that the indices are developed for large units (districts, wards) which may not be very useful for policy purposes at the local level.

With these considerations in mind, this project was set up to use fine-grained socio-economic data available in the city, and use GIS as a way of integrating these data sets, and analyse them over small geographical units to support local area planning. The methodology developed and the data utilised are described in the following section.

8.3 Methodology

8.3.1 The Needs Analysis and Mapping Project

According to the project design, three main questions about children and young people needed exploring; firstly, the significant needs of under 18s in the city which affect their educational achievement, health and welfare; secondly, the distribution of these needs according to age, gender, ethnicity and geography; thirdly, the geographical distribution of children in areas affected by multiple deprivation. The project was organised in two phases: the first for data collection and input in GIS, the second for data analysis and discussion with the partnership.

The project brief contained a list of 33 data sets to collect from the participating agencies reflecting several dimensions of children and young people's lives. The list was based on the *Children's Services Planning: Guidance* (DfEE, 1996) and included information on children and young people relating to the following issues: disabilities, mental health, distribution of under 8 years olds, looked-after children, runaways, adopted children, children leaving care, protected children, young carers and children in conflict with the law. The project steering group also decided that the information was to be collected at the most disaggregated level, focusing on the post-code unit as the most appropriate scale. The time period to which the data referred was limited to one particular period (1997–8) to facilitate the collection due to the restricted time scale of the project. In some instances adjustments had to be made in relation to specific data sets. For instance, the time period chosen for education data was the academic year, rather than the calendar year. In other cases, as detailed below, it was not possible to have a whole year's worth of data but only a snapshot at a

particular time. However, in all cases, questions about particular trends affecting the data were asked of the data owners to ensure that the data sets were not affected by any particular bias.

In spite of the support verbally committed by the partners in the Joint Commissioning Group, who also 'owned' the data, it proved impossible to collect all 33 data sets. After three months of efforts, only 18 data sets were made available, even though all 33 existed, mostly already in digital form. Four data sets were dropped because they were only available in paper format or they were too time consuming to collect; for two variables only sample data were available, while nine data sets were not received. As outlined before, the problems associated with data sharing were largely due to organisational issues and the different level of priority accorded to the project in the participating agencies. Following an assessment of the overall quality and robustness of the 18 data sets received, and discussions with the steering group representing the agencies involved, six data sets were selected for analysis to detect areas where children are affected by multiple needs, and thus identify areas for priority action and funding.

For the present work it was decided that a simple but effective methodology should be employed. Thus the use of statistical tests usually included in specialised software, which may not be available to local government data analysis and research units, was avoided. The six variables utilised represent different dimensions of children's life in terms of health, education, crime and social background, these are:

- children with disabilities and special needs;
- children on the Child Protection Register;
- children in families on income support;
- children with low weight at birth;
- children excluded from school; and
- children and young people in conflict with the law.

Each variable represents a group of young people with specific needs, and their combination points out areas where children's needs are more acute.

Initially each data set was checked for invalid postcodes, and then the remaining postcodes were georeferenced using the ED/Postcode directory provided by Manchester Information & Associated Services (MIMAS, www.mimas.ac.uk) at the University of Manchester. The postcoded data were aggregated at the enumeration district level (using the 1991 boundary provided by EDINA Edinburgh University Data Library, http://edina.ac.uk), since this level would preserve the anonymity of single individuals but at the same time was fine enough to pick up pockets of deprivation within Sheffield. The six variables were combined to produce two indices: one was derived using count data while the other rates, thus reflecting different policy needs, both operational (where are the largest number of children in need?) and strategic (where do we have more or less children in need than we would expect other things being equal?). The indices measure needs of children and young people in Sheffield, not material deprivation as for instance in the Townsend Index, and are *indirect* indicators of deprivation as they represent the victims of particular disadvantaged circumstances (for more details on this issue, see

http://www.cabinet-office.gov.uk/seu/2000/pat18/depindices.htm). A description of the six variables and the denominators used is given below.

8.3.2 Description of the Data Sets Utilised

The data set on *Children with Disabilities and Special Needs* was delivered by Sheffield Social Services and includes four data sets (Children registered disabled with Sheffield Social Services, Children with a user group for disabilities, Children referred during the required period to the Social Work Team for Children with Disabilities, Children and Families User Group with a referral reason of mobility problems, disability problems or mental health). The steering group decided to include all four data sets, as this would give a reliable picture of the problem in Sheffield. Ninety-two per cent of the records could be mapped while the remaining 8% had an invalid postcode. *Children on the Child Protection Register* was also delivered by Sheffield Social Services. Ninety per cent of the records were mapped while the remaining 10% had an invalid postcode. Data on *Children aged 0–17* in families on income support was a snapshot at December 1998. This was because the data set was derived from a system designed for administrative purposes which could not easily respond to the requirements of this project. The data was supplied by the Central Policy Unit at Sheffield City Council. *Children born less than 2.5 kg* was derived from a file supplied by Sheffield Health Authority on the children born in Sheffield in 1998 with details of their weight. The steering group selected the threshold of 2.5 kg because this is the value at which health practitioners define 'under weight'. Ninety-nine per cent of the records delivered were mapped. The data set *Children excluded from school* was based on data delivered by the Department of Education and includes children aged 3–16 permanently excluded from school during the academic year 1997–8. A permanent exclusion applies when pupils are excluded from the school on a permanent basis because the school does not wish them to return. Ninety-nine per cent of the total number of records were mapped. Finally, the Youth Offending Team supplied the data set on *Children aged 10–17 in conflict with the law*. The data set contained the cases brought to court during April 1997 to March 1998. From this initial data set information on young offenders was extracted and 90% of the records were geocoded.

As far as the denominators are concerned four data sets were used: total number of children aged 0–17 (disabled children, protected children, children in families on income support), total number of children aged 3–16 (children excluded from school), total number of children aged 10–17 (children in conflict with the law) and total number of children born in Sheffield during 1998 (babies born less than 2.5 kg). The data were delivered by the Central Policy Unit; 98% of the records were geocoded. The method to combine the variables to obtain the indices is explained in the next section.

8.3.3 Construction of the Two Indices

The methodology deployed included the following steps. Firstly, for each variable we computed rates and counts at the ED level. Rates were calculated as the proportion of observed cases in each ED over the total population at risk in that ED (e.g., number

Table 8.1 *Score attributed to each class*

Class	Score
Worst 20%	5
Second worst	4
Mid-range	3
Second best	2
Best 20%	1
No cases	0

of disabled children aged 0–17 in ED/Total number of children aged 0–17 in ED). Secondly, we classified each variable in quintiles to identify the worst 20% of EDs. This was done for both sets of counts and rates. For all variables, only the EDs with cases were included in the classification and a score from one to five was assigned to the EDs falling in each group (Table 8.1), with the worst 20% having the highest score.

A score of zero was given to the EDs with no cases. In this way, each ED ended up having a score assigned for each variable for both sets of counts and rates. Thirdly, the scores given to each ED were summed and two total scores were derived, one for counts and one for rates. Finally, the two total scores were grouped in quintiles and then mapped. This methodology makes it easy to assign different weights to each variable prior to the construction of the composite index, and thus could be applied in the context of multi-criteria evaluation (see for example Henig, 1996; Hill, 1972). In the case of this project, however, the stakeholders represented in the steering group decided that differential weighting was not warranted, and therefore none was applied.

8.4 The Spatial Distribution of Child Deprivation

As far as the initial three questions are concerned, the project investigated the overall multiple needs of children and young people and their geographical distribution in Sheffield. Gender and ethnicity issues were not incorporated in the analysis due to the incompleteness of the data sets collected but will be part of the Plan update. Out of a theoretical maximum score of 30, which would indicate that an ED was consistently among the worst 20% on all six variables, the maximum score obtained in practice was 27 on counts, and 26 on rates (Figures 8.2 and 8.3).

As far as the total score on rates is concerned the worst EDs (first two categories), appear to be concentrated to the east of the city centre, with a similar pattern when looking at the counts. The figures also highlight the outliers. The outliers common in both indices are located in Southey Green, Firth Park, Manor, Norfolk Park and Park Hill, i.e. many of the areas that have been significantly impacted by economic restructuring as discussed in Section 8.1. It is important though to acknowledge that even within an estate or neighbourhoods there can be significant variations, with problematic areas sitting right next to others that are not. Here lies the value of working with fine-scale data. This issue is all the more apparent if one used wards, as suggested by PAT 18, as the basic unit for neighbourhood data collection and

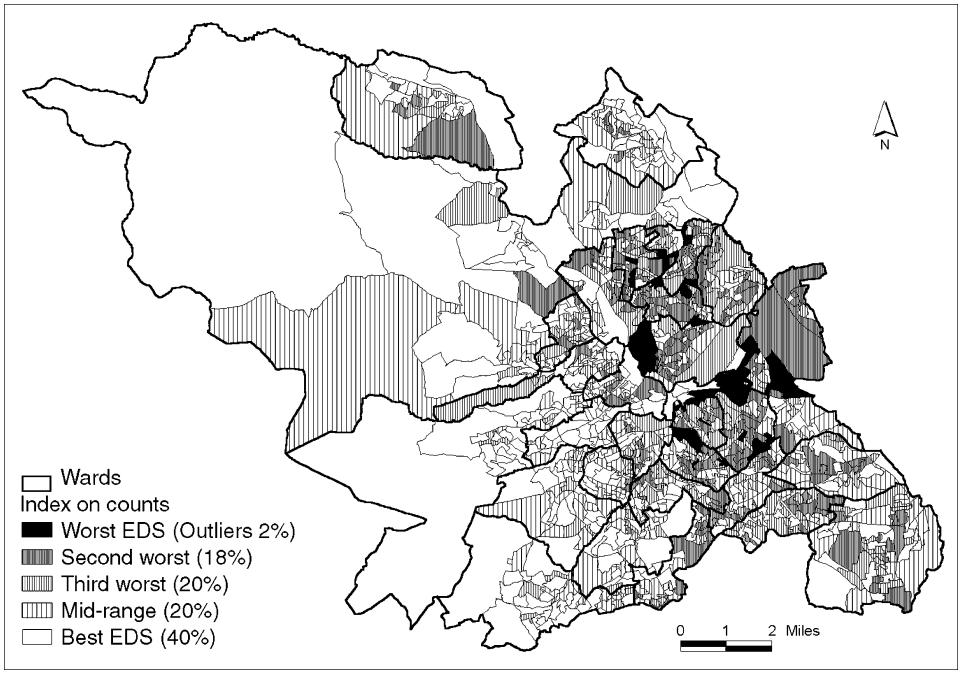

Figure 8.2 *Index based on counts*

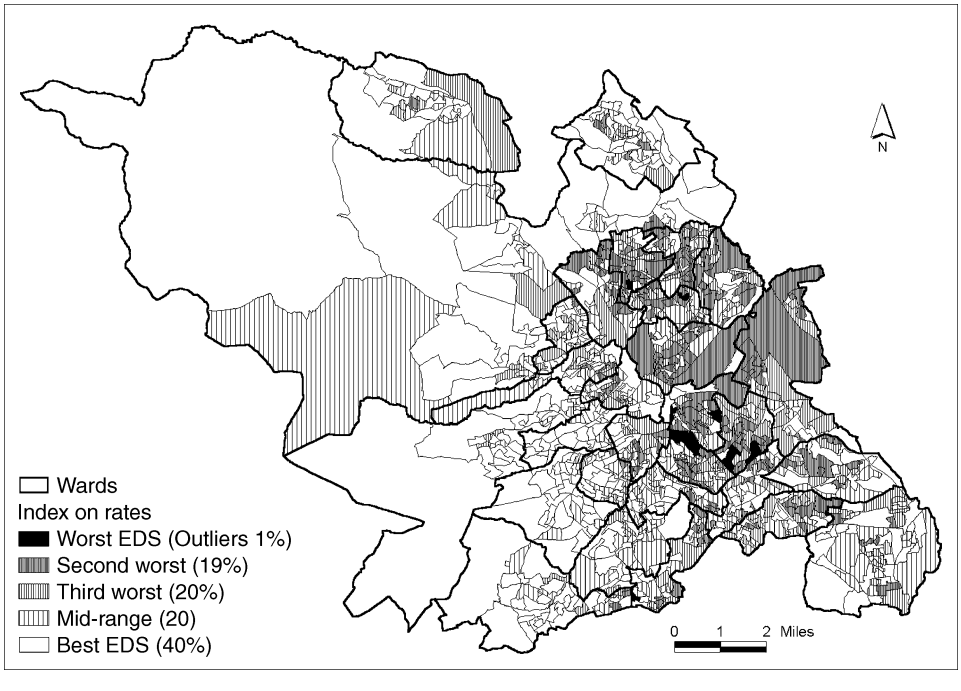

Figure 8.3 *Index based on rates*

dissemination. The figures show this by superimposing the ward boundaries onto the ED framework thus confirming the unsuitability of aggregating data at the ward level for local planning and service delivery purposes. This is yet another example of the Modifiable Areal Unit Problem (MAUP), i.e., of the extent to which the outcome of spatial analysis depends on the nature of the chosen spatial framework. Whilst well known to academics, highlighting this type of problems to the partnership funding the project was particularly useful. Partly as a result of that, the City Council is currently in the process of revising both ward and corporate area boundaries to maximise the homogeneity of key social indicators.

The advantage of the method described above to combine different variables, and identify areas affected by multiple needs lies in its arithmetic transparency, which makes it ideal for use by local authorities and agencies engaged in needs assessment and planning. Moreover, the simplicity of the method makes its outcomes more easily understood by local stakeholders and community groups. The potential drawback is that this methodology disregards any spatial structure in the data and gives no measure of statistical significance. Cognisant of these potential limitations, we undertook further analysis using the Besag–Newell test (Besag and Newell, 1991). This is a test for detecting clusters in rare events over a geographical area that has been divided into small zones (in the present study enumeration districts). For each zone, data on the population at risk must be available and a coordinate assigned to represent the location of the zone – such as the population-weighted centroid. Each event occurring in the ED is then allocated to the centroid. For each ED a population-centroid is available and for each variable and each ED a population at risk (which as in the first method will depend on the particular variable) is available and a count of the number of cases. In this application all EDs that were included in a cluster test attained the 5% significance level (for more details on the procedures followed see Craglia *et al.*, 2003). The results confirmed that the simpler method described in this chapter to create composite indices was more than adequate in identifying the key problem areas in the city. This finding is important as the methodology adopted can be easily employed for similar analysis especially in the context of local government, with some confidence that the results are similar to those obtained with more sophisticated, and complex, statistically based methods.

The results of this project proved very helpful for the planning and programming of priority actions for all the agencies involved, and gives a benchmark to evaluate the effectiveness of strategies over time. The results formed the basis for consultation by the area groups of the Young Children Service with the local communities, and were also utilised for subsequent projects. For example, the data on disabled children supported the Residential Respite Service project and the provision of additional services for disabled children in the northern part of the city. A final result was the setting up of 14 multi-agency groups each with the task to investigate issues relating to children and young people's welfare.

8.5 Conclusions

This chapter has presented a case study based on the *Needs Analysis and Mapping Project* within the context of the preparation of the Children Service Plan 2000–03

in Sheffield. In order to identify priority areas for intervention, the methodology developed has produced two indices based on a total score for counts and rates using six variables. The analysis carried out identified areas where children and young people are most affected by multiple needs. One advantage in the context of local government is that this methodology overcomes the difficulties associated with sophisticated statistical tests that are usually included in specialised software developed and mainly utilised in academic environments. One additional advantage of the present work was the small level (ED) of analysis adopted that allowed the identification of pockets of deprivation within wards which would not have emerged as affected by multiple needs.

This project demonstrated the high value that data collected from several local sources and integrated through GIS can offer to policy making in tackling local problems. The difficulties encountered in sharing the data among agencies have raised awareness among all the participant organisations of the practical difficulties of 'joined-up' working. As a result, more formalised arrangements have been put in place among all the stakeholders with written protocols committing each partner to provide key data sets to the University at regular intervals. In this context, the role of the University has been crucial as a neutral broker, able to collect highly disaggregated data, and develop small area analyses that add value to the data for policy making without infringing the requirements of the Data Protection Act. From a policy perspective, the analysis pointed out that the most deprived areas in terms of the six variables selected are still, not surprisingly, the same areas that started suffering from economic decline over 30 years ago. As this analysis concerned young people, the future for these areas and consequently for the people that live in them looks unpromising unless sustained action is taken. There are now new opportunities to help the local economy through the structural funds awarded to South Yorkshire and Sheffield from the European Union for the period 2001–06. Hence, the added importance of having in place an analytical framework to target intervention and monitor outcomes. GIS has a key role to play in this framework, as shown in this chapter. More practical applications like this will do much to raise further the awareness among policy makers of the opportunities of this technology and method of analysing spatial data.

Acknowledgements

The authors would like to thank the Young Children's Service and the Joint Commissioning Group in Sheffield for providing the data used in this analysis. However, the views expressed are those of the authors and not necessarily of the agencies involved. This work is based on data provided with the support of the ESRC and JISC and uses boundary material which is copyright of the Crown and the ED-LINE Consortium.

The Application of New Spatial Statistical Methods to the Detection of Geographical Patterns of Crime

Peter Rogerson

Abstract

The evolution of geographic information systems has spawned a resurgence in the development of spatial statistical methods. In this chapter, several recent developments in the field of spatial statistical analysis are summarised and applied to burglary data for census tracts in Buffalo, New York. The methods employed here are concerned with the detection of spatial patterns in geographic data. Some of the methods are concerned with finding regions with rates that are significantly higher than those that could be expected under the null hypothesis of no geographic pattern, relative to prior expectations. Others have as their goal the detection of temporal change in spatial data.

9.1 Introduction

As the value of geographic information systems (GIS) has become more evident to researchers and practitioners in an expanding array of disciplines, the demand for spatial analysis, spatial modelling and spatial statistics has witnessed substantial growth. Although the early benefits of GIS derived primarily from their ability to store, retrieve and display spatial information, GIS is now increasingly used in the analysis of spatial data. The addition of modules such as Spatial Analyst and

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

Geostatistical Analyst to ArcView, and Spatial Statistics to S-PLUS represent examples of how vendors are beginning to meet the needs of the new marketplace for geographical analysis. The effects of these changes vary from one subfield to another. In epidemiology, the use of spatial modelling and spatial statistics has soared in recent years. Many new methods for the statistical assessment and modelling of spatial patterns have been developed recently (e.g., Elliot *et al.*, 2000; Lawson *et al.*, 1999; Lawson, 2001). In crime analysis, the development of new statistical methods has perhaps been less apparent, but the use of GIS by police agencies as well as by other local government agencies has been much more widespread than in public health and epidemiology.

This chapter demonstrates how recent advances in spatial statistical analysis may be used in the context of crime analysis. Section 9.2 provides a brief description of the burglary data (from Buffalo, New York) that will be used to illustrate the various methods. Section 9.3 describes several alternative approaches to detecting geographic patterns in the data, and in each case the approach is illustrated by using the burglary data.

9.2 Burglary Data

Data on burglary incidents in the city of Buffalo, New York, for 1998 is used to illustrate the methods. Buffalo has a population of approximately 300 000 residents. Its population has declined steadily over the last several decades as it has coped with the difficulties associated with transforming its economy and becoming less reliant on what was a once-strong manufacturing base. The maintenance of infrastructure and the provision of services are, of course, difficult for declining manufacturing cities. In part reflecting these difficulties, the Buffalo Police Department (BPD) has had to operate with a crime analysis unit that is understaffed. Consequently, the crime analysis unit has a greater focus on database development and reporting, and less of a focus on statistical analysis.

The BPD has simultaneously maintained strong links with the University at Buffalo, and the two have been involved with several joint projects. Within this context, and with the funding of a grant from the National Institute of Justice to (a) develop new methods, and (b) work with local agencies, an effort was made to examine geographic aspects of crime. In particular, we worked with the Crime Analysis Unit to develop new methods for monitoring temporal changes in the geographic patterns of crime.

Information is available on the number of burglaries by census tract, as is information on the coordinates of tract centroids. In addition, the data for 1998 is disaggregated by quarter; a summary of the number of incidents in each quarter is given in Table 9.1. Since there are 90 census tracts in the city, there is an average of approximately 15 burglaries per tract, per quarter.

The data are spatial in the sense that regional frequencies are available for the 90 census tracts that comprise the city of Buffalo. Consequently, the methods discussed in this chapter focus on those that are useful for spatial data. Other methods are relevant for situations where coordinates are available for the point locations of events; these latter methods are not covered in this chapter.

Table 9.1 *Burglary incidents by quarter in 1998, Buffalo*

Period	Number
January–March	1364
April–June	1540
July–September	1645
October–December	1564
Total	6113

Table 9.2 *Chi-square test comparing observed frequency of burglaries with that expected under the null hypothesis of no spatial pattern*

Period	χ^2
January–March	810.3
April–June	925.6
July–September	1027.8
October–December	875.5

Note: The critical value of chi-square, when $df = 89$ and $\alpha = 0.05$, is approximately 112.

9.3 Analysis of Burglary Data Using Alternative Spatial Statistical Methods

9.3.1 Expected Versus Observed Frequencies

The expected numbers of burglaries in each tract were calculated by assuming that there was no spatial pattern in the burglary data, and by conditioning on the total number of burglaries in each quarter. Specifically, expected values were determined by multiplying the total number of burglaries in a quarter by each tract's share of city-wide population. One straightforward way to compare observed and expected frequencies is via the common, aspatial, chi-square test:

$$\chi^2 = \sum_i \frac{(f_{obs,i} - f_{exp,i})^2}{f_{exp,i}} \tag{9.1}$$

where the fs refer to tract i-specific observed and expected frequencies, and the sum is over all tracts. This statistic has a chi-square distribution with degrees of freedom equal to the number of tracts minus one, under the null hypothesis that the number of burglaries observed in tracts is generated by distributing the total number of burglaries randomly across tracts, in accordance with tract population shares.

The results, shown in Table 9.2, indicate a very high degree of statistical significance. In all cases the observed value of the chi-square statistic exceeds greatly the

critical value of 112, and the pattern of crime is thus substantially different from the underlying pattern of population. This is not particularly surprising; it is well known that crime tends to cluster geographically, and the results are consistent with the visual impression one obtains from Figure 9.1. Of interest is the fact that the fit is different in each quarter; the burglary pattern most closely resembles population distribution in the first quarter (even though it is very different from it), and the

Figure 9.1 *Burglary incidences in Buffalo by census tract, 1996*

pattern of burglaries is most different from the spatial distribution of population in the third quarter. We will investigate these differences in more depth in the following sections.

9.3.2 Changes in Spatial Pattern: Redefining Expectations

After finding that the spatial pattern of burglaries differs significantly from that which would be expected if the true probability of a burglary were proportional to population, we now turn our attention to the changes in spatial patterns that occur from one quarter to the next. An alternative way to derive expected frequencies is to use the spatial pattern of crime itself, rather than the spatial pattern of population. One might, for example, choose to use the spatial pattern of burglaries that prevailed during the previous year as a basis for expectations. Then, any significant difference between what is observed in the current year and what is expected (on the basis of the past year) would pertain to *changes* that had occurred in the spatial pattern. Since we do not have access to 1997 burglary data for Buffalo, we will simply use the complete set of data for 1998. Thus the expected frequency of burglary in a census tract, in a given quarter, is now derived as the total number of burglaries in the quarter, multiplied by the fraction of all 1998 burglaries that occurred in that particular census tract. Note that this particular calculation of expectations uses some of the actual data, and hence judgements of statistical significance based on these expectations might be viewed as conservative. An alternative might be to calculate expectations for each quarter based upon the spatial pattern that prevailed during the other three quarters, but that seems to be even more *ad hoc*. Clearly the question of what data to use in the definition of expectations is an important one. Most often one will want to use previous, historical data. Even then, the question of how much historical data (e.g., last quarter, last year or last three years) is a difficult one.

Table 9.3 reveals that only the first quarter, January–March, has a spatial pattern that differs significantly from the pattern that prevailed for the entire year. Of course it is of interest to know *how* the January–March pattern differs from the remainder of the year (e.g., where are burglaries higher or lower than expected?). This question will be addressed in section 9.3.4.

Table 9.3 *Chi-square test comparing observed frequency of burglaries with that expected under the null hypothesis of no spatial deviation from the annual pattern*

	χ^2	Significance (p)
January–March	129.9	0.003
April–June	63.9	0.979
July–September	106.4	0.101
October–December	77.6	0.800

9.3.3 A Spatial Chi-Square Test

When the categories in a chi-square test represent a set of geographic regions, the observed frequencies in each category/region may be spatially dependent, and one approach to account for this dependence is to deflate the usual chi-square statistic in an appropriate manner (Fingleton, 1983, 1986). Cerioli (1997) has indicated how chi-square tests should be modified in the presence of spatially autocorrelated data for 2×2 tables. A specific weakness of the chi-square goodness-of-fit statistic, when applied to spatial data, is that it does not account for *where* the greatest deviations between observed and expected values are, relative to one another. Figure 9.2, taken from Rogerson (1999), shows that both (a) and (b) have the same chi-square statistic, and yet the spatial pattern of deviations is quite different. In (a), there is a distinct cluster of regions where the fit is poor, while in (b), the spatial distribution of deviations is more random. Suppose that the usual, aspatial chi-square statistic is computed for (a) and (b), and it is found that it is almost, but not quite, significant. It would be desirable to have a statistic with which we would conclude that in (a), the combination of the aspatial deviations *and* the spatial pattern of deviations could not have occurred by chance (that is, where the observed *spatial* pattern of frequencies is not likely under the null hypothesis of independent, expected regional frequencies).

Likewise, Moran's *I* statistic might be used to examine the spatial pattern of deviations but, by convention, the diagonal elements of the spatial weight matrix are zero, implying that deviations between the observed value and the expected value within

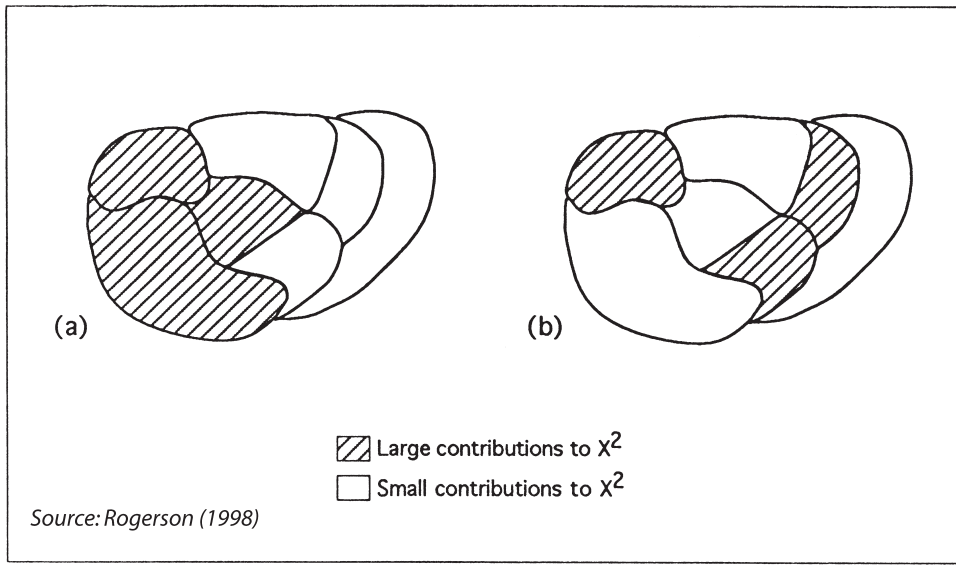

Figure 9.2 *Two patterns of deviations (observed–expected) yielding identical χ^2 values. From Rogerson (1998)*

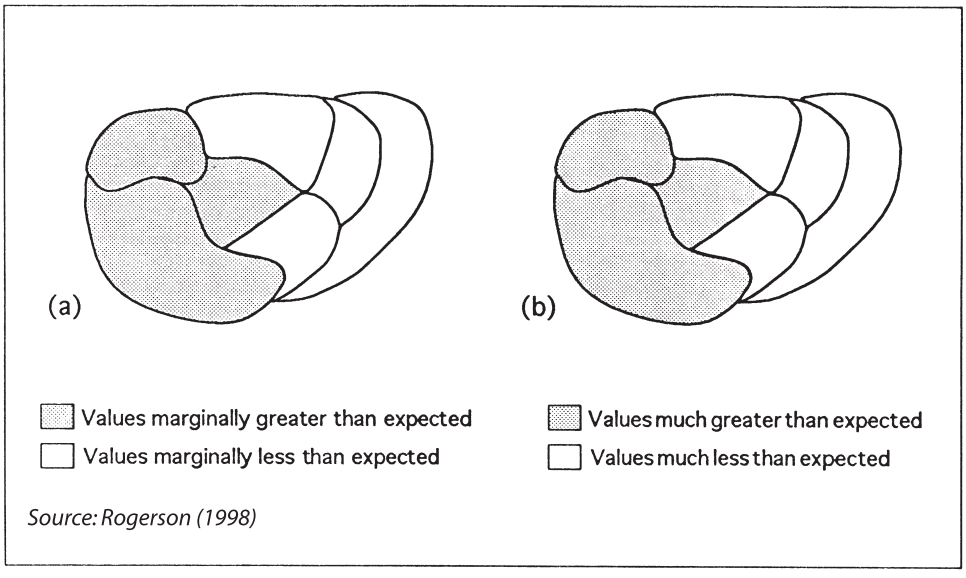

Figure 9.3 *Two patterns of deviations (observed–expected) yielding identical I values. From Rogerson (1998)*

each of the regions are not accounted for. Figure 9.3, also from Rogerson (1999), shows two situations that could have identical I values, and yet in (a) the pattern is consistent with the null hypothesis, while in (b) the deviations are unlikely to have arisen under the null hypothesis. Whereas the chi-square goodness-of-fit test focuses upon individual regions and ignores the geographical pattern of deviations, Moran's I focuses upon the pattern of deviations, but ignores the fit *within* regions.

Rogerson (1998, 1999) introduced the spatial chi-square statistic, R, to construct a test of the null hypothesis that a set of m observed regional frequencies, N_i, $i = 1, 2, \ldots, m$, could have occurred under the following null hypothesis:

$$H_0: E[N_i] = \lambda\xi_i, \quad i = 1, 2, \ldots, m. \tag{9.2}$$

For example, in the case of the spatial pattern of crime, the population of each region is given by ξ_i, the overall crime rate in the population is λ, and the expected number of cases in each region is $E[N_i]$.

Rogerson defines the spatial version of the chi-square goodness-of-fit statistic as

$$R = (\mathbf{r} - \mathbf{p})' \mathbf{W} (\mathbf{r} - \mathbf{p}) \tag{9.3}$$

where there are m regions, and the observed frequencies are used to construct the $m \times 1$ vector of proportions $\mathbf{r}$, where $r_i = N_i/N$ and N is the total number of observed cases. The values $\xi_1, \xi_2, \ldots, \xi_m$ are known quantities, which, for example, might be taken as the populations of the regions. The nonrandom $m \times 1$ vector of expected

proportions is **p**. A natural definition is to have $p_i = \xi_i/\xi$, where $\xi = \xi_1 + \xi_2 + \ldots + \xi_m$ and $\lambda = N/\xi$. Also, **W** is an $m \times m$ matrix containing elements w_{ij} (including elements along the diagonal, where $i = j$):

$$w_{ij} = \frac{a_{ij}}{\sqrt{p_i p_j}} \tag{9.4}$$

The elements of a_{ij} measure the 'connectedness' of region i to region j, and are discussed further below. The spatial chi-square statistic tests the null hypothesis by combining terms that focus on within-region deviations (as does the chi-square goodness-of-fit statistic) and the spatial pattern of deviations found in nearby regions (as does Moran's I).

High values of the statistic indicate that there may be single regions where observed and expected proportions differ significantly, and/or there may be areas where positive (or negative) deviations between observed and expected proportions exhibit significant spatial autocorrelation. Since R may also be written as

$$R = \sum_i \sum_j w_{ij}(r_i - p_i)(r_j - p_j) = \sum_i \frac{(r_i - p_i)^2}{p_i} + \sum \sum_{i \neq j} a_{ij} \frac{(r_i - p_i)(r_j - p_j)}{\sqrt{p_i p_j}} \tag{9.5}$$

it may be conceptualised as the sum of two terms – the aspatial chi-square statistic, and a term that accounts for the spatial pattern of deviations between observed and expected values. High values of R will lead to the rejection of the null hypothesis for at least one of two reasons: either there are large deviations between observed and expected regional values (in keeping with the usual interpretation of the aspatial chi-square test), or the deviations exhibit a significant spatial pattern, or both.

The spatial chi-square statistic is closely related to Tango's (1995) statistic:

$$C_G = (\mathbf{r} - \mathbf{p})' \mathbf{A} (\mathbf{r} - \mathbf{p}) \tag{9.6}$$

where **A** is a $m \times m$ matrix containing the elements a_{ij} that measure the degree to which regions are connected. Tango uses

$$a_{ij} = e^{-d_{ij}/\tau} \tag{9.7}$$

$$a_{ij} = 1 \tag{9.8}$$

where d_{ij} is the distance between regions i and j, and τ is a measure of the importance of distance (where larger values of τ correspond to larger 'spheres of influence' around each region). Tango gives the expected value and variance of C_G as

$$E[C_G] = \frac{1}{N} \mathrm{Tr}(\mathbf{A}\mathbf{V}_p) \tag{9.9}$$

$$V[C_G] = \frac{2}{N} \mathrm{Tr}(\mathbf{A}\mathbf{V}_p)^2, \tag{9.10}$$

where

$$\mathbf{V_p} = \Delta(\mathbf{p}) - \mathbf{pp}' \tag{9.11}$$

with $\Delta(\mathbf{p})$ defined as an $m \times m$ diagonal matrix containing the elements of $\mathbf{p}$ on the diagonal. Furthermore, the null hypothesis may be tested using the chi-square distribution. Specifically, the quantity

$$\nu + \frac{C_G - E[C_G]}{\sqrt{V[C_G]}}\sqrt{2\nu} \tag{9.12}$$

has an approximate chi-square distribution, with ν degrees of freedom, where

$$\nu = \left[\frac{(\mathrm{Tr}(\mathbf{AV_p}))^{1.5}}{\mathrm{Tr}(\mathbf{AV_p})^3}\right]^2 \tag{9.13}$$

The significance of the spatial chi-square statistic, R, may be assessed by replacing $\mathbf{A}$ with $\mathbf{W}$ in equations (9.9)–(9.13).

Results for the burglary data are shown in Table 9.4 for various choices of τ (which can be roughly interpreted as proportional to cluster size). For a Type I error of $\alpha = 0.05$, the statistic is significant only for the January–March data (though note that the statistic would be barely significant at $\alpha = 0.10$ for the July–September data). For January–March, the significance is highest ($p = 0.002$) when $\tau = 0.9$. As τ increases, the results approach those of the aspatial chi-square test. The results here are similar to those for the aspatial chi-square test (Section 9.3.1); when used in an exploratory fashion, by examining different values of τ, the spatial chi-square test has the additional capability of better capturing the scale on which clustering is occurring.

9.3.4 Outliers and Local Tests

When the global chi-square test (spatial or aspatial) is significant, it is of interest to know which categories (in this case, census tracts) contributed to the significant value. Perhaps it was simply one or two tracts that might be then considered as potential

Table 9.4 *Spatial chi-square tests*

τ	(0.9)		(0.2)		(1.3)		(0.2)	

outliers. Also, when the global test is insignificant, it is still possible that an examination of individual categories will uncover instances where the observed value differs significantly from the expected value (and these might then be considered local hotspots). Fuchs and Kennett (1980) propose the *M* test to find outlying cells in the multinomial distribution. The test may be used in conjunction with the global, aspatial chi-square test (and the related quadrat test). Their statistic is the maximum adjusted residual. For cells $i = 1 \ldots, m$ define

$$z_i = \frac{N_i - Np_i}{\sqrt{Np_i(1-p_i)}} \tag{9.14}$$

A one-sided test is based on max z_i; $i = 1 \ldots, m$, and bounds for the critical value are

$$\Phi^{-1}\left\{1 - \frac{m - [m^2 - 2\alpha m(m-1)]^{1/2}}{m(m-1)}\right\}, \Phi^{-1}\left\{1 - \frac{\alpha}{m}\right\} \tag{9.15}$$

where Φ is the cumulative distribution function for the standard normal distribution. The upper bound can be recognised as the common Bonferroni adjustment. Fuchs and Kennett (1980) show that the test is more powerful than the global chi-square test in the presence of a single outlier. Thus the *M* test can be used in conjunction with the global test – when the global test is significant, the *M* test may be useful in determining whether the global significance is achieved via contributions from many regions, or via contributions from only a small number of outliers. Similarly, when the global test is not significant, the *M* test may still uncover anomalous values that remain hidden in the global statistic, since it is more powerful at detecting outliers.

To determine those census tracts that contributed significantly to the overall chi-square value in the burglary data, the tract-specific local *z*-statistics were calculated using equation (9.13). Using (9.12), with $k = 90$, $\alpha = 0.05$, bounds for the critical values of $M = \max z$ are $\Phi^{-1}(.99943, .999444) = \{3.253, 3.261\}$. The observed maximal *z*-values for each quarter are shown in Table 9.5. In each of the first three quarters, the observed value of $M = \max z$ is significant (though only marginally so in quarters two and three). The most significant value is found in the first quarter – a result that is consistent with the global analysis summarised in Table 9.3. Table 9.5 also depicts the tract number associated with the maximal *z* value; in all four quarters, only one of the 90 tracts had a *z*-value exceeding the critical value, and thus there were no other tracts that contributed significantly to the overall chi-square.

Table 9.5 *Results of M test*

Period	Maximum *z*	Tract
January–March	3.68	69
April–June	3.29	87
July–September	3.30	26
October–December	2.67	75

9.3.5 A Local Version of *R*

A recent development in spatial statistics has been the advent of 'local' spatial statistics that focus more specifically upon the possible existence of spatial association as viewed from a particular local region (e.g., Getis and Ord, 1992; Ord and Getis, 1995; Anselin, 1995). Thus 'hotspots' of significant local positive spatial autocorrelation may be detected, despite the absence of pattern on a global scale. Also, as Anselin has indicated, local statistics are useful in detecting outliers when the global indicator is significant. For example, in their application to international trade, O'Loughlin and Anselin (1996) found that a significant global measure of autocorrelation was due to a small number of outliers, and when these were removed, the spatial pattern of the remaining values was essentially random. The local version of the spatial chi-square statistic, R, for a given location i, is:

$$R_i = \frac{(r_i - p_i)}{\sqrt{p_i}} \sum_j \frac{a_{ij}(r_j - p_j)}{\sqrt{p_j}} \tag{9.16}$$

Under the null hypothesis, the quantity

$$1 + \frac{R_i - \mathrm{E}[R_i]}{\sigma[R_i]}\sqrt{2} = \frac{R_i}{\mathrm{E}[R_i]} \tag{9.17}$$

can be approximated by a chi-square distribution, with one degree of freedom. The expectation is defined as

$$\mathrm{E}[R_i] = \frac{a_{ii}(1 - P_i)}{N}$$

This local test can be thought of as a spatial generalisation of the aspatial M test, so that the assessment of fit in individual sub-regions also includes an assessment of how similar the fit is in nearby sub-regions as well.

Table 9.6 displays the maximum value of R in each of the four time periods. This is done for that value of τ which yields the highest local value of R. The results are similar to those shown in Table 9.5 – the first time period has the most significant local spatial association, around census tract 69. The next two quarters are

Table 9.6 *Local R tests*

Period	Local statistic	Max τ	Observation number
January–March	13.53	τ = high and flat	69
April–June	10.85	τ = 1.7 (flat)	87
July–September	12.358	τ = 0.46	26
October–December	10.175	τ = 0.52	75

Note: (R/E[R]) is approximately chi-square with 1 degree of freedom; under the null hypothesis we use $3.26^2 = 10.63$ as the critical value (where 3.26 is the critical value of a standard normal random variable with $n = 90$ tests).

marginally significant, and the last quarter fails to reject the null hypothesis that any single tract significantly differs from the expected number of burglaries (where expectations are based here upon the annual pattern). For the first two quarters, the value of τ leading to the maximum value of R is quite high; the results of the maximum local R test approach those of the M test as τ gets large.

9.3.6 The Q^2 Statistic for Detecting Change in Multinomial Distributions

When spatial data are available for a number of time periods, it is of interest to test the null hypothesis of no change in spatial pattern, versus the alternative that a shift in pattern occurred at a particular point in time. Srivastava and Worsley (1986) discuss how changes may be detected retrospectively in data that come from a multinomial distribution. Let $\mathbf{x}_t$ be a $1 \times (m-1)$ row vector with elements indicating the number of crimes in each of $m-1$ tracts during period t. There are m tracts in the study region, and so one region is arbitrarily omitted from the vector. For n time periods, the data may be given as an $n \times (m-1)$ matrix, $\mathbf{X}$, consisting of n of these row vectors. Srivastava and Worsley (1986) derive a likelihood ratio statistic that is asymptotically equivalent to the maximum of χ_r^2 over r. Here χ_r^2 is the usual chi-square statistic used for testing for association in the $2 \times (m-1)$ table formed by first segmenting the observations into the two sets $t = 1, 2, \ldots, r$ and $t = r+1, \ldots, n$ and then forming the two aggregate row vectors corresponding to the two sets of observations. The distribution of the test statistic, $Q^2 = \max\chi_r^2$, under the null hypothesis of no change, is given by

$$p(Q^2 > c) = 1 - F_m(c) + q_1 \sum_{r=1}^{n-2} t_r - q_2 \sum_{r=1}^{n-2} t_r^3 \tag{9.18}$$

where $f_m(c)$ and $F_m(c)$ are, respectively, the probability density and cumulative density function of chi-square random variables with m degrees of freedom. Furthermore,

$$q_1 = 2(c/\pi)^{1/2} f_m(c) \tag{9.19}$$

$$q_2 = \frac{q_1}{12}\left[\frac{(m^2-1)}{c} + c - 2m + 1\right] \tag{9.20}$$

and

$$t_r = \sqrt{1-\rho_r} \tag{9.21}$$

$$\rho_r = \left(N_r / N_r^*\right)^{1/2} \Big/ \left(N_{r+1} / N_{r+1}^*\right)^{1/2} \tag{9.22}$$

where N_r is the total number of observations in the first r rows of the table, and $N_r^* = N - N_r$, with the total number of observations equal to N.

Extramultinomial variation may be due either to situations where (a) the probabilities of falling into particular categories are themselves subject to uncertainty, or

(b) where there are correlations between successive rows of the contingency table. To model this, one first calculates

$$\hat{\sigma}_r^2 = \frac{Q - Q_r^2}{(n-2)m}; \quad n \geq 3 \tag{9.23}$$

where Q is the value of χ^2 measure of association between rows and columns for the entire $n \times (m + 1)$ table. Then define $K_r^2 = Q_r^2/\hat{\sigma}_r^2$ as the test statistic. Under the null hypothesis, K_r^2/m has an F distribution with m and η degrees of freedom, where $\eta = (n - 2)m$.

Results are shown in Table 9.7. These results were derived by omitting the last census tract from the analysis; again the results are consistent with those found previously. The most likely 'change point' is between the first quarter and the remainder of the year (p-value = 0.004); no other break-point yields a greater distinction between 'before' and 'after' patterns. The geographic pattern of burglaries during the fourth quarter is very similar to the pattern during the first three quarters ($p = 0.94$).

Once a change point has been found, it is then of interest to see whether other change points exist within either the 'before' or 'after' segments of the data. The bottom part of Table 9.7 reveals that further disaggregation of quarters 2, 3 and 4 does not uncover additional, significant change in the spatial pattern of burglaries.

9.3.7 Spatial Outliers

As we have seen, local spatial statistics may be used to pick out local regions with values that are significantly higher or lower than expected. They are defined for individual regions as a function of the value of the variable in that region, and values of the variable in nearby regions. Local statistics are designed primarily for testing hypotheses of spatial association for particular localities; the issue of multiple testing arises when one wishes to test more than one local statistic for significance. The M test applied to spatial data and the local R test were implemented with a Bonferroni adjustment. However, since there is correlation among tests of local statistics that are near to one another in space, the Bonferroni adjustment is conservative, and a more refined adjustment is desirable. The method summarised in this section addresses this issue.

Bailey and Gatrell (1995) and others have described the use of kernel-smoothing as one way to represent the spatial variability in the mean of a variable of interest. The value at any particular location is taken to be a weighted function of the values

Table 9.7 *Srivastava and Worsley's maximal chi-square*

	χ_r^2	σ_r^2	$K = Q_r^2/\sigma_r^2$	K/m	p-value
Quarter 1 vs Quarters 2, 3, 4	167.2	1.16	143.9	1.62	0.004
Quarters 1, 2 vs Quarters 3, 4	126.6	1.39	91.1	1.02	0.44
Quarters 1, 2, 3 vs Quarter 4	101.3	1.53	66.1	0.74	0.94
Quarters 2, 3 vs Quarter 4	107.3	1.13	94.8	1.07	0.38
Quarter 2 vs Quarters 3, 4	85.8	1.37	78.1	0.70	0.95

in the neighbourhood of the location, with closer locations receiving higher weights. The result is a surface portraying the regional variation in the underlying value, smoothed enough to eliminate the roughness of the image that would result if the original data were used, but not so much that underlying geographic variability is eliminated. Although these images represent a useful visual way to explore data, one often wishes to assess the significance of peaks in the surface. Attempts at such hypothesis testing have been limited to Monte Carlo simulation (e.g., Kelsall and Diggle, 1995, for an application to point data) or to more formal statistical methods that do not control properly for the likelihood of a Type I error (e.g., Bowman and Azzalini, 1997).

In this section, there is a summary of a statistical method for the detection of geographic clustering that is based upon Worsley's (1996) work on the maxima of Gaussian random fields and developed further in Rogerson (2001). The method provides a way to assess the significance of the maximum of a set of local statistics. It also may be viewed as a method that allows for the assessment of the statistical significance of a kernel-based, smoothed surface. Finally, the method is similar in concept to spatial scan statistics (e.g., Kulldorff and Nagarwalla, 1995) since, like the scan statistic, it considers many possible sub-regions and evaluates the statistical significance of the most extreme value. In addition, the method yields a calculable critical value that may be derived without resorting to Monte Carlo simulation methods.

The method assumes that the underlying data are normally distributed, and a Gaussian kernel is then used to smooth individual values and to construct local statistics. The steps involved may be described as follows:

1. Standardise the original observations so that the regional values may be considered as observations from a normal distribution with mean zero and variance one.
2. Construct local statistics z_i for each region using the standardised original observations (denoted y), and weights defined as

$$w_{ij} = \left(\sqrt{\pi}\sigma\right)^{-1} \exp\left(-d_{ij}^{\,2} \big/ 2\sigma^2\right) \tag{9.24}$$

   where d_{ij} is the distance from cell i to cell j and σ is chosen as the standard deviation of a normal distribution that matches the size of the hypothesised cluster. Then define the local statistic as

$$z_i = \sum_j w_{ij} y_j \Big/ \sqrt{\sum_j w_{ij}^2} \tag{9.25}$$

   To account for edge effects, it can be useful to add a guard area around the study region, with values for sub-regions in the guard area assigned from a standard normal distribution.
3. Find the critical value M^* such that $p(\max z_i > M^*) = \alpha$ by using that value of M^* that leaves probability $(1 + .81\sigma^2)\alpha/A$ in the tail of the standard normal distribution, where the study region has been subdivided into a grid of A square cells, each having side of unit length. Alternatively, M^* may be approximated by

$$M^* = \sqrt{-\sqrt{\pi}\ln\left(\frac{4\alpha(1+.81\sigma^2)}{A}\right)} \tag{9.26}$$

Alternative improvements to the Bonferroni adjustment are addressed in Rogerson (2002).

Figure 9.4 displays the areas where the observed number of burglaries is significantly greater than expected (where expected numbers are based upon the background population). Dots on the maps represent census tract centroids. Of interest is the degree to which the shaded regions are changing over time. Although there are no strong visual changes from one figure to the next, the results are consistent with the tests described above, since the clustering shown in Figure 9.4a (January–March) is, visually, somewhat different from Figures 9.4b–d. The clustering shown in Figures 9.4b–d occupies a greater sub-area, and the intensity of clustering (which can be determined from the scale) is stronger in these figures than it is in Figure 9.4a. This is consistent with the findings of the global, aspatial chi-square test, which found that the pattern of crime was most similar to the underlying population in the first quarter.

9.4 Summary

In this chapter, we have reviewed some recent developments in spatial statistical analysis, and their applications to crime analysis. The methods discussed here are for spatial data, and they have as their objective the detection of any deviations from expected geographic patterns. A key element of their use is to pay important attention to the definition of expectations. It is well known that patterns of crime exist, over and above their relation to background population, or to, say, the size of the male population in the young adult age groups. One approach would be to introduce other, known covariates (such as measures of socioeconomic status) in the definition of expectations. If the interest is in changes in patterns over time, the geographic patterns that held during some previous period may be used for the expectation.

The focus in this chapter on the temporal differences in geographic patterns has been one that assumes such detection is retrospective; i.e., a given set of data covering multiple time periods is searched for potential change points. When interest is in the *prospective* detection of change, the goal is to uncover any changes in spatial patterns as quickly as possible. If the time series of data describing the geographic pattern is of sufficient length, and if data on the areal location of successive observations is available, Rogerson (1997) suggests how quick detection may be carried out by combining Tango's statistic with the cumulative sum methods used in industrial process control (see also Montgomery, 1996). When the objective is similar and the data are for point locations, Rogerson and Sun (2001) demonstrate how quick, prospective detection of changes in spatial patterns may be achieved by combining the nearest neighbour statistic with cumulative sum methods.

As the development of spatial statistical analysis and spatial modelling continues to evolve, there will be a continuing need to embed the tools of spatial analysis within GIS. The emergence of packages such as *CrimeStat* (Levine and Canter, 1998) and

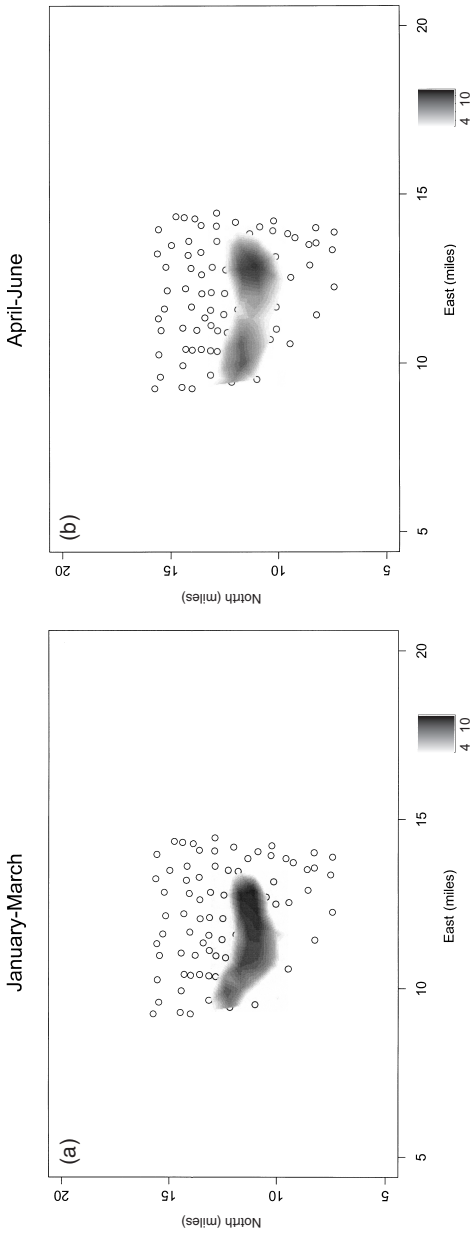

Figure 9.4 *Burglary clusters in Buffalo in (a) January–March, (b) April–June, (c) July–September and (d) October–December*

the Spatial Statistics package associated with SPLUS is an encouraging sign that these needs of spatial analysts will be met.

Modelling and Assessment of Demand-Responsive Passenger Transport Services

Mark E.T. Horn

Abstract

An investigation of public transport options was carried out for the central Gold Coast region of Queensland, Australia, using the LITRES-2 public transport modelling system. Several road-based demand-responsive passenger transport services were modelled in combination with conventional buses, trains and taxis, under a range of assumptions about future demand. The demand-responsive options included multiple-hire taxis, 'roving buses' and a 'smart-shuttle' local service between railway stations and their immediate suburban localities. These were shown to be valuable and operationally credible as complements to the conventional timetabled modes. Besides substantive conclusions of this kind, the project raised some methodological issues concerned with project planning and execution, and the capabilities and usage of a modelling system such as LITRES-2.

10.1 Introduction

The responsibility for public transport in Australia lies with state rather than with local governments; nevertheless, many local councils take an active interest in the provision of such services, working in consultation with state transport departments. Such was the case in the project described in this chapter. An Integrated Regional Transport Plan was prepared by the Queensland Transport Department for the south-eastern section of Queensland during the mid-1990s. The Integrated Plan

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

included ambitious targets for increased usage of public transport services, and the achievement of those targets was one of the considerations leading to the initiation of a Public Transport Passenger Study by the Gold Coast City Council (GCCC) in 1997. The Passenger Transport Study included the modelling project described in this chapter, and was in turn one of the main inputs to the Gold Coast City Transport Plan, a joint undertaking of the GCCC and the Queensland Departments of Transport and Main Roads (GCCC, 1998).

The main task of the Gold Coast modelling project was to assess the viability of several proposed road-based demand-responsive transport modes, which were envisaged as supplements to anticipated bus, rail and taxi services in the near and medium-term future: that is (approximately) the period 2000–2010. The work was carried out by the Commonwealth Scientific and Industrial Research Organisation (CSIRO), in collaboration with Booz Allen and Hamilton (BAH). BAH's main role was to supply estimates of key parameters concerned with current and forecast demand, service levels and fares. BAH subsequently also used the results of the project in formulating a wider range of recommendations for the enhancement of passenger services and infrastructure (BAH, 1998).

The main analytical tool used in the project was a specialised transport modelling system called LITRES-2, which embodies research carried out by the author and his CSIRO colleagues over several years (Horn, 2002; see also Smith, 1993; Rawling *et al.*, 1995). No proprietary GIS software was used: all data were stored in ordinary Unix files, and all data preparation was carried out using standard Unix tools, or using editing and display programs developed as adjuncts to LITRES-2. The supplementary software includes a graphical program for browsing spatial inputs (see Figures 10.5 and 10.6); there is also a graphical version of the modelling system itself, which has proved useful in demonstrating and validating the system's operation (see Figures 10.3 and 10.4). Besides the substantive issues under investigation, the project involved extension and refinement of the software, and an effort to assess the software's capabilities in practice.

Section 10.2 of this chapter surveys urban patterns in the Gold Coast, states the objectives of the project, and introduces the transport modes under investigation. Section 10.3 describes the LITRES-2 modelling system and the main categories of data involved. Section 10.4 outlines the scenarios tested in the project and the results obtained in each case. The chapter concludes in Section 10.5 with a summary of substantive conclusions from the project, a discussion of methodological issues, and an assessment of LITRES-2 in comparison with alternative modelling packages.

10.2 Project Objectives

The City of the Gold Coast comprises a stretch of Pacific seashore and estuarine hinterland commencing some 32 km south of the Brisbane central business district, and extending another 60 km south to Coolangatta on the New South Wales border. Figure 10.1 covers the more densely settled parts of the region, running 40 km from north to south between Oxenford and Coolangatta. During the past 50 years the region has evolved from a collection of small farming, fishing and holiday towns,

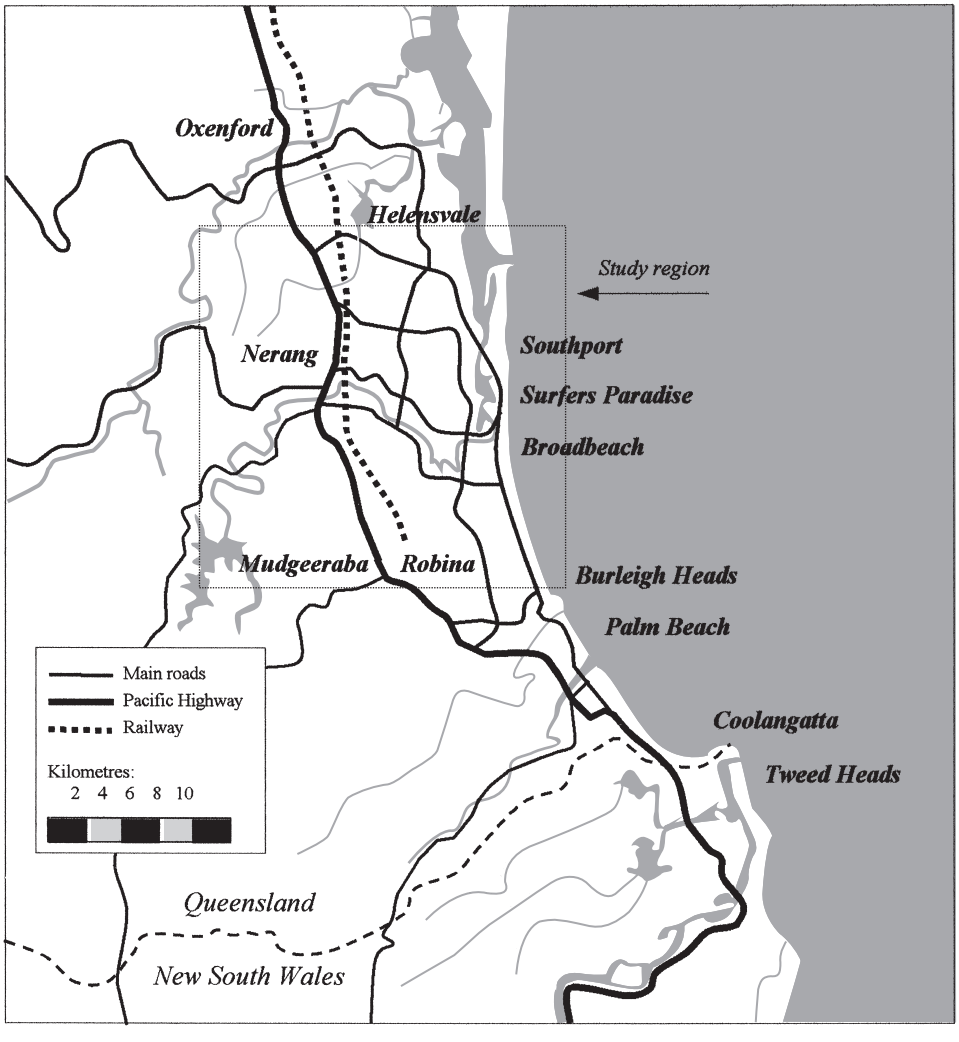

Figure 10.1 *Sketch map of the Gold Coast region*

into a leading tourist destination, favoured also as a residential location by many elderly people on account of its mild climate. Substantial numbers of residents commute to work in Brisbane, and the region now houses a diversified range of industries in its own right. It is one of the fastest-growing urban areas in Australia, with a permanent resident population already exceeding 425 000.

A chain of high-density urban development (e.g., apartment buildings, hotels and other tourism facilities) follows the main north–south coastal road, concentrating especially in the north around the regional centres of Southport and Surfers Paradise. West of the coast there are extensive low-density residential areas built on the banks of estuaries and canals. This waterfront zone is bounded on its western

edge by the Pacific Highway, which traverses regional centres at Helensvale, Nerang and Mudgeeraba, from which suburban developments extend farther westward into the foothills of the coastal ranges.

The Gold Coast City Council initiated the project with the general objectives of reducing growth in car traffic and congestion, improving accessibility within the region for residents and visitors, reducing dependence on the private car and the need for new roads and parking facilities, and improving environmental sustainability. These objectives were to be pursued by increasing the range of choice, convenience and integration of the public transport system, improving the accessibility and affordability of public transport and, in general, improving the balance between private and public modes of transport (BAH, 1998).

In preliminary discussions with the GCCC and BAH, it was decided that the analysis should concentrate on a study area measuring approximately 21 by 15 km. This covers the central part of the Gold Coast region, and includes all the main regional centres mentioned earlier. In some respects the region is well served by public transport: there are high-frequency bus services along the coastal strip, and a railway line has been built from Brisbane to Helensvale, with extensions to the south under way at the time of the project. Even so, current levels of passenger transport usage are very low (GCCC, 1998, Section 4.3), and the Gold Coast's generally dispersed settlement pattern constitutes a difficult environment in which to sustain geographically comprehensive bus or rail services.

The public transport modes covered by the project (see Table 10.1) included the existing bus network, the railway line with its projected extensions, and a variety of demand-responsive services. The attraction of the latter in the context of a region such as the Gold Coast is that they can be operated more flexibly than fixed-route services, and thus should be more effective in serving spatially dispersed urban areas. They may be envisaged as variants of conventional taxi services, designed to achieve economies of scale through the use of larger, shared vehicles. The demand-responsive modes are characterised by the use of recently developed technologies to handle communications between vehicles and a central dispatching facility, and to allow prospective travellers to make enquiries and bookings. Beyond that, their viability will often depend on the use of automated, centrally located scheduling software to obtain an effective and efficient deployment of vehicles.

Table 10.1 *Characteristics of transport modes*

Transport mode	Pickup and setdown	Advertised service	Routing
Walking	Stop to stop	–	Euclidean or Manhattan path
Bus, Rail	Stop to stop	Timetabled	Fixed
Taxi	Door to door	Free-range	Demand-responsive
TaxiMulti	Door to door	Free-range	Demand-responsive
RovingBus	Stop to stop	Free-range	Demand-responsive
SmartShuttle	Stop to stop	Timetabled, stops or zones	Demand-responsive

The main demand-responsive modes modelled in the Gold Coast project are outlined below.

- *Taxis*: single-hire, door-to-door taxi service. As with the other demand-responsive service modes, provision is made for advance bookings. The traditional 'step-in' style of taxi service was not modelled in the Gold Coast project.
- *TaxiMulti*: multiple-hire taxis guaranteeing service within prescribed travel-time standards.
- *Roving Bus*: multiple-hire services like TaxiMulti, but picking up and setting down passengers at designated stops.
- *SmartShuttle*: a bus service based on an advertised timetable but run on demand. That is, the actual route taken by a SmartShuttle bus needs to traverse only the locations for which demand has been registered, and the service can be omitted altogether on occasions when no demand is registered. The timetabled locations may be points (e.g., bus stops), or sets of points (in spatially defined zones), or a combination of the two.

10.3 Methodology

The LITRES-2 modelling system provides a fine-grained representation of demand and transport services, with particular focus on the operational characteristics of demand-responsive modes (Horn, 2002). The system's modelling architecture is outlined below, before proceeding to the data framework and modelling strategy used in the Gold Coast project.

10.3.1 Modelling Framework

LITRES-2 applies a microsimulation strategy to the representation of events and processes evolving over a given period of time (some alternative approaches are discussed at the end of this chapter). By contrast with more statistically based approaches, the parameters are all empirically based, and a formal calibration of the system is thus not required. A primary distinction between simulation and control modules (Figure 10.2) provides a clear conceptual basis for the system, and is consistent with the intended future usage of the control modules in a real-time context. In particular, the request-brokering and journey-planning modules embody algorithms that are applicable in a public transport information system, while the fleet-scheduling module comprises procedures designed to manage bookings and deployment for a fleet of demand-responsive vehicles in real time. The simulation modules embody representations of real-world processes, and are the source of the control systems' knowledge of critical real-world phenomena such as passenger requirements and vehicle movements. By contrast, the role of the control modules is to influence the simulated processes, this influence being exerted by means of messages (e.g., dispatch commands) sent to the simulation modules.

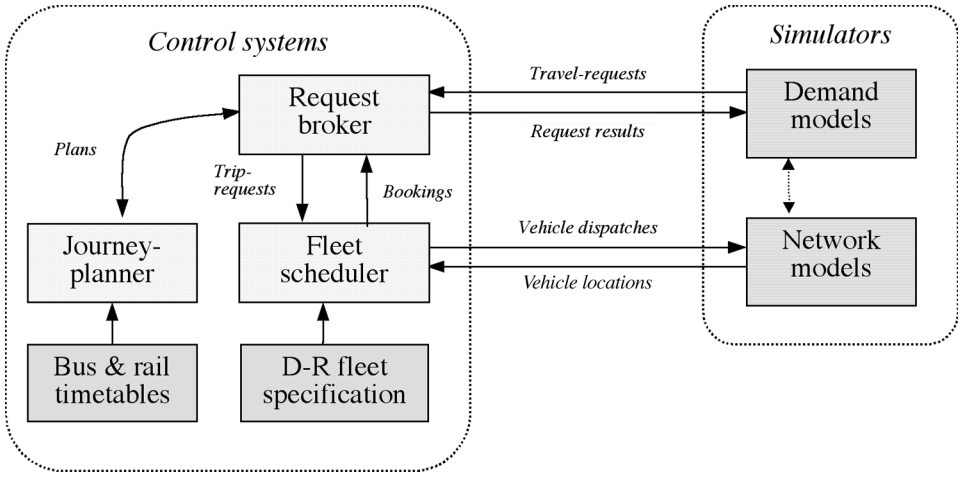

Figure 10.2 *LITRES-2 modelling framework. Reprinted from Horn, M., Multi-modal and demand-responsive passenger transport systems,* Transportation Research A, ***36****(2): 167–88. Copyright 2002, with permission from Elsevier Science*

The main simulation modules are demand simulators and a network simulator. The demand simulators convert predefined models of aggregate demand into a stream of travel-requests, which is sent to the control modules. The network simulator tracks the movements of demand-responsive vehicles through the road network, and interacts mainly with the fleet-scheduling module. Several additional simulation models (not shown in Figure 10.2) provide for the modelling of randomly occurring contingencies, such as vehicle breakdowns and delays, and passenger bookings and no-shows. The simulation models are executed in a temporal context provided by the C++Sim toolkit (Little and McCue, 1993), which ensures that timed processes evolve in a chronologically consistent time-sequence. Outside the simulation modules, the time-sequence is manifest as time-stamps on messages sent to the control modules.

Aggregate demand for passenger transport is represented as a collection of predefined demand models, each associated with a particular market segment, parameters for party size (i.e., the number of people travelling together in a given journey), and a given time period (e.g., 8:00 to 9:00 a.m.). Two types of demand model were used in the Gold Coast project. An origin–destination (OD) model is a matrix of which a given element specifies the total number of journeys from one zone to another during the period covered by the model. A source–sink (SS) model consists of an array of which a given element specifies the aggregate demand for travel from a given point to a given zone, or vice versa: such a model provides a straightforward way to represent demand associated with a major regional facility, such as a shopping complex or tourist venue, as an overlay on the more uniformly distributed patterns associated with an OD model.

The task of a demand simulator is to disaggregate a demand model in a randomised fashion, so as to generate a stream of travel-requests: each such request refers to a person (or party of people) belonging to a particular market segment, requesting travel between a given origin and a given destination point, within a given journey-envelope specifying an earliest departure and a latest arrival time. As a

typical example of the simulation techniques employed in LITRES-2, we shall consider the demand-simulation process for an element (i,j) of a given OD model. This element specifies the total number of journeys k_{ij} to be made from zone i to zone j during the period (*tlo*,*thi*) covered by the model.

In summary, there are k_{ij} travel-requests to be generated for element (i,j), consistent with the aggregate parameters mentioned above but differing from each other in a random fashion. To generate the starting-point for one such request, we refer to the bounding rectangle of zone i (i.e. the smallest rectangle enclosing all parts of the zone), with width and height w_i and h_i respectively. We use a random-number generator to obtain a pair of numbers (p,q), both in the range (0,1), and hence generate a point (x,y), with x located at $p \cdot w_i$ units from the left-hand edge and y at $q \cdot h_i$ units from the bottom of the bounding rectangle. We check that (x,y) lies within the boundaries of the zone and, if not, we obtain a new pair of random numbers and repeat the process. The same technique is used to obtain a destination point in zone j for the travel-request. The commencement-time *tstart* for the request is interpolated at random within the model period (*tlo*,*thi*); that is, given a random number r $(0 \leq r < 1)$, $tstart = tlo + r\ (thi - tlo)$. The end-time *tterm* is found by reference to walking-time and travel-delay parameters of the market segment s associated with the OD model: $tterm = tlo + wmax_s + ttmin_{ij} \cdot kmax_s$, where $wmax_s$ and $kmax_s$ are obtained by uniform random interpolation in ranges specified for market segment s, and $ttmin_{ij}$ is the shortest possible travel time by road from i to j.

10.3.2 Journey Planning

The travel-requests generated by the demand modules are passed, one by one, to a request-broker module, whose task is to plan an optimal journey that satisfies the requirements of each incoming request. A journey consists of a sequence of one or more legs; a journey-leg carried by a vehicular mode is called a trip. A single-leg journey may be walked all the way or carried by a door-to-door vehicular service (i.e., taxi or TaxiMulti). A multi-leg journey involves a sequence such as 'Walk → Bus → Train → SmartShuttle → Walk'; or more precisely, 'Leave origin-point at 10:10 a.m., walk to bus stop, catch 290A bus at 10:15, alight at Nerang at 10:25, take the train from Nerang to Robina at 10:30, alight at Robina at 10:40, take SmartShuttle at 10:45, alight at local stop at 10:50, walk to destination, arriving at 10:56 a.m.'. An example is shown in Figure 10.3.

The planning of multiple-leg journeys is carried out by a journey-planning module, an optimisation procedure embodying a branch and bound algorithm. The journey-planning process is subject to behavioural constraints specified for each market segment, such as the maximum distance that the traveller is prepared to walk at a single stretch. The availability of service is determined by timetable data, or in the case of demand-responsive modes, by reference to the fleet-scheduling module. The objective in planning a journey is to minimise the generalised cost of travel, defined as the sum of any fares, together with the imputed cost of time for the person or persons making the journey. This imputed cost is estimated using valuation factors for the various time components of the journey, namely waiting at the origin, waiting

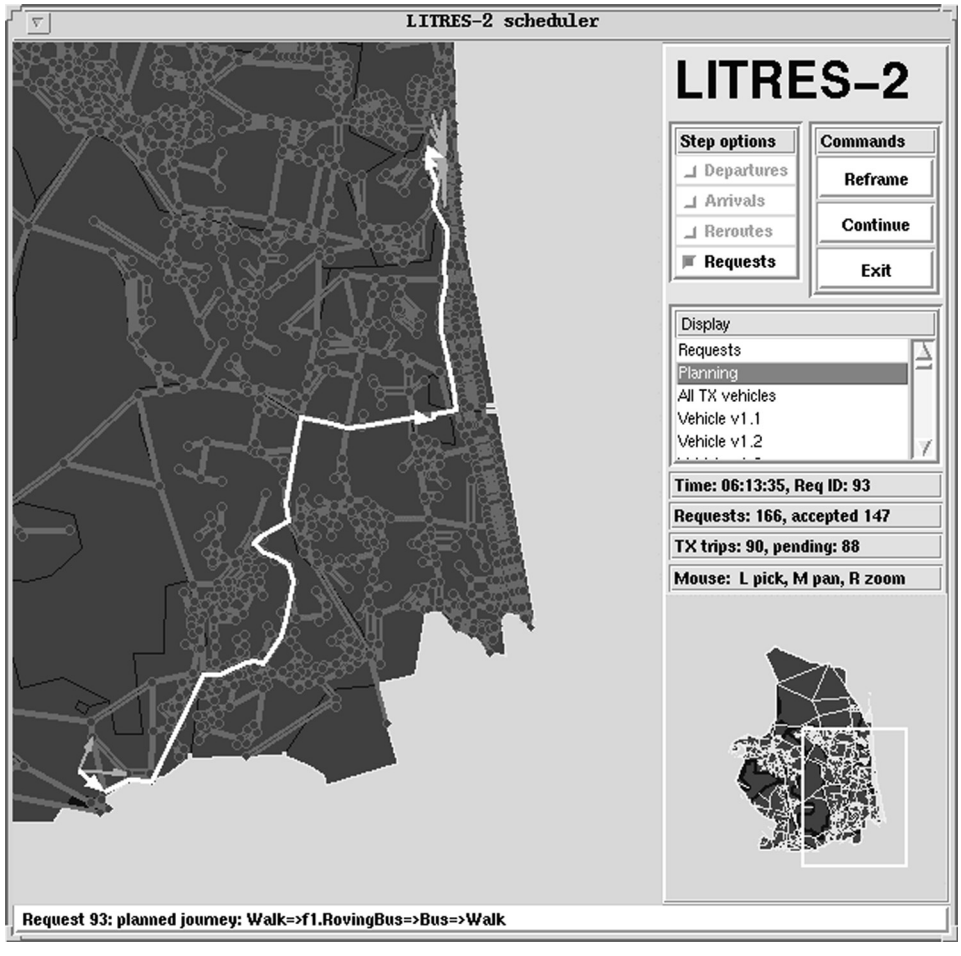

Figure 10.3 *Planning a journey*

at interchanges, walking and travelling. Travel times are estimated as follows. For a walked leg, the time is simply the length of the leg divided by the walking speed associated with the market segment associated with the traveller; while for a leg carried by a timetabled mode, the travel time is obtained from the timetable. For a leg carried by a non-timetabled mode (i.e., RovingBus, TaxiMulti or taxi), travel time is calculated by reference to the mode's service-quality standards (see Section 10.3.4 below).

10.3.3 Fleet Scheduling

The LITRES-2 fleet scheduler manages the deployment of a fleet of demand-responsive vehicles, by planning each vehicle's itinerary in response to trip-requests received over time from the request-broker. Figure 10.4 shows one such itinerary,

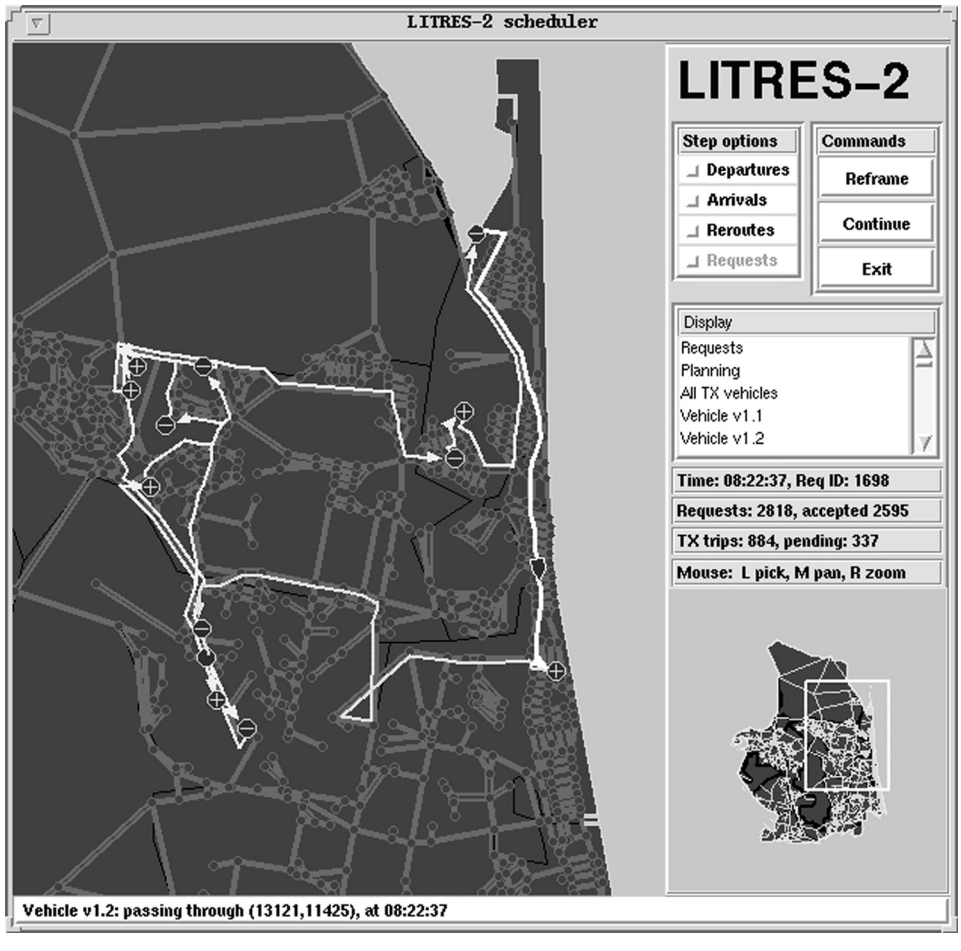

Figure 10.4 *Itinerary of a demand-responsive vehicle*

including the vehicle's current location and its planned pickup and setdown points ('+' and '–' respectively). A trip-request refers to a particular transport mode, and has explicit time-windows specifying early and late limits for departure from the start and arrival at the end of the trip: these limits are defined by the journey-planning module by reference to the service-quality standards pertaining to the mode. The overall objective when choosing an implementation for a trip is to produce favourable operational outcomes for the fleet operator (e.g. by minimising fuel costs). The finding of shortest-time paths between each successive pair of stops in a vehicle's itinerary is a scheduling sub-task, and is discussed below in connection with the road network model. A distinction is made between the routes and timings planned by the scheduling module, and on the other hand the actual trajectory of a vehicle as it moves through the road network. In particular, the fleet scheduler sends dispatch

commands (e.g., 'Cab 99, proceed at 10:10 to location (x,y)') to the network simulation module, which simulates the movement of each vehicle through the road network, and reports back to the scheduler when a vehicle arrives at a pickup or setdown point or is affected by an incident such as a breakdown.

10.3.4 Inputs and Outputs

The Gold Coast project was planned as a series of scenarios, each specified as a set of inputs to a run of LITRES-2. In particular, a Base scenario provided a check of LITRES-2's predictions against current conditions, while other scenarios were constructed as variants of the Base scenario, so as to investigate the performance of various postulated sets of passenger service options over different levels of demand. A LITRES-2 scenario is defined by input data of the following kinds.

- A model of the road network is used as a basis for estimating travel times, and for routing vehicles in the fleet-scheduling and network simulation modules. The network model comprises a set of nodes and a set of directed links connecting the nodes, together with link speeds and distances. This is a format used in many commercially available GIS, but the intensive use of network calculations has required special attention to the algorithms and storage strategies used for network calculations. For the Gold Coast project, a single speed was defined for each link and path durations were precalculated: subsequent extensions allow for fluctuation in link speeds over the course of a day. The techniques used to find shortest-time paths and their timings are variants of Dijkstra's label-setting algorithm, with allowance for off-network travel between the (Euclidean) starting point of a path and a nearby network node, and vice versa at the end of the path.
- A division of the study region into polygonally bounded small-area units called zones provides spatial reference for demand models. Zonal decompositions are used also as bases for defining fare structures and zone-based SmartShuttle services.
- Behavioural characteristics of travellers are defined in market segments. A market segment defines travel parameters for a particular set of travellers, such as elderly people. These parameters include a set of acceptable modes, valuations of time pertaining to generalised costs, a walking speed and a maximum walking distance. In addition, there are parameters for acceptable travel duration, and for the 'notice period' between the time when travel is requested and when it is to take place.
- As indicated earlier, aggregate demand is represented in the form of origin–destination (OD) and source–sink (SS) models, each of which is associated with a market segment, party-size parameters, and a time-range.
- Specifications of timetabled services include locations of the points served (e.g., bus stops and railways stations), and service routes (sequences of points). The specifications for each route include a transport mode (e.g., bus), a fare structure, and a timetable.
- Demand-responsive services are defined by specifying the vehicles in a demand-responsive fleet or fleets. Each vehicle has a passenger-carrying capacity; a list of

the modes offered; and an operating shift, specified as the period when the vehicle is in service, with a corresponding pair of terminal points. Associated with each demand-responsive mode are parameters specifying a fare structure, pickup and setdown times, and service quality. The service-quality standards comprise a waiting-time limit and a travel factor, the latter specifying an upper limit on the ratio of actual to minimum possible travel time: this ratio is one for single-hire taxi, and more than one in the case of the multiple-hire modes.

The main outputs from LITRES-2 are outlined below. The volume of these outputs makes them somewhat unwieldy in their raw form, and their interpretation in practice requires considerable care in the selection and examination of a smaller number of key indicators (for this purpose the outputs are now provided in a coded format, to facilitate transfer to spreadsheets).

- *Travel statistics* include the total numbers of passengers carried and journey-legs completed, with average travel times, distances and costs, for the whole simulation period and for nominated time-intervals. These statistics are broken down by leg-sequence, by market segment, and by transport mode.
- *Scheduling statistics* include the total numbers of passengers carried, with mean trip time and distance per passenger, for the demand responsive fleet(s), for each mode, and for each vehicle. As with the travel statistics, statistics are aggregated for the whole simulation period and also over nominated time-intervals. They include measures of efficiency (e.g., the ratio of travel time to the least possible travel time, relevant in the case of multiple hire modes) and of vehicle occupancy (i.e., the average number of passengers on board at any given time).
- *Route-usage statistics* include the total numbers of passengers carried on each timetabled mode, and the totals for each route and each service run along each route, with average trip times and occupancy ratios. Again, statistics are aggregated for the whole simulation period and for nominated time-intervals.

10.4 The Case Study

The Base and other scenarios were planned in advance, and then adjusted and extended in the course of the project. The most demanding and time-consuming task was to fine-tune the considerable range of data inputs in the Base scenario, so as to obtain a credible match between model outputs and known conditions (Horn *et al.*, 1998). The simulations themselves incurred little real delay: the run time for each scenario was generally between 20 to 40 minutes, on a Sun UltraSparc workstation.

10.4.1 The Base Scenario

An eclectic approach was required in the preparation of the 'Base scenario', involving the use of sources whose applicability to the project was often somewhat

indirect. Outlined below are the main sources for the data categories described earlier, and the adjustments applied to them in preparing the Base scenario.

The Road Network

The GCCC provided a road network data set covering nearly all roads in the region, and comprising 4166 nodes and 9472 links. This was somewhat excessive in terms of the computational resources available; furthermore, it included a great deal of geometric detail which would be irrelevant to the analysis carried out by LITRES-2. The network was therefore reduced in size through the application of a filtering program, followed by manual correction of a few remaining anomalies. The filtering program was developed especially for this purpose. It removed 'superfluous' dead-end links (i.e., each link to a node with no other links inward or outward), and 'superfluous' intermediate nodes (i.e., each node with exactly one inward and one outward link). Aggregate distances were preserved in this process (e.g., where a chain of links representing a curved section of road was reduced to a single link). The reduced network comprises 1686 nodes and 4515 links, and is illustrated in Figure 10.5.

Link speeds were defined initially by applying speed limits corresponding with the road classifications provided with the network. These speeds were then systematically scaled down in the light of a preliminary simulation of taxi system performance, and ground speed checks carried out by BAH. For off-network vehicular travel, a uniform speed of 25 km per hour was assumed.

Zones

A zonal division of the study region was needed to provide spatial reference for bus fares and demand models. The zones were defined as those used by the Surfside Bus Company in determining fares, with unpopulated areas removed. These excisions – mainly in the estuarine parts of the region – were made in order to minimise distortions in the representation of demand, which is assumed within LITRES-2 to be distributed uniformly within each zone.

Market Segments

BAH identified six market segments as a basis for modelling demand. The market segments may be characterised informally as follows:

- *Mainstream*: regular users of public transport when service is readily available.
- *Captive old and captive young*: people who have no real alternative to public transport.
- *Tourists*: tourists who choose to use public transport.
- *Car-oriented*: people who currently travel by car but may decide to switch to public transport if service of sufficiently high quality is available.
- *Rail commuters*: people who live within the corridor served by the railway and its planned extensions, and are likely to commute by train to workplaces in Brisbane.

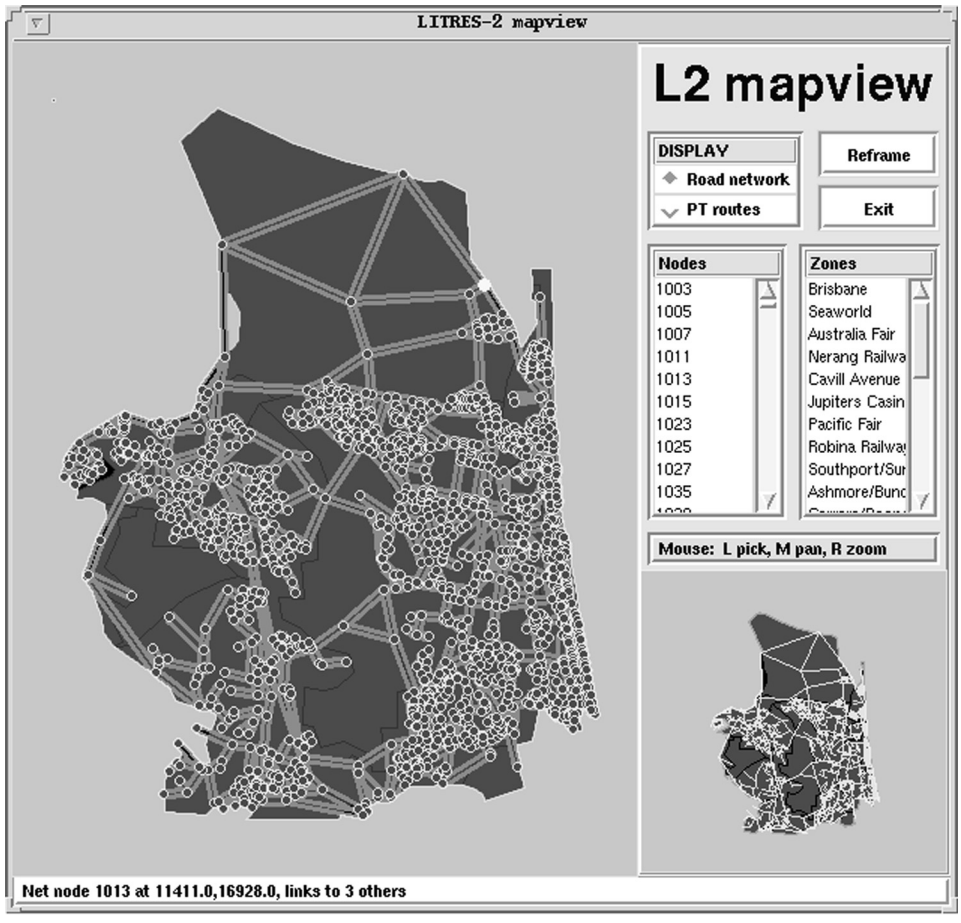

Figure 10.5 *The road network*

Demand Models

Estimates of current demand were obtained from a variety of sources (BAH, 1998). Demand specifically associated with regional attractors (e.g., shopping malls, casinos and funfairs) was modelled in the form of source–sink models, using estimates from economic studies of these facilities. Other demand was modelled in several series of origin–destination matrices, specified (as for the source–sink models) at hourly intervals over a 24-hour period (notionally a weekday). These OD series were compiled by GCCC staff from the Surfside Bus Company's fare-collection data, Queensland Rail passenger data, and estimates of private car journeys from an earlier study in that region. The Base demand amounted to 21 148 travel-requests (31 722 travellers) during a 24-hour period. In temporal terms the patterns of demand were generally similar to those seen in other metropolitan areas, but with smaller peaks around the start and end of the conventional working day, and with a continuation

of activity into the evening (or the early morning, in some of the entertainment districts).

Timetabled Transport Services

The geographic locations of bus stops and railway stations were digitised, and a small proportion of them were designated as interchange points for transfer on multi-leg journeys (this restriction proved to be unnecessary, since subsequent testing yielded very similar results with transfer allowed at every bus stop). The published timetables were transcribed and then elaborated, as follows. First, each route was defined as a bi-directional pair (e.g. an advertised north–south route 290 yielded two routes, 290N and 290S); second, variant routes implied by the timetables (e.g., with skip-stop service during peak periods) were generated explicitly; third, arrival times at stops without explicitly advertised times were interpolated in proportion to distances along the routes; and fourth, services on the projected extension of the railway line were extrapolated from existing timetables. Figure 10.6 shows a snapshot of the graphical browser, with a list of the routes connecting a designated pair of bus stops shown in the right-hand panel, and with one of those routes highlighted on the main map display window.

Demand-Responsive Services

About 220 taxis currently operate in the wider Gold Coast region, under the aegis of Regent Taxis Limited. Some of the drivers specialise in traditional 'step-in' service from cab-ranks, and some – with larger vehicles – specialise in multiple-hire work from specially designated cab-ranks; most drivers, however, rely mainly on Regent's central dispatching centre for most of their work (Horn *et al.*, 1999). The simulation involved a taxi fleet about half the size of the actual Regent fleet, reflecting the approximate proportion of taxi activity encompassed by the study region. As with the timetabled modes, service details and fares for taxis were matched to existing conditions as closely as possible. The new demand-responsive services (TaxiMulti, RovingBus and SmartShuttle) were conceived as intermediate in terms of service quality and fares between taxis and buses. The fare structure in each case was defined as a base fare and a distance-based component, with group discounts for parties of two or more people.

10.4.2 Future Transport Scenarios

Low, medium and high demand scenarios were constructed by scaling up demand from the Base scenario to represent (notionally) the range of conditions possible in the study region within the next decade. Different scaling factors were applied to the various demand components, yielding estimates of 42 291, 53 997 and 65 799 passengers respectively for the three scenarios, compared with 31 722 in the Base scenario. To avoid excessive optimism regarding the prospects for new transport services, the

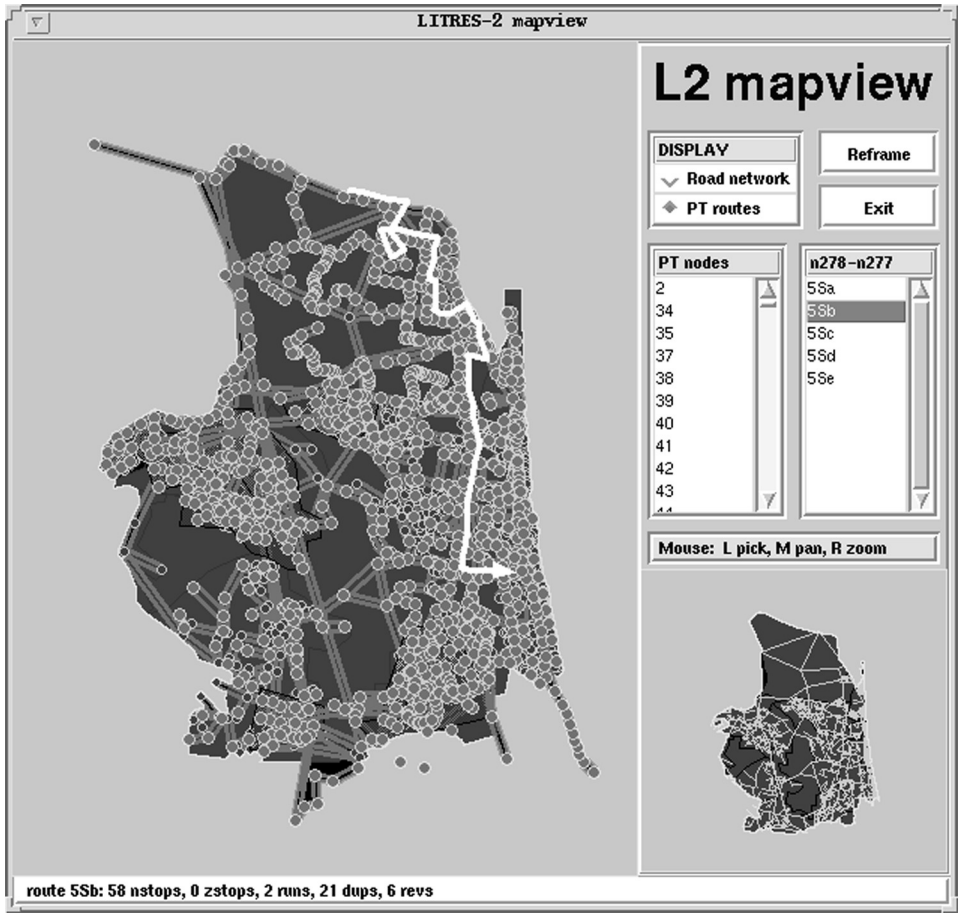

Figure 10.6 *Bus and rail routes*

analysis focused mainly on the *low* demand scenario. A more extensive study might well encompass a wider range of possibilities in this respect, for example with geographical differentiation in the rates of growth in demand.

Fixed-Route Services

The assumptions in the future scenarios regarding rail, bus and taxi services were the same as those in the Base scenario. As might be expected, the simulations indicated that bus usage would increase substantially under increasing demand. In fact, there is probably scope for augmentation of bus services and routes in some areas: an investigation of such possibilities was beyond the scope of the project, but – with the Base scenario already available – would require little additional effort.

Multiple-Hire Services

Demand-responsive services were modelled in each scenario as a single fleet of vehicles, with each vehicle dedicated to a single mode. The low, medium and high demand scenarios included 40, 60 and 80 mini-buses respectively, divided equally between TaxiMulti and RovingBus service. The simulations showed these vehicles carrying several passengers for much of the time, although they were rarely close to their maximum carrying capacity (Figure 10.7). High occupancy ratios are obviously desirable from a fleet operator's point of view, but saturation of fleet capacity prevents additional passengers from using the fleet; thus if the fleet were larger, it might be chosen by passengers who currently use other modes. Consequently, the simulated patronage of multiple-hire services in the main scenarios does not fully reflect the

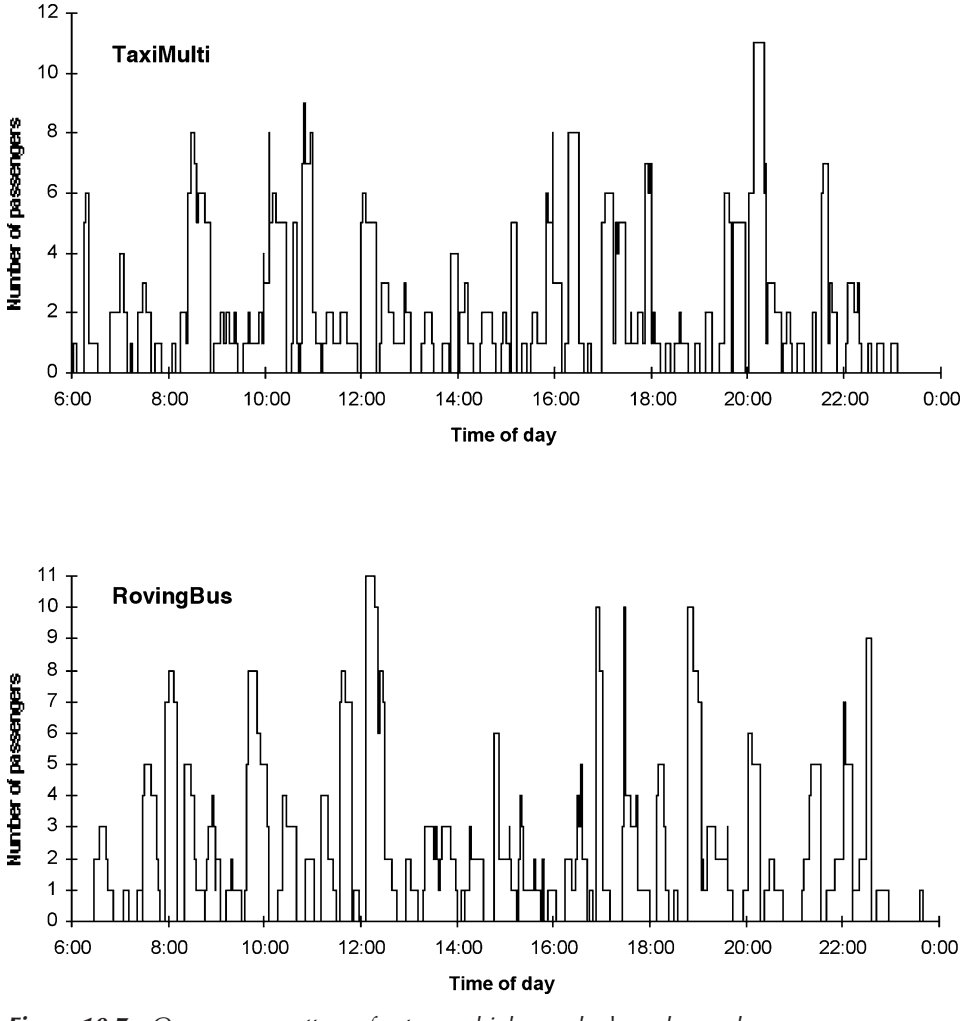

Figure 10.7 *Occupancy patterns for two vehicles under* low *demand*

attractiveness of these services to the travelling public, a deduction that was borne out by supplementary simulations with larger fleet sizes. More generally, the 'carrying capacity' of a fleet is a somewhat ambiguous concept, since 'heavily loaded' or 'saturated' conditions are characterised by a gradual decline – rather than a complete disappearance – in the additional trips that can be accepted under marginal increases in demand: the limit, where no further passengers can be accepted, is arbitrary, fluctuating over time and sensitive to arbitrary variations in current fleet deployment. A reasonably precise estimate of fleet capacity may be obtained, however, by allowing a progressive stretching of service standards under saturated conditions (Horn *et al.*, 1999; Horn, 2002).

Results from the *low* demand scenario (Figure 10.8) indicate that the TaxiMulti and RovingBus services should generate gross earnings per vehicle greater than those obtainable from single-hire taxis, and carry roughly twice as many passengers, provided that fleet sizes are matched to demand as discussed above. These and other results also suggest that trips on multiple-hire modes are on average comparatively long. The trip-makers highlighted here presumably are those who wish to travel between extremities of the region, and are deterred from using alternative services by their unavailability or excessive slowness; thus the multiple-hire modes may be particularly useful in spatially dispersed conditions.

Analyses of usage for RovingBus and TaxiMulti suggested how these modes might be managed in practice. For example, given the temporal patterns illustrated in Figure

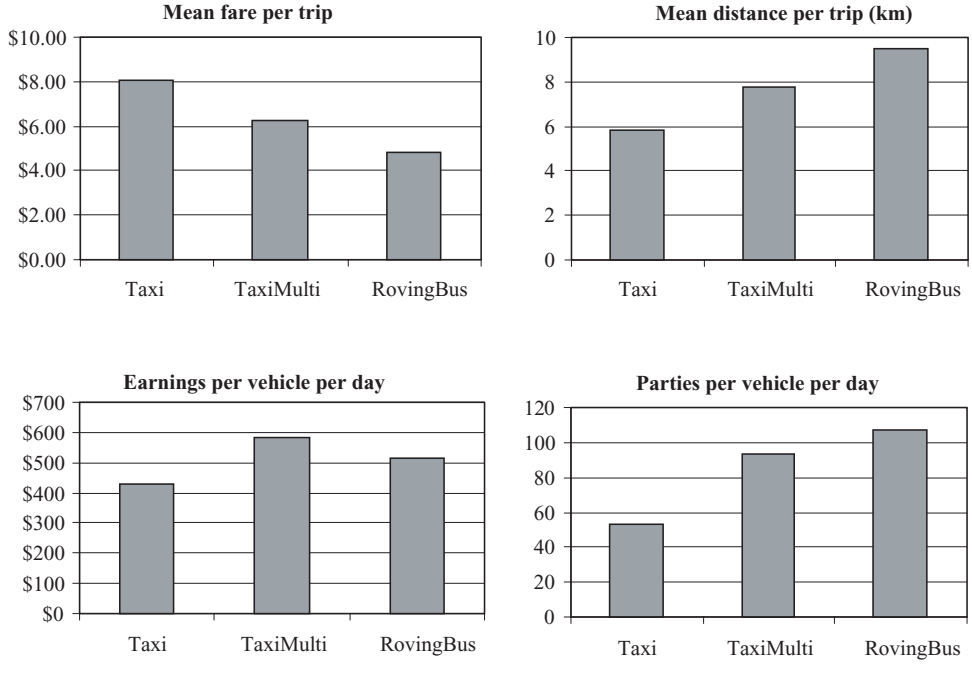

Figure 10.8 *Total trips on demand-responsive modes under* low *demand*

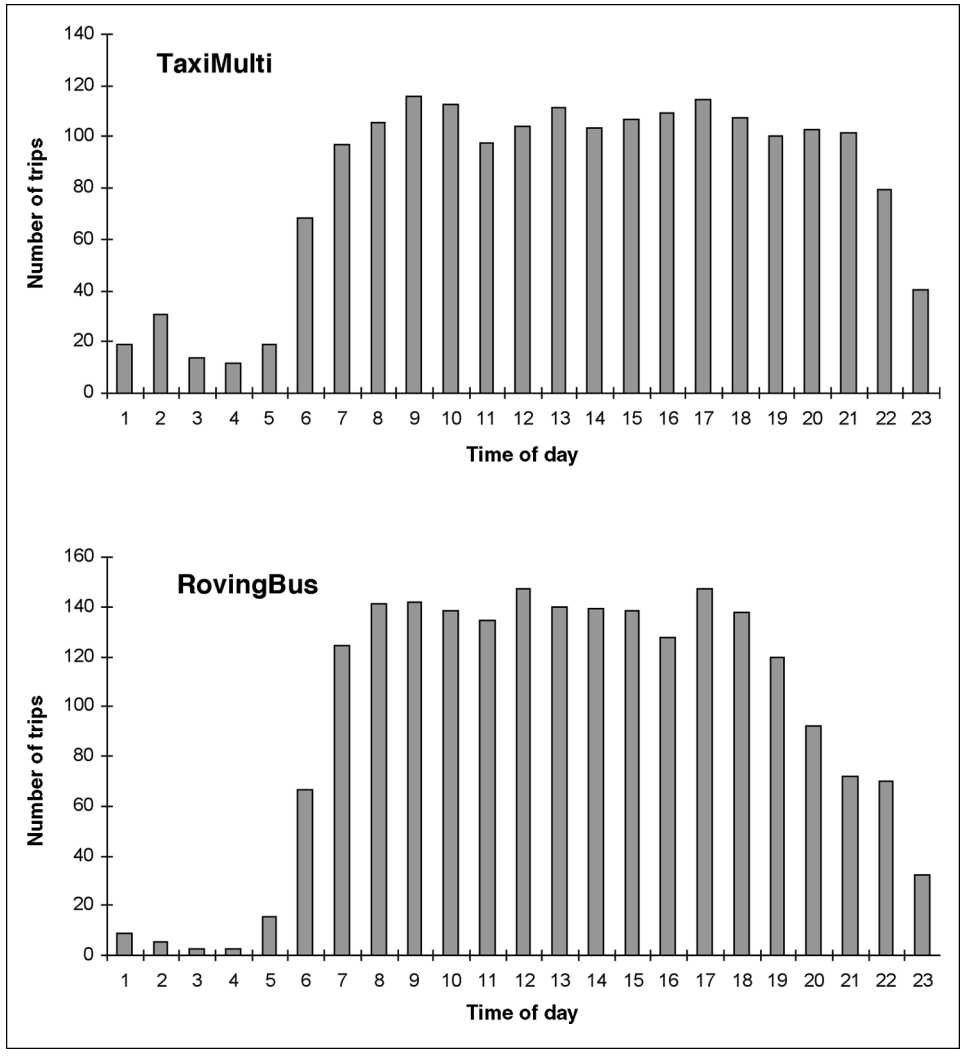

Figure 10.9 *Trips by TaxiMulti and RovingBus services under* low *demand*

10.9, an adequate service might be maintained by replacing RovingBus with TaxiMulti late at night, the latter perhaps run with a fleet reduced to one-third its daytime size. It may be observed also that although each vehicle was assumed to be able to accommodate 11 passengers in the low, medium and high demand scenarios, the actual occupancies rarely reached this level (Figure 10.7). A separate series of tests indicated that with capacity reduced to seven passengers per vehicle, the reductions in fleet performance and fleet-wide carrying capacity would be fairly small (of course this ignores less tangible considerations such as the sense of crowding that passengers would experience under pervasively nearly full conditions).

SmartShuttle

As indicated earlier, a SmartShuttle service is advertised in the form of a timetable, but the actual routes taken by vehicles are defined on demand. A 'feeder' role was envisaged for SmartShuttle in the Gold Coast, with vehicles plying between local railway stations and their residential catchment areas. The following account concerns a series of tests focused on the new Nerang railway station and its catchment area, which was divided into five SmartShuttle zones. One SmartShuttle vehicle was provided per zone, and timetables were designed in coordination with the railway timetable so that (notionally) each vehicle could tour its zone between visits of the mainline train, generally at 30-minute intervals. For comparison, an approximately equivalent set of fixed-route bus services was designed for the same area.

Two series of simulations were run to test these arrangements, one with SmartShuttle feeders and one with buses, the level of service in each case being held constant while the 'rail commuter' component of demand was scaled up incrementally from the Base scenario. These simulations showed that the SmartShuttle vehicles could serve nearly all prospective passengers under Base scenario assumptions while satisfying the journey-planning conditions discussed in Section 10.3 above; by contrast, fixed-route buses would leave about 8% of travellers beyond walking distance. With multipliers of 100–500% applied to base commuter demand, the proportion of requests that could be feasibly satisfied by SmartShuttle would decline steadily from 100% to 85%; the simulations suggested that the corresponding proportion for buses would be approximately constant across the same range of demand. On closer examination, however, it became apparent that the latter figure significantly overstated the performance of buses, which LITRES-2 currently models in less detail than demand-responsive vehicles; in particular, no allowance is made for passenger-capacity constraints or for delays incurred when picking up and setting down passengers. Thus on local routes and under moderate demand, small buses running in SmartShuttle mode would almost certainly be more convenient for travellers than the same vehicles run in conventional fixed-route mode.

Mode Usage by Market Segment

Figure 10.10 shows aggregate mode choice results for each market segment in the *low* demand scenario. In summary, *car-converts* are relatively heavy taxi users because they place high value on their own time. *Tourists* are heavy bus users, their activities being concentrated in the coastal strip where the bus service is frequent and convenient. The *captive old* are willing to walk only short distances, and so are the heaviest users of TaxiMulti.

10.5 Conclusions

10.5.1 Effectiveness of Transport Services

The effectiveness of the new demand-responsive service modes as demonstrated in the project has led to a recommendation that they be implemented on a pilot basis

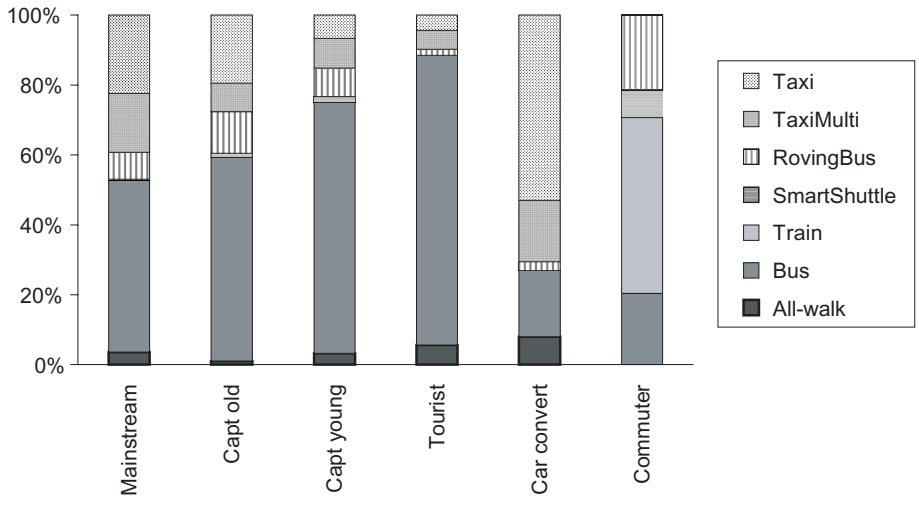

Figure 10.10 *Mode usage by market segment under* low *demand*

(GCCC, 1998, Section 5). The recommendation has not so far been implemented, presumably due to reluctance on the part of the Queensland Government to commit the substantial resources that would be required. In general, however, the project confirmed the benefits of a coordinated, multi-modal array of transport services. Those benefits were apparent in the way that the various modes complemented each other with respect to service quality, geographic coverage and market segments: even RovingBus and taxi, which are closely related in logistical terms, were mutually competitive only to a marginal extent.

Multiple hiring of vehicles in demand-responsive fleets was shown to be effective in terms of service quality, fleet economics and market share. It appears that TaxiMulti and RovingBus may best cater to longer journey-legs for which bus services are either unavailable or too slow to meet travellers' requirements, while taxis are more suited to shorter legs. SmartShuttle was investigated only to a limited extent, but as a feeder to railway stations and other regional interchanges, this mode appears to have advantages over a conventional scheduled bus service.

A critical requirement for TaxiMulti and RovingBus is the achievement of reasonably high occupancies in order to obtain substantial economies of scale over conventional taxi services. Occupancy rates in turn are directly sensitive to the travel factor, which defines the maximum allowable deviation from direct routing (see Section 10.3.4 above, and Rawling *et al.*, 1995). Increasing the travel factor above the value of 130% assumed in the Gold Coast project would provide broader time-windows and hence greater flexibility for scheduling, making it easier to achieve high vehicle occupancies. This would be a desirable outcome, but a reduction in fares might then be needed to compensate travellers for longer travelling times.

Taxi services were not a major concern in the Gold Coast project reported here, but were investigated more thoroughly in a related study that concentrated on the Regent taxi fleet over its full geographical range (Horn *et al.*, 1999). That study was

concerned mainly with operational issues such as the balance between phone bookings and traditional 'step-in' services at cab-ranks, the impact of advance notice on carrying capacity and waiting times, and temporal staggering of shift changeovers. The availability of historical booking records made data preparation much easier than in the wider-ranging project reported here; the methodology was also more straightforward, since the focus was on individual initiatives and changes, rather than broader combinations of assumptions and proposals like those discussed elsewhere in this chapter.

10.5.2 Methodological Considerations

Data Preparation and Validation

For CSIRO and its collaborators the most difficult challenges posed by the Gold Coast project were those arising in the preparation of a credible Base scenario, especially with respect to data items – market-segment parameters, demand models, and road speeds – defining behavioural characteristics of transport system users. Here there was no alternative but to make the most of whatever data sources were available, often in an indirect way or by reference to prior experience in other locations. The empirical foundation of the project cannot therefore be regarded as definitive, and the conclusions are best seen as indicative rather than strictly predictive. Even so, detailed examination of Base scenario outcomes, and sensitivity analyses of key variables (Horn *et al*., 1998), showed a satisfying conformity with known aspects of transport system operation.

Apart from these substantive concerns, the effort involved in data preparation constituted a large proportion of that invested in the project as a whole, and it seems clear that an effort of this kind might be difficult to justify in a once-off consultancy exercise. Conversely, however, the project suggests a framework within which public authorities might accumulate information on transport demand and system usage, the long-term benefits in this respect lying in the ease with which new proposals can be investigated once a suitable database is established.

Investigative Strategy

Some other methodological issues were concerned with the relations between modelling – the central task of the project – and other phases of the planning process. In a naive view, design or planning may be regarded as proceeding in a linear sequence from the enunciation of a problem (e.g., as a set of objectives and conditions), to the formulation of a proposal (e.g., by proposing new transport services), to assessing the implications of that proposal (e.g., by means of a LITRES-2 simulation), and then to evaluating those implications (e.g., by interpreting simulation outcomes). However, in any substantial planning exercise it can be expected that there will be backtrackings or feedback cycles to complicate a simple sequence like this, and it must be admitted that the extent of these complications was underestimated when the Gold Coast project was planned. The lesson here is that modelling should not be

treated as an isolated task: although the broad outlines of transport options could be sketched in advance, the development of those options as credible proposals was intertwined with the modelling process and with the interpretation of its outputs.

For example, the main simulations of multiple-hire demand-responsive services involved the testing of a small number of proposals, each comprising specifications of fleet size, the carrying capacities of vehicles, the fares to be charged, service-quality standards, and so on. In fact these proposals themselves emerged from a preliminary series of simulation runs, in which a range of plausible values was explored for each of the main parameters. There was a similarly close relationship between design and simulation in the tests of SmartShuttle feeder services, which involved the additional design task of formulating 'benchmark' bus services for comparative purposes.

A further point concerns the criteria applied in assessing simulation outcomes. Besides convenience, accessibility, and so on, it emerged during the course of the project that the clients believed that new passenger services should be able to operate with little or no public subsidy. The desire for operationally attractive performance entailed considerable effort in tuning the various proposals, and led to the exploration of demand-responsive services on a smaller scale than might have been undertaken otherwise. In retrospect, the rationale for this approach seems questionable, given the emphasis elsewhere on the benefits of consistency and integration in the provision of transport services. Operational viability is certainly a significant planning consideration, but to require that demand-responsive services should be fully self-supporting could prejudice their availability at the lower end of the socioeconomic spectrum. It would be unfortunate indeed if an effort to modernise transport services were to involve the relegation of traditional fixed-route modes to a second-class or 'safety-net' role.

Modelling Tools

Experience in the Gold Coast project shows that effective usage of LITRES-2 requires a considerable level of interpretive intelligence, as indeed with any modelling system of comparable scope. This is illustrated by the counter-intuitive results encountered in the SmartShuttle tests, which highlighted an anomaly in the level of detail applied to fixed-schedule as opposed to demand-responsive vehicles (see Section 10.4 above). The anomaly can be removed by applying the same operational constraints and detailed simulation to buses as to demand-responsive vehicles, and further attention might be given also to the system's representation of passenger behaviour (Horn, 2000). In addition, an interface between LITRES-2 and a GIS might facilitate the preparation of input data and the analysis of modelling outputs.

There appears to be no immediate prospect of overcoming LITRES-2's reliance on external estimates of passenger transport demand (Horn, 2002). In this respect it is interesting to contrast the microsimulation approach adopted in LITRES-2 (see also Tong and Wong, 1999), with network-equilibrium models such as EMME/2, in which probabilistic methods are used to estimate the distribution of *all* journeys, including those made by private car (Spiess and Florian, 1989). From a planning perspective, the main differences between the two approaches have to do with granularity and scope: where the equilibrium models are coarse-grained and comprehensive,

microsimulation is typically fine-grained and specialised (consider for example the practical difficulties attending a microsimulation of all road traffic).

It is interesting also to consider the use of GIS buffering capabilities in estimating 'catchment areas' and latent demand in the vicinity of transport routes, bus stops, railways stations and so on. This is clearly pertinent to analyses concerned with accessibility, especially where bus or rail routes are to be planned in conformity with official standards (e.g. maximum walking distances to bus stops). But accessibility by itself must be reckoned a weak indicator of transport system quality, since it is concerned merely with identifying the transport services that are physically available to people in a given area, rather than the services that those people are likely to use in practice. This criticism applies even to some interesting recent research involving the generalisation of temporal and operational aspects of accessibility (O'Sullivan *et al.*, 2000).

The foregoing discussion has highlighted some strengths and weaknesses of LITRES-2 in the context of projects such as the one described in this chapter. In summary, LITRES-2 emerges as a very suitable means for assessing passenger transport operations and performance, with unique capabilities with respect to demand-responsive services. Considerable effort must be devoted to data collection and validation; nevertheless, once that investment is made, it is possible to explore a wide range of passenger transport planning options, to a level of detail that is not available elsewhere.

The South and West Yorkshire Strategic Land-use/ Transportation Model

David Simmonds and Andy Skinner

Abstract

A major multi-modal transport study is currently being carried out in South and West Yorkshire. This chapter outlines the land-use/transport/economic modelling system that has been developed for the study. This system is being used at the strategic level to forecast future land uses and travel demands, and to examine the impact of alternative transport and development plans.

11.1 Introduction and Client Needs

The South and West Yorkshire Multi-Modal Study (SWYMMS) is one of a series of studies which were proposed in *A New Deal for Trunk Roads in England*, published by the Department for Transport in July 1998 (Department for Transport, 1998). The overall aims of the study are to make recommendations for:

- an integrated and sustainable plan for the strategic road, rail and water networks in the study area; and
- a plan of specific interventions to address the most urgent key strategic problems in the study area through to 2021.

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

The study is required to address the Government's aims for transport, which refer to economy, accessibility, safety, integration and environment. It is also required to address a set of study-specific objectives, which are

- to reduce congestion on the motorways and A1;
- to re-establish the primary role of the trunk network for strategic traffic flows;
- to facilitate sustainable economic regeneration of depressed areas, especially the Objective 1 area of South Yorkshire and the Objective 2 area of West Yorkshire; and
- to sustain economic growth in other parts of the study area.

At the time of writing,[1] the study, which is being carried out for the Government Office for Yorkshire and the Humber, is still ongoing. Further details of the team, the work and the findings of the study can be found at www.swymms.org.

At an early stage in the development of the study, it was decided that it would be necessary to use both a strategic model and a detailed model in the analysis of transport options. The need to use both reflects the fact that with present technology (in terms of modelling methods and computing power) transport planners are forced to choose between:

- models which allow detailed representation of the origins and destinations of travel (zone system) and of the transport network, but represent only a few of the choices which households and businesses make in response to changing travel conditions; and
- models which represent more of the choices and linkages between choices, and hence are more appropriate to forecasting reactions to change, but which incorporate much less details about the spatial system and the transport network.

The study-specific requirements imply that it is necessary to study not only the impacts of transport change on transport use, but also the interactions between transport change and local economic performance. It therefore needs to examine how demand for transport is affected by land-use changes and how changes in transport may affect land use – with particular reference to impacts on economic performance. The consideration of transport must take account of both planned interventions and other changes such as worsening congestion.

In order to examine these changes and their linkages systematically, particularly to compare the consequences of different strategies, it was recognised that a strategic land-use/transport model was required, i.e. a model considering a wide range of responses to change with relatively little spatial detail, and that this should be used as the main tool in developing the proposed strategy. At the same time, it was also necessary to use more conventional, detailed models to examine alternative changes to the transport infrastructure in the process of developing the recommended *plan* of interventions within the preferred strategy. To ensure maximum consistency

[1] July 2002.

between the two levels, the outputs from the strategic model are used as a way of generating the levels of travel demand which are assumed in the detailed model.

In the remainder of this chapter, we explain the components and structure of the strategic transport and land-use/economic models in Sections 11.3 and 11.4 respectively and briefly recognise the interaction between them in Section 11.5. Section 11.6 demonstrates how the model is used for testing particular policies. We begin, however, with an explanation of the overall design of the model.

11.2 Model Design and Application

11.2.1 Scope of the Model

The strategic model draws heavily on the study team's previous experience with a number of similar models developed since 1995 (see, for example, Copley *et al.*, 2000; Simmonds and Skinner, 2001). The approach adopted is that of a linked model system which brings together distinct transport and land-use/economic models. The basis of the approach is that the land-use/economic model generates the activities (and in some cases the interactions between activities) which generate the demand for transport; and that the transport model represents the interaction between demand and supply in transport, and generates information about the ease or difficulty of travel which influences subsequent land-use and economic change.

A significant advantage of this approach is that because the land-use/economic and transport models remain distinct entities, it is very easy to run each one on its own. This helps in the development stage, where to a considerable extent the two models can be developed in parallel. It is also useful in the application stage: the transport model can be used on its own to test the transport impacts of different alternatives under common land-use forecasts, and the land-use/economic model can be run to test (for example) the land-use impacts of different economic scenarios assuming no change in transport conditions.

The transport model was implemented using MVA's START package (Roberts and Simmonds, 1997). The land-use/economic model was implemented using DSC's DELTA package (see Simmonds and Still, 1999; Simmonds, 2001). The MapInfo GIS package is used extensively in mapping the inputs and outputs of the model. In the following sections we describe the design of the South and West Yorkshire Strategic Model (SWYSM) model and illustrate its application.

11.2.2 Scope of the Model – Space and Time

The focus of the study is on the 'motorway box' formed by the M62, A1(M), the M18 and the M1. It was recognised that the forecasting process needs to consider not only what happens within this box, but also to consider in equal detail what happens in a significant area around it, and in less detail what happens further away. Accordingly the model covers the whole of South and West Yorkshire plus a ring of adjoining areas such as Skipton and Harrogate; this is the fully modelled area (Figure

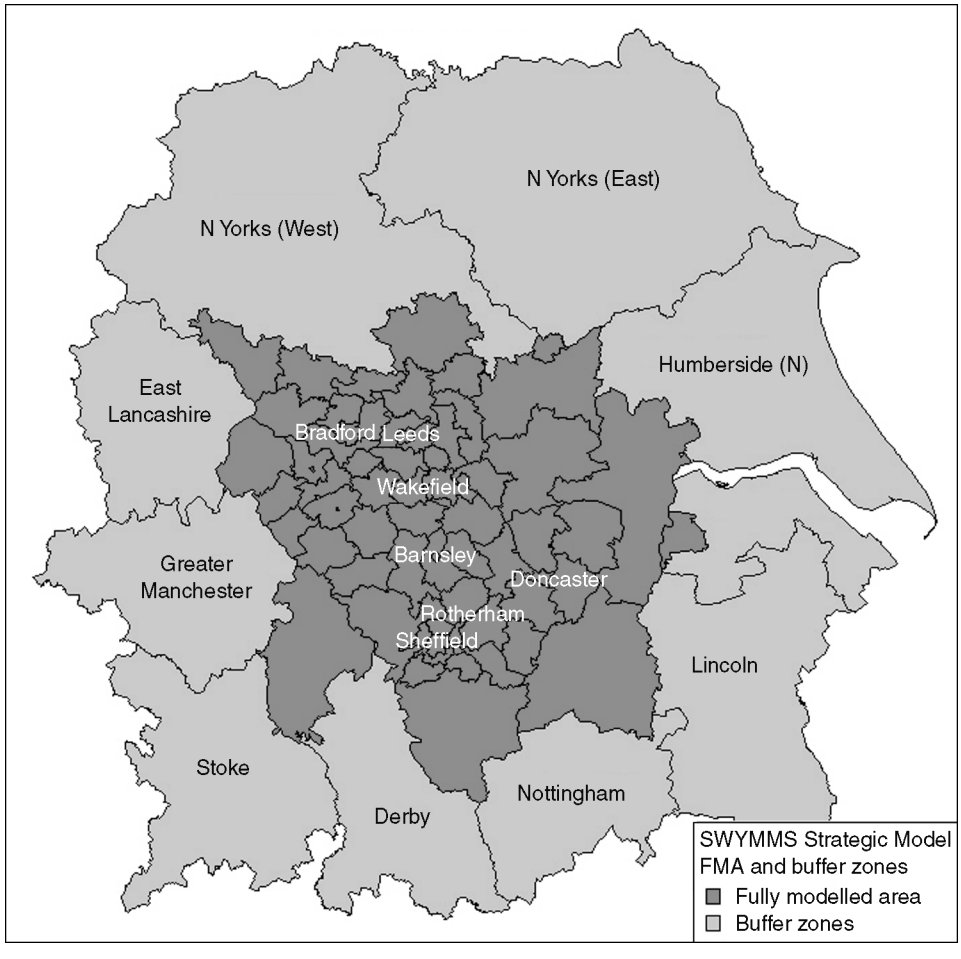

Figure 11.1 *SYMMS strategic model: fully modelled area and buffer area*

11.1). Around this, a wider ring of adjoining areas (the 'buffer area', extending westwards to Manchester and eastwards to Hull) is covered in less detail, with larger zones and fewer model processes working. Beyond these is a set of 'external zones' used to represent movement to and from the rest of Britain.

Within the fully modelled area, the zones were defined initially as 1991 wards, or groups of wards, within district boundaries; these conditions facilitate the use of data both from the 1991 Census of Population and from other sources. The grouping of wards into zones within districts was intended to distinguish the main urban centre of each district (in the event, some subdivision of wards was required), and then as far as possible to create zones of reasonable size and shape in relation to the transport networks. The process was constrained by the number of zones which is compatible with practical computing times and memory requirements, especially in the transport model where both time and memory increase as the square of the number

of zones. In total, there are 92 zones in SWYSM – in contrast with the 570 zones in the more detailed highway and public transport models. The model was set up so that the base year is 2000 and the forecasting process works forward to 2020; this involved an element of forecasting to create the 2000 base.

11.3 Transport Modelling: The START Package

Unlike many conventional transport models which have to be calibrated to reproduce the base year situation, START is incremental in approach: matrices of trips are estimated outside the model to describe the base year pattern of travel, making use of all available data. The model then modifies the pattern of travel in response to factors 'external' to transport – mainly changes in land-using activities such as the number, mixture and car-ownership of residents, the number and type of jobs, etc. and to changes within the transport system itself. The following sections summarise the preparation of the data for the base situation, the external forecasting model and the transport model proper.

11.3.1 Transport Model Base Data

Data on base year travel by motorised modes were obtained from the SWYMMS detailed highway and public transport models, which were in turn developed mainly from the extensive surveys carried out during 2000. Walking and cycling, which are not represented in the more detailed models, were estimated separately. Most of the START supply representation was obtained by aggregating data already assembled in the detailed models. The primary sources of data for the detailed models were surveys of road traffic and public transport trip making undertaken in spring 2000. Approximately 140 road traffic interview sites were employed, covering all entry points to the motorways and the A1 within the study area. Public transport passenger surveys were undertaken in the centres of the 10 largest study area towns, with details of non-central movements provided via operator ticketing systems. Cartographic network data for the highway system were created using GIS techniques, and public transport networks were coded from timetables.

11.3.2 External Forecasting Model

The external forecasting model (EFM) predicts changed travel patterns due to zonal changes in land use, including population, employment and car ownership. The model requires considerable detail about present and future land-use by zone (age groups, household types, etc.), since such factors are known to influence the amount and the type of travel. In SWYSM, all of these are forecast by the land-use model (see below).

The EFM assumes that future residents of a given age, employment status, car-ownership level, etc. will, if other factors remain equal, wish to make the same trips

as comparable present residents. It works by factoring the different trip matrices in proportion to the numbers of residents by type and zone, i.e., in proportion to changes in the land uses that produce and attract trips. The output of the EFM is therefore an artificial travel pattern – what would happen if the land-use changes occurred but the time and money costs of travel were unchanged? The impact of time and money changes is considered in the transport model proper.

11.3.3 The Transport Model

The transport model (Figure 11.2) contains the demand model, which adjusts travel in response to changes in transport conditions; and the supply model, which adjusts transport conditions in response to changes in the pattern of travel. These are

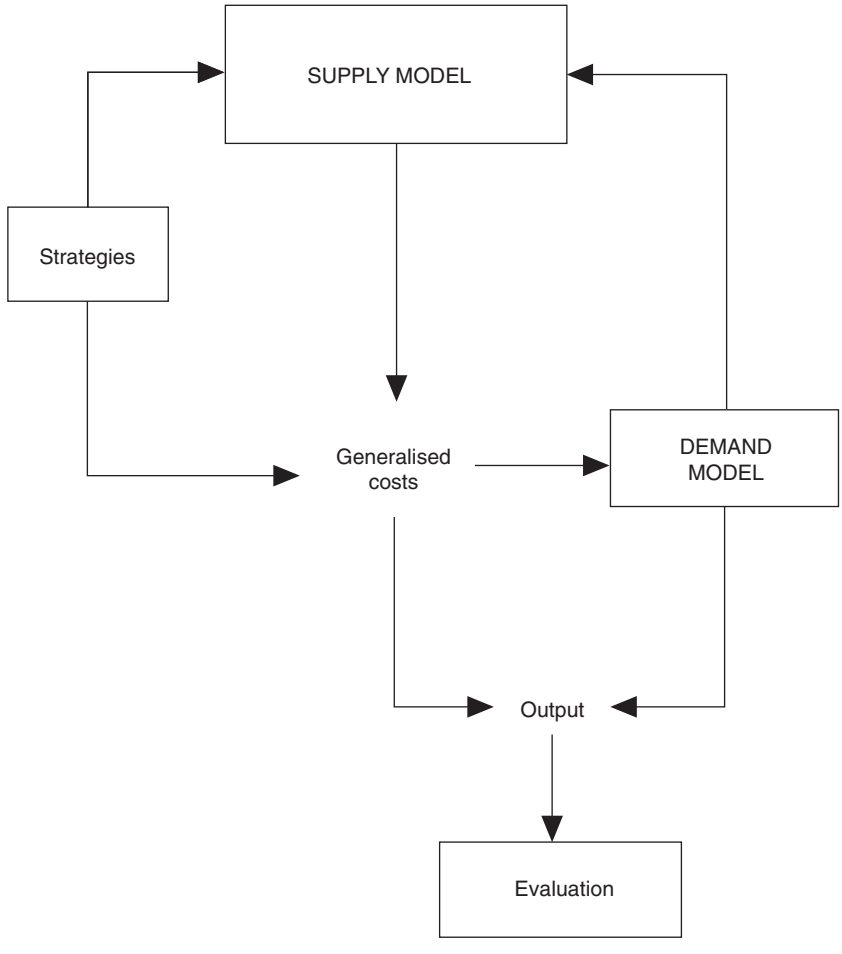

Figure 11.2 *The structure of the START transport model*

automatically run in turn until the travel pattern and transport conditions are consistent with each other. The key variable linking them is generalised cost, which is used to describe every journey within the modelled area by a single value bringing together money, time, inconvenience or discomfort, etc.

The *Demand* component of the transport model deals with all of the key choices available to travellers. These are:

- frequency – how often to travel;
- destination – where to travel to;
- mode – car, bus, rail, tram, walk, cycle, taxi;
- time of day – when to travel;
- route – highway or public transport route alternatives; and
- parking – type, location and duration.

These choices are organised into a hierarchy. The most sensitive choices are dealt with first, at the bottom of the structure, and the least sensitive choices at the top of the structure. The relative sensitivities, and hence the hierarchy, differ between trip purposes.

Changes in the pattern of freight movement are forecast by the land-use/economic model. Only road freight is currently represented in SWYSM; this is equivalent to assuming that the road share of freight movement for each commodity and each origin-destination (OD) pair will remain constant. Growth in road goods vehicle movements is forecast by DELTA as a result of changing land use and economic conditions. The prospects for modal shift in freight are being considered within SWYMMS, but outside SWYSM.

The *Supply* component of the transport model ensures that the level of service of the transport system, as defined by monetary costs and the various components of travel time, is compatible with the flows on the various transport networks. The highway supply definition is based upon the following key features:

- links that represent the speed/flow relationships for flow groups in each zone (typically defined in terms of inbound and outbound radial, clockwise and anticlockwise orbital);
- motorway and other 'limited access' links defined as specific roads; and
- a set of fixed car routes for each OD pair, including intra-zonal movements, defined in terms of distance travelled upon each link (with allocation of trip proportions to routes carried out via the demand model).

A similar arrangement is applied to public transport, with the addition of specific rail network links. The public transport definition allows for mixed mode trips. Crowding relationships are included so that generalised costs increase as demand approaches capacity. Fares and frequencies can be made responsive to changes in patronage. A number of indicators of the environmental impact of transport are calculated within the transport model, and some of these influence subsequent land-use change. In addition, for SWYMMS, more extensive analysis of environmental impacts was carried out by Environmental Resources Management as an input to the strategy appraisal process.

11.4 Land-Use/Economic Modelling: The DELTA Package

The DELTA land-use/economic modelling package has been developed by David Simmonds Consultancy since the mid-1990s. It was designed as a practical tool to represent urban and regional change and to interact with an appropriate transport model. The approach draws upon previous modelling experience and upon the wide range of relevant research carried out in geography, urban economics, etc. (for a fuller description of the model, see Simmonds, 2001).

Since land uses take a long time to respond to transport changes, the land-use model needs to represent change over time, in contrast with the transport modelling which describes transport supply and demand at particular points in time. Another requirement is to recognise that different processes operate at the urban and the regional levels: for example, different factors affect the total economic activity *in* an area and the location of employment *within* it. The model accordingly contains urban processes which change in or between the 92 zones, and regional processes in which the units are (approximate) travel-to-work areas – typically districts, in SWYSM.

The urban processes represent both changes in buildings and changes in activities. The processes of physical change are:

- development: the amount of floorspace by zone and type (residential, retail, office, industrial); this is driven by the economic scenario and the modelled property market, and controlled by inputs measuring what is allowed by the planning system; and
- the housing quality model, which models the way in which an area may decline to slum status, or be revived from slum to high-quality.

The urban activity sub-models are:

- the transition model, which represents household (and hence population) changes in terms of movements through a simplified lifecycle;
- the car-ownership model, which predicts the proportions of households by type and zone owning 0, 1 or 2+ cars, mainly in response to increasing incomes;
- the location model, which locates or relocates a proportion of households and of employment in each year, and also models the property market within which location occurs; and
- the employment status model, which updates the work status of residents and the commuting pattern in response to the spatial changes in households and employment.

At the regional level, there are three models, all of activities. These are:

- the migration model moves households between areas;
- the investment model allocates investment to areas (taking account of changes in accessibility and property costs); and
- the production/trade model (a spatial input–output model) estimates production by sector and area and the patterns of trade between areas.

The processes are considered in a fixed sequence within each one-year step, as shown in Figure 11.3. However, there are also numerous time lags between the different

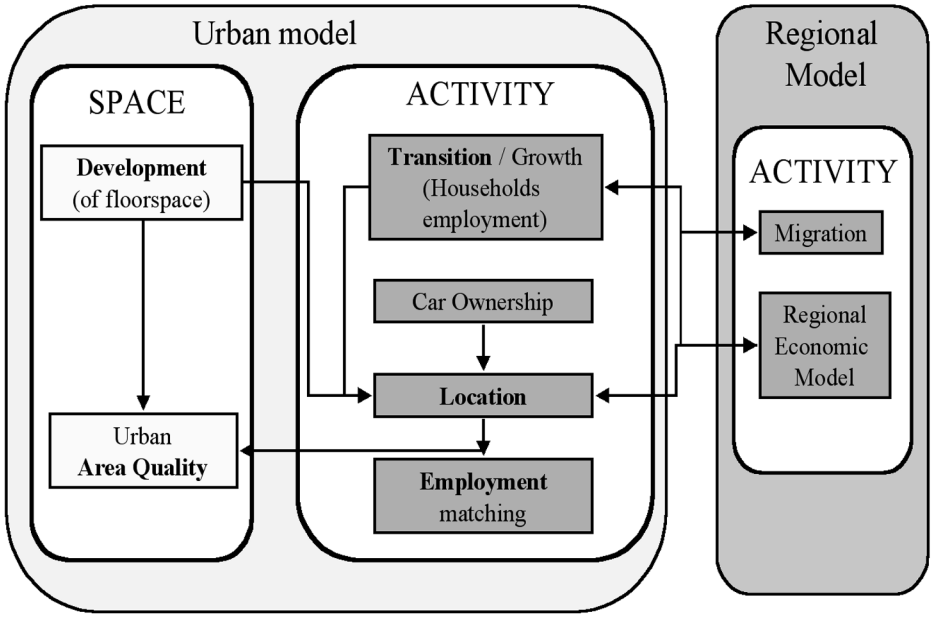

Figure 11.3 *The DELTA sub-models: land-use/economic model structure*

processes which are equally or more important to the overall performance of the model.

11.5 Land-Use/Transport Interaction

The model operation over time is a sequence of five one-year steps through DELTA, followed by a run of START to represent the resulting state of the transport system (Figure 11.4). Land-use changes have immediate impacts on transport, through the EFM described earlier. At the area level, changes in the costs of trade (goods and passengers) affect the location of production and of new investments. At the urban level, generalised costs are used to calculate various accessibility measures which affect the location of households and businesses within each area. In addition, the environmental impacts of transport influence the locational preferences of households.

11.6 Use of the Strategic Model

11.6.1 The Strategy Testing Process

As with most models, the strategy testing process using SWYSM is comparative. A strategy option is examined by appropriate changes to the model inputs; running the

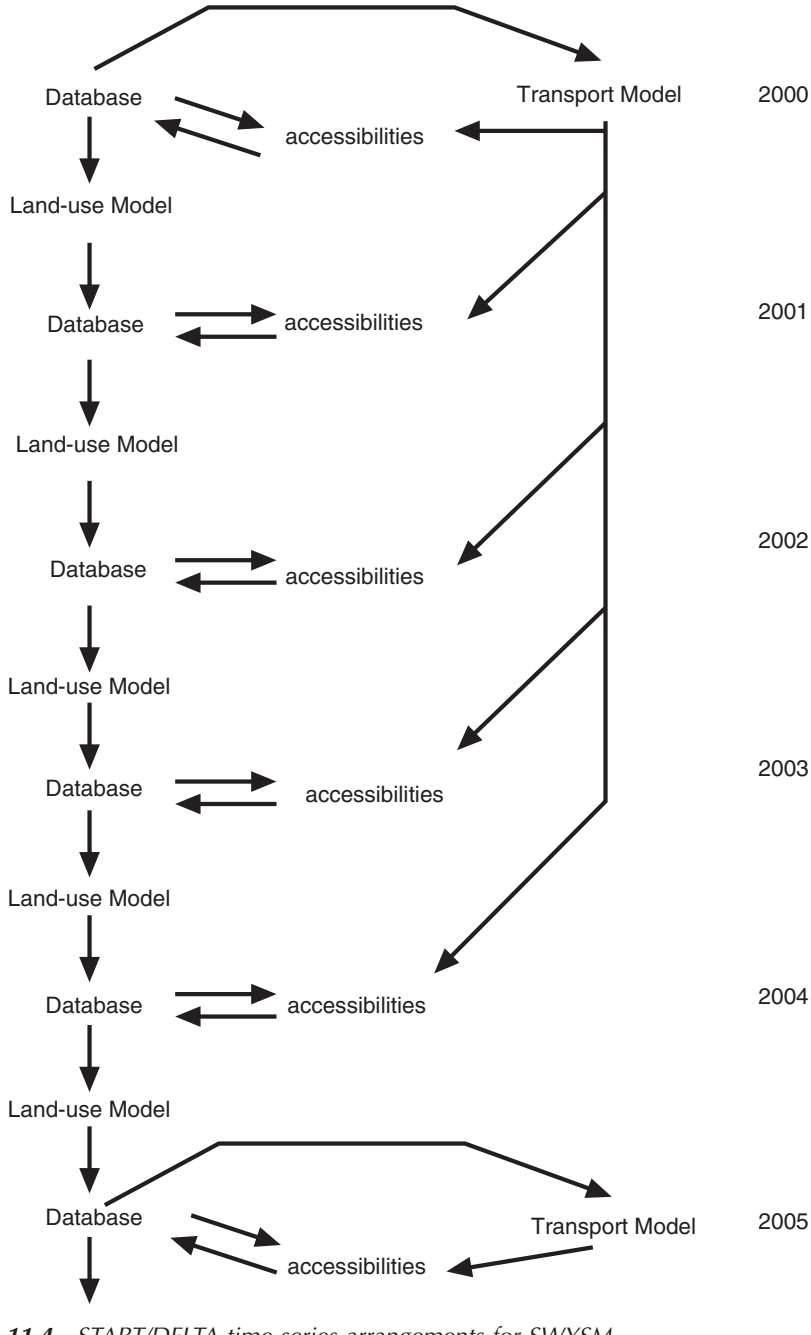

Figure 11.4 *START/DELTA time series arrangements for SWYSM*

model over time; and comparing the resulting outputs with those from a previously run reference case. This process applies whether transport options, land-use options or combinations of the two are to be tested.

Transport policy changes are introduced into START either as direct adjustments to costs or as changes in the characteristics of the transport supply. They influence land-use and economic change through the accessibility and environmental values that are passed from START to DELTA. Land-use policy changes are introduced into DELTA via a special policy file, which is used to specify changes in the amount of land available for each type of development in each zone in each year. Policies may not have immediate effects: for example, an additional allocation of land may not be used immediately or at all.

An important characteristic of using a land-use model is that land-use policies are tested in the same way as transport policies. This is not always the case. Whilst it is conventional for transport policies to be tested by forecasting their effect taking account of user preferences and interactions, land-use planning often assumes simple linkages between policy changes and outcomes. Formal land-use modelling allows a more rigorous approach to be taken.

11.6.2 Strategy Testing in SWYMM

The strategic model was used extensively in the Strategy Development phase of SWYMMS. This was divided into three main themes: travel reduction options; economic development options; and combined transport/economic development options. For the first theme the transport model was frequently used on a stand-alone basis, as direct transport effects were dominant. The full model was used for investigation of options for the second and third themes. The following paragraphs illustrate the results from just one part of this exercise.

11.6.3 Example Strategy Results

One of the tests carried out under the economic development options theme (identified as test ED3 within SWYMMS) was to look at the combined impact of two packages of road building and widening schemes. The packages were a group of schemes aimed at economic regeneration, and a group of schemes aimed at the relief of traffic congestion in areas where economic regeneration is a priority concern.

These schemes were concentrated in the South Yorkshire area between Sheffield and Doncaster, plus improvement to the A1 north of Doncaster; they are illustrated in Figure 11.5. They were introduced into the transport supply in 2005, and the model system was run to 2020. The following discussion of their impacts is based on comparison with the reference case; except for the road schemes, there were no other differences in transport or land-use policy between the ED3 test and the reference case.

The changes in the road networks are introduced into the model through the supply side of the transport model in 2005 (and in all the subsequent transport model years). These changes have the effect of allowing faster travel by road for some parts of

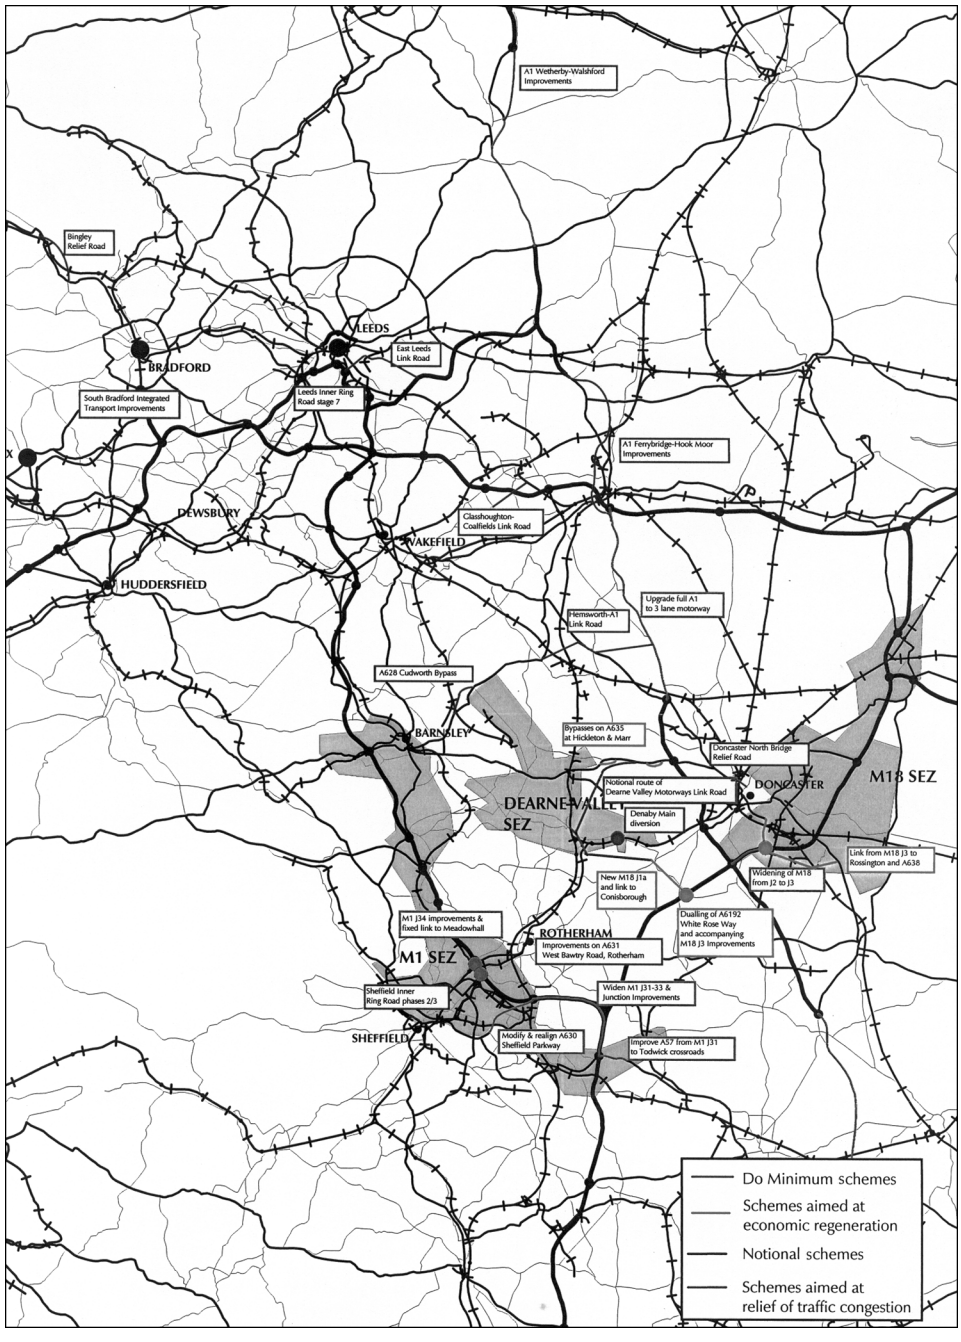

Figure 11.5 *The location of ED3 road building/improvement schemes*

journeys in South Yorkshire (including some journeys between origins and destinations outside South Yorkshire). The journey time reductions come about partly from higher road design speeds, and partly from increases in capacity which reduce the effects of congestion.

As a result of the journey time reductions, the generalised cost matrices output from the transport model show very slight reductions for affected zone pairs relative to the equivalent matrices for the reference case. As a result, there are some very slight changes in trip patterns, including a slight increase in commuting between Doncaster and Sheffield/Rotherham.

All of these effects are very slight – mostly measured in fractions of 1% change from the reference case. The average cost of delivering goods from the Doncaster area to the Sheffield/Rotherham area, for example, falls by slightly less than 1%. These effects are apparent in the data passed to the land-use model at the end of the 2005 run of the transport model (that is, they are slightly different from the equivalent data in the reference case). The differences from the reference case will affect the land-use/economic model in a number of ways. At the area level:

- the changes in cost or generalised cost of travel will have some impact on the pattern of trade, and this will have an immediate impact on the level of production of each sector in the affected areas; and
- the same changes will also affect the accessibility of each area and hence its attractiveness to investment: the change in the level of investment (or reinvestment) will affect the output of each local economy in the longer term.

The effect on investment is, as one would expect, slight, and markedly different across sectors. Figure 11.6 shows the percentage changes in capacity by sector in the Doncaster area in 2020, i.e., the accumulated effect on investment (relative to the

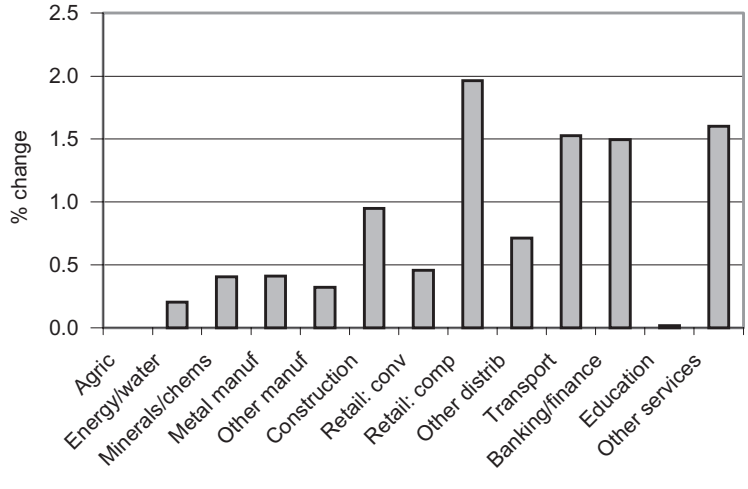

Figure 11.6 *Changes in productive capacity, Doncaster area, 2020, test E3 compared with reference case*

reference case) of slightly better accessibility over 15 years. It can be seen that the greatest impact on capacity is a 2% increase for comparison retailing, followed by increases of around 1.5% for transport and communications, banking/finance and other services.

Most of this increase occurs over the period 2006–2015, and the increased investment is largely responsible for the resulting slight increase in economic activity in the Doncaster area. As is shown in Figure 11.7, total (all-sectors) value added in the area gradually increases very slightly compared with the reference case, reaching a gain of slightly more than 1% after 10 years.

Figure 11.7 also shows the much smaller positive impact on the Barnsley and Sheffield/Rotherham areas. It should be noted at this point that the model system reflects what has become known as the 'two-way road effect', that is, that transport improvements intended to benefit a specific area may assist the economic regeneration of that area, or they may increase the problems of the area by making it easier to serve that particular market from other locations. In the present case, the concentration of schemes in South Yorkshire does have a (very slight) positive effect in that sub-region, though it will be seen below that not all of the indicators are positive for all the districts affected. This comes about mostly through the improvement in accessibilities making South Yorkshire in general, and Doncaster in particular, a marginally more attractive location for investment in various sectors.

The gain in value-added in Doncaster in 2006, the first year after the opening of the road schemes, is rather larger than that in any subsequent year. This is due to the initial impact on the pattern of trade, as Doncaster businesses find it marginally easier to win custom elsewhere as a result of the decreased transport costs. Note that within the results for later years there are multiplier effects:

- the additional production due either to the initial impact on the pattern of trade or to the additional investment creates additional intermediate demand for goods and services; and

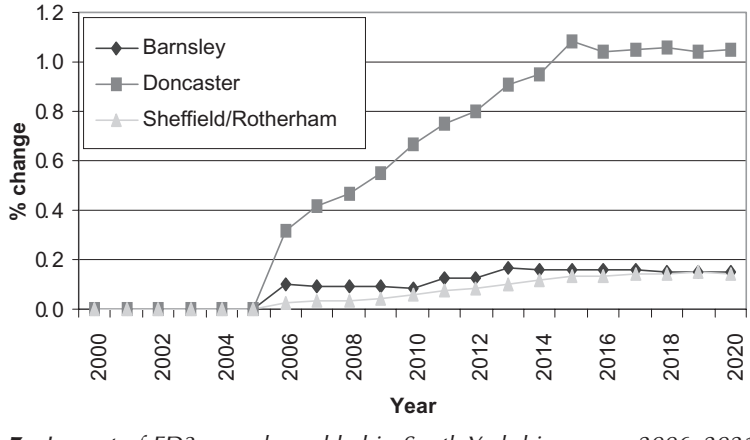

Figure 11.7 *Impact of ED3 on value added in South Yorkshire areas, 2006–2021*

- the increases both in capacity and in production create additional employment which leads to increases in consumer final demand.

The additional employment opportunities affect the pattern of migration, leading to a slight increase in population of the Doncaster area relative to the reference case, which in turn helps to retain expenditure within the area and to reduce the 'leakage' of multiplier effects which would otherwise occur.

Returning to the aspects of the model which are directly affected by the outputs from the transport model, at the urban (zonal) level:

- the local pattern of location of households and businesses will be affected by the changes in accessibility resulting from the changes in generalised cost (with further consequent impacts through competition in the housing and commercial floor-space markets); the pattern of household location will also be affected to some extent by the environmental changes resulting from the changed traffic patterns; and
- the likelihood of working-age individuals being in or out of work will be slightly modified, with consequent impacts on residential location.

These effects and their further consequences (for example, in the development model) work through over a number of years.

The increases in economic activity generate increases in employment. These are shown by district for the South and West Yorkshire authorities, in Figure 11.8. Note

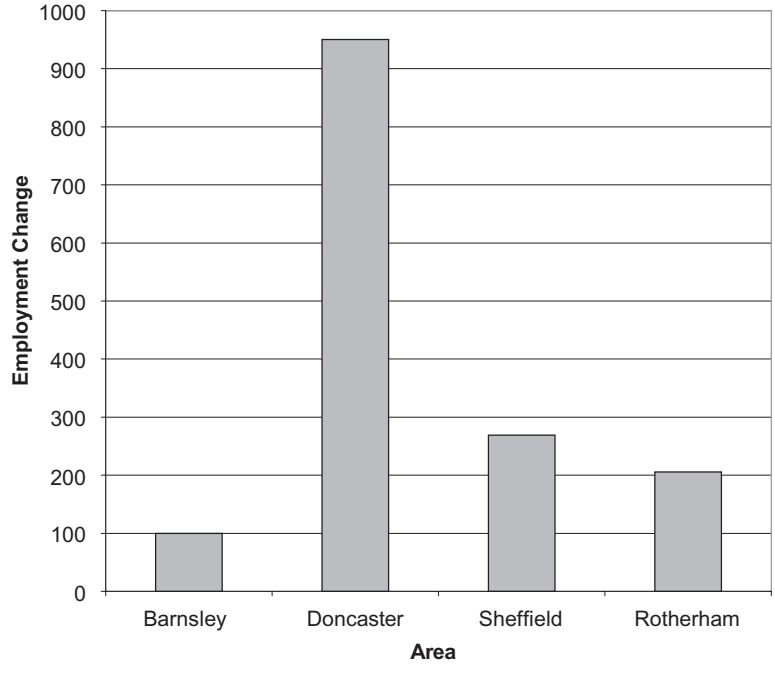

Figure 11.8 *Impact of ED3 on employment in South Yorkshire authorities, 2020*

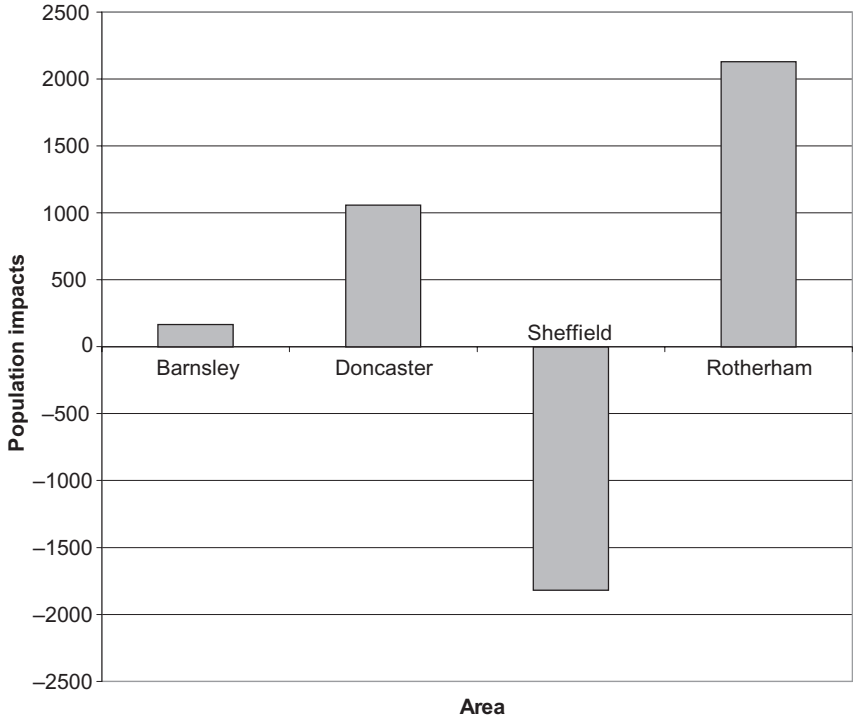

Figure 11.9 *Impact of ED3 on population in South Yorkshire authorities, 2020*

that whilst there are some very slight negative impacts on parts of West Yorkshire, the gain to South Yorkshire is greater, i.e., the gains to South Yorkshire are largely at the expense of other areas rather than of West Yorkshire.

The growth in employment in Doncaster makes a slight improvement to the relative employment prospects there, and this, as already noted, leads to some changes in migration patterns. The overall population impacts by 2021, inclusive of migration effects, are shown in Figure 11.9. Whereas the largest change in employment was in Doncaster, followed by Sheffield and Rotherham, the largest change in population is in Rotherham, with half as much growth in Doncaster and a negative effect on Sheffield.

The localised differences between the employment and population impacts illustrate the scope for transport improvement to modify commuting patterns as well as economic activity. One can see that there is a risk that measures which help to capture additional employment may also promote an exodus of population, and in a small way that is happening to Sheffield in this particular case.

It has to be kept in mind that the impacts considered here are very slight when considered as percentage changes though, as one would expect, there is greater variation between individual zones than between local authorities. This is illustrated in Figures 11.10 and 11.11, which show the percentage impacts of the ED3 test in 2021 on employment and population. The impacts of this particular test are small enough

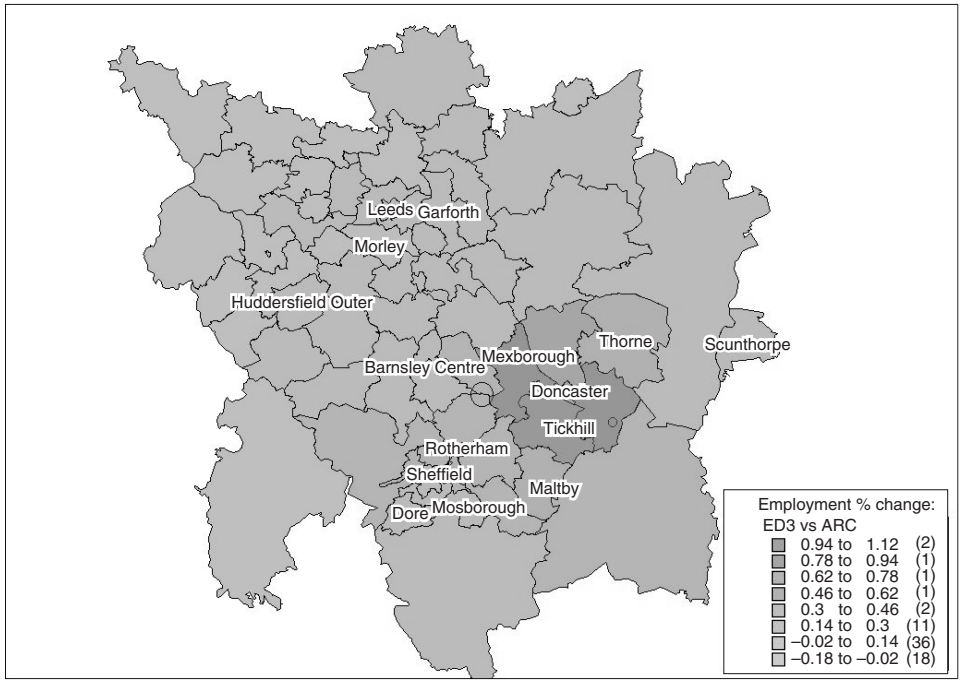

Figure 11.10 *Impact of ED3 on employment by zone, 2020*

that there are no significant impacts either in the land-use impact (little change in residential or commercial rents) or in transport (little additional congestion due to the growth in economic activity and population). In other tests, however, we found that these induced effects could be significant. Indeed we found that land-use policies aimed at encouraging growth in certain locations without complementary transport measures to provide the necessary capacity could actually have negative effects, that is, could actually have the effect of discouraging growth in their target locations.

11.7 Discussion

11.7.1 The Role of the Model in the Study

One of the objectives of using the strategic land-use/transport interaction model in SWYMMS was to provide a formal, quantified analysis of the likely impact of transport and other schemes intended to promote economic regeneration. As we have seen in the ED3 results discussed above, the strategies designed to improve access to regeneration areas and to relieve congestion in their vicinity would have very slight but generally positive impacts in South Yorkshire (particularly the Doncaster area), whilst being neutral for West Yorkshire. Whilst the impacts identified are very small percentage changes from the underlying reference case, it is worth remembering both

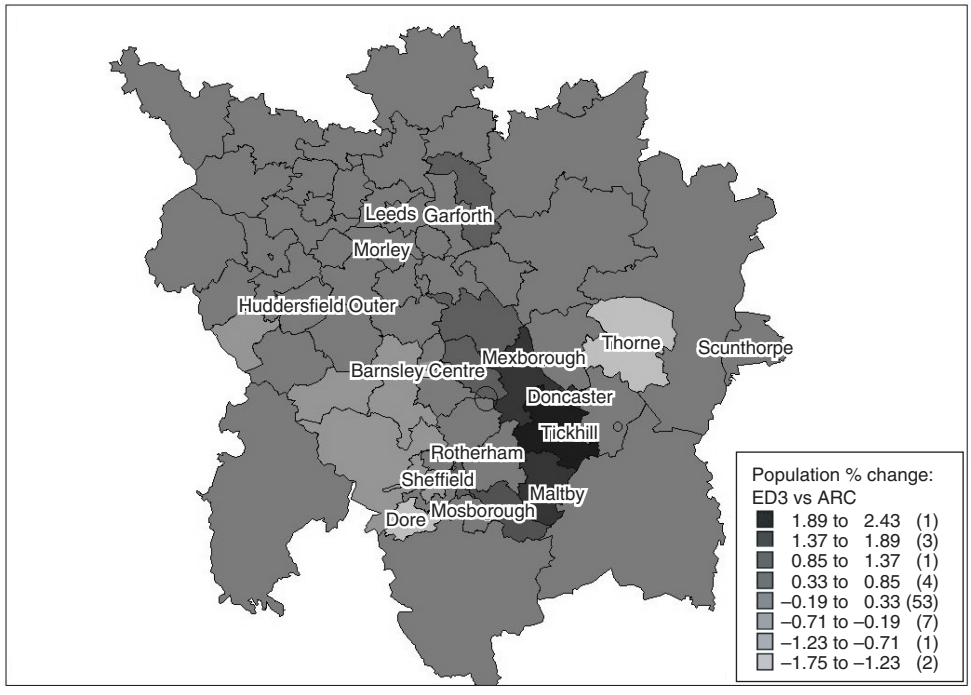

Figure 11.11 *Impact of ED3 on population by zone, 2020*

- that the formal analysis of such impacts may serve as much to guard against exaggerated claims about the economic consequences of transport strategies as to support reasonable claims (whether the consequences are expected to be positive, as in the ED3 case, or negative as might be expected for some demand management measures); and
- that in many cases the small percentages nevertheless represent politically significant numbers of people and jobs.

It is also appropriate to note that the impacts predicted by the land-use/transport interaction model do not always go in the expected direction. An example of this arose in testing another strategy within SYWMMS, which involved substantial (and entirely hypothetical) incentives to the development of retail, office and industrial floorspace in town/city centres and selected Strategic Economic Zones of South Yorkshire. (Details can be found in the SWYMMS Scenarios and Strategies Report, as test ED6.) No other changes were introduced. The development incentives did lead to significant extra construction in the zones affected, but, to the initial surprise of the modelling team, the impact on total employment in South Yorkshire was negative. Detailed examination of the model outputs showed that this was due to

- much of the additional development in South Yorkshire being in congested locations;

- businesses relocating into the additional floorspace thus moving into congested locations and contributing to making congestion even worse (with no provision in the strategy for transport improvements); and
- the resulting increases in congestion, and the increases in the proportion of activity in the most congested locations, making South Yorkshire slightly less competitive as a location for production and slightly less attractive as a location for investment.

Other planners with whom we have discussed these results have described them as an entirely unsurprising and intuitively obvious example of what is likely to happen if land-use and transport plans are not properly integrated!

11.7.2 Model Development

Without embarking on a general review of land-use/transport interaction models, or of the SWYMMS project, it is appropriate to note some of the technical characteristics of the modelling process adopted, and to consider how these are being developed in subsequent projects and may develop further in future.

As noted earlier, the strategic transport model was supported by more detailed highway and public transport models, which were used both to prepare the aggregated descriptions of transport supply used in the strategic model and as the modelling tools for more detailed analysis of highway and public transport impacts in the subsequent development of the plans through which the preferred strategy may be implemented. The possible integration of the detailed and strategic levels of modelling into a single model system, combining the land-use and time-of-day responses currently unique to the strategic model with the more detailed zone system and network representation of the detailed models, is one of the possibilities for future application. This would of course be more demanding of computer resources, but might be justified in terms of avoiding the need for complex interfaces between the two levels, and in terms of the benefits of having a finer zoning system in the land-use/transport interaction modelling. To some extent this approach is already being adopted in work by the authors' firms for the Central Scotland Transport Corridor Studies, where a land-use/transport model with over 700 zones is being used.

Another important aspect is the treatment of land-use planning in the modelling system. The treatment of planning policy and of the planning process in land-use/transport interaction models is typically one of extreme simplification, requiring inputs which tend to imply a very simple 'zoning' system of planning rather than the more subtle approach which operates in the UK. Current developments of the DELTA model are seeking to improve on this, particularly to represent the ways in which the planning process can influence the type of development within broad categories such as 'housing', and in particular to represent the possibility that planning activities in regeneration areas can introduce developments radically different from the existing stock (such as new luxury housing in decaying inner-city industrial areas). More broadly, attention is also being given to the possibility of modelling the planning process as a responsive system working within a quantified policy context,

rather than simply quantifying the expected outputs of the planning system – the amounts of development which will be permitted – as is done at present.

11.8 Concluding Comment

We believe that the SWYMMS strategic model has made a valuable contribution to the study for which it was commissioned, which may well continue to be used on behalf of the various regional and sub-regional planning bodies in relation to other strategic issues. It is representative of the state-of-the-art in forecasting land-use/transport interaction for major UK studies, but further developments in this field can be expected and indeed are already emerging.

Acknowledgements

The authors are grateful to the numerous organisations which contributed to the study and to the work described here; to the editors for the invitation to publish this paper, and to the Government Office for Yorkshire and the Humber for permission to do so; and to their respective colleagues under the overall direction of Dr Denvil Coombe for their strenuous efforts in data collection and in the development and operation of the model. The authors remain responsible for this description of the model and of the use made of it.

The Relocation of Ambulance Facilities in Central Rotterdam

Stan Geertman, Tom de Jong, Coen Wessels and Jan Bleeker

Abstract

This chapter considers an important strategic planning question – the relocation of emergency service facilities – as the focus for applied research and, in so doing, exemplifies the reciprocal relationship between academic (or fundamental) and applied research in the field of geo-information and communication technology (geo-ICT). The underlying indicators of accessibility used in the application are introduced initially and a set of optimal locations of ambulance facilities in the study area of central Rotterdam are determined for the client using a planning support tool known as *Flowmap* in conjunction with a proprietary GIS. Some further experiments to improve the solution are also presented.

12.1 Introduction

Since the early 1990s, interest in information systems for storing, managing, processing, analysing and displaying geographical data has boomed. The last decade has witnessed some new areas of application for this 'geo-information and communication technology' (geo-ICT). The expansion started in sectors such as defence, forestry and mining and has extended into geo-marketing, insurance, car navigation and telecommunications. Moreover, geo-ICT expanded in size, functionality and diversity (Tomlinson, 1987; Burrough, 1986; Ottens, 1993; Steinitz, 1993). Increasing numbers of commercialised information systems were put on the market and new systems, or updated versions of old systems, have been developed, offering novel

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

capabilities (e.g., Internet-GIS) as well as traditional functions in a way not previously available (e.g., three-dimensional mapping/animation) (Geertman, 1999).

Research activities within the field of geo-ICT can be broadly divided into those that are fundamental and those that are applied. Fundamental research is frequently referred to as 'blue skies' research and is often undertaken in an academic context. Examples of fundamental research include studies of ontological and/or semantic issues (e.g., Winter, 2001), advances in the use of open technologies (e.g., OCG, 2002), the creation of new error propagation methods (e.g., Burrough and McDonnell, 1998), and the development of geographical modelling methodologies such as those based on artificial intelligence (Openshaw, 1997; Fischer, 1999). Applied research involves the application of these new technologies in real-world contexts, frequently in public sector planning at local or regional level. Whilst the distinction between fundamental and applied research is drawn for purposes of clarification, most institutions involved with geo-ICT related research undertake a mixture of both types of activity. This has led to the critical view amongst commentators in the higher education sector that there is a growing amount of research, which is money-driven, and that fast, clear-structured and short-term applied research is taking priority over more fundamental longer-term research, which is suffering as a consequence. However, there are some advantages of applied work, not least of which is the necessity to develop policy-relevant tools for understanding problems and providing solutions. Consequently, an appropriate combination of more theoretical fundamental research activity and more applied developmental work seems desirable. At Utrecht University in the Netherlands, for almost two decades now, various research groups have been working with geo-ICT. Although some of these are more oriented towards fundamental research and others towards applied work, in general all groups show elements of both and, in certain cases, their research activities have resulted in the commercialisation of geo-ICT products (such as *Flowmap* and PCRaster) and in the creation of (quasi-) private organisations (such as Nexpri and Carthago).

Flowmap, for example, is a stand-alone software package dedicated to the analysis of spatial interaction data, data that describes movement of people, goods, energy or information through space on a regular or irregular basis usually via some form of transport network. An example of regularly occurring interaction is commuting whereas irregular interaction might be residential migration. *Flowmap* has capabilities for the selection and display of this kind of data, together with various methods and models to analyse historical flows and predict potential interaction. These latter capabilities make *Flowmap* a very suitable tool to incorporate in planning support systems, especially in the field of facility/service localisation (Geertman *et al.*, 2002). Although *Flowmap* has many GIS functions, it is not designed as a full GIS package, but rather as an extension for specific spatial analyses that are difficult or impossible to realise within mainstream GIS packages.

Nexpri, the Netherlands Expertise Centre for Geographical Information, can be regarded as an example of a spin-off organisation. It began its existence in 1989 as a subsidy-based institution related to five Dutch universities, but in 1996 it became an entirely market-oriented organisation related to Utrecht University and is soon to change its status to that of a private company. Its activities primarily concentrate on two fields of applied geo-ICT research: one concerns the organisational issues related

to the implementation and functioning of geo-ICT in organisations; the other concerns different kinds of location-oriented research questions such as the identification of the best location for a new dealer in the branch network. There is a strong interrelationship and active interaction between the research groups at the University and the applied research undertaken by Nexpri.

In this chapter we discuss one particular example of the benefits of this reciprocal interrelationship between fundamental and applied Geo-ICT research and endeavour to demonstrate how the two-way interaction between the two research communities can be of considerable advantage to both. The example involves an important strategic planning question – the relocation of ambulance facilities. Nexpri was contracted by the Rotterdam Municipal Health Authorities to undertake a study of the provision of ambulance services in the Rotterdam Harbour area and to identify how the location of ambulance stations might be altered to improve the efficiency and effectiveness of the service.

Initially, attention is focused on some of the underlying concepts related to the research question in general terms, i.e., how can facility siting be performed and how to measure accessibility. Thereafter, the real-world planning question will be elaborated in more detail, followed by an explanation of the way in which the *Flowmap* software has been applied to solve this planning question. Subsequently, reflections on the application will be presented and recommendations made about future applications of this instrument to these kinds of research questions. Finally, some remarks are provided on the experience of working in this reciprocal interrelationship between fundamental and applied geo-ICT research.

12.2 Facility Siting with Accessibility Analysis

12.2.1 Introduction

Facility siting is a form of applied research aiming at finding the absolute or relative optimal location or set of locations for a predefined facility or group of facilities. Facility location is closely related to the concept of geographical accessibility that can be defined as the effort taken to get to some place and the level of acceptability to the target group. So the concept of accessibility incorporates the transport link between origin and destination and the ability to travel by the target group, as well as the characteristics of the destination and the objective of the trip. For example, what is accessible by private car may be inaccessible by public transport; what is within an accessible walking distance for younger people may be effectively inaccessible for senior citizens; what is an acceptable effort to travel to buy antique furniture is likely to be unacceptable when shopping for daily groceries.

Moseley (1979) has put the concept of accessibility into a schematic framework in which activities require transport and transport involves people; from this it follows that actual accessibility depends on the properties of each of the components in this scheme. However, accessibility can be measured in many different ways. Robinson (1990) distinguishes between composite measures, comparative measures and time–space approaches. The time–space approaches are most useful for studies based

on the perspective of the individual: 'Is service C accessible for a person living in place P with mode of transport T?' The other approaches are more useful for measuring aggregate accessibility. Composite measures are a combination of several different individual measures like 'How many buses arrive before 8.00 a.m.?' or 'Is there a Sunday bus service?'. Comparative measures also take differences into account between social groups like car users or public transport users. In addition the comparative measures can be further subdivided into potential and actual accessibility measures (Hilberts and Verroen, 1992). Moreover, accessibility can be measured for many individual locations or these measures can be combined into an aggregate measure for a whole region. The latter is relevant, for instance, when one wants to measure the effect of infrastructure changes on the accessibility of (or inside) a larger region. Finally, accessibility measures can be based upon a single-purpose trip as presented in the scheme above or on multipurpose trips (also known as combination trips) where for instance the accessibility of a shopping centre is based on its location relative to the home–work trip of the customer (Dijst and Vidacovic, 1995).

Despite its geographical dimension, facility siting is not a field of study restricted to human geography. Other disciplines, such as operations research, have made contributions too and still do. Therefore, before discussing the methodology of accessibility analysis in depth, we discuss some alternative approaches for research on facility siting: the optimisation approach from operations research; the buffer/overlay approach from geographical information science; and the values of accessibility potential that have their roots in quantitative geography.

12.2.2 The Optimisation Approach

Whenever a facility-siting project is considered, there is always the question of whether or not it really involves an optimisation problem and requires an optimisation approach. This is because there are several reasons why such an approach is not appropriate (Floor *et al*., 2001):

- not all factors of relevance in a public planning or policy environment can be included in an optimisation approach;
- the typical 'hard' and 'singular' result of an optimisation approach often is very difficult to incorporate in a public planning or policy environment;
- optimal results can be highly sensitive to the choice of spatial aggregation and also to temporal changes; a good example of this is the sensitivity to the modifiable area unit problem (MAUP) as described by Fotheringham *et al.* (1995);
- there is not necessarily one optimal solution, but many different optimal solutions depending on the chosen target functions (like minisum or minimax);
- although exact solution methods are known for these target functions, for most practical applications they require a prohibitive amount of computer memory or time, in which case usually some approximation method has to be used;
- it is very difficult to optimise using transport network-based impedance functions instead of airline distances. The traditional optimisation approach is exemplified by the ALA and NORLOC algorithms described by Cooper (1964) and Törnqvist

et al. (1971) for locating services in a plane and Maranzana (1964) for locating services on a transport network. There is no known published example of locating services in a plane using distances via a transport network.

In a recent publication (de Jong *et al.*, 2001) we argue that the only useful part optimisation techniques can play in a public planning or policy environment is to provide a yardstick against which the outcome of a project can be measured in terms of accessibility.

12.2.3 The Buffer/Overlay Approach

In an earlier study (de Jong and Ritsema van Eck, 1997), the traditional GIS approach was outlined. It mainly involves the use of buffer techniques to determine a straightforward 'accessible' area followed by overlay techniques to clip out this buffer area and to present the remainder as the 'inaccessible' area. This approach can be criticised for a number of reasons. Firstly, transport networks are not taken into account. Not only does travel speed differ depending on mode of travel and network quality but also natural (waterways, steep slopes) or man-made (railway tracks, airfields) barricades will have a diminishing effect on accessibility. Secondly, all sites within the buffer zones have similar weight, so a location with all opportunities at the maximum allowed distance scores just the same as a location with all opportunities at minimum distance. Depending on the type of facility siting that is being undertaken, other shortcomings of the buffer/overlay approach may also be of relevance: competition with already established service outlets is not taken into account; and depending on the subject of analysis, sometimes the limited capacity of service outlets cannot be ignored.

12.2.4 Potential Values

To overcome some of the shortcomings of the GIS approach, Geertman and Bosveld (1990) used the potential value technique based on a transport network instead of using buffers. This can be seen as a first attempt to incorporate some accessibility analysis into GIS. Potential values are the best-known measure for the nearness of clients/customers/potential users and were first introduced by Hansen (1959) to describe accessibility. Potential values can be calculated as follows:

$$Pot(i) = \sum_j D_j \cdot C_{ij}^{-\beta} \tag{12.1}$$

in which:

$Pot(i)$ is the potential value for client site i;
D_j is the weight (size or number) of services provided for service location j;
C_{ij} is the distance between origin site i and destination site j; and
β is the distance decay parameter.

This equation can be used to find good sites for new residential areas, for example, based on the number of jobs offered at the destination locations. Sites relatively close to a large D_j score a higher potential value than sites further away. However, being relative measures, potential values are difficult to interpret. This problem can be overcome by calculating two sets of potential values where the distance decay parameter differs by exactly one. After dividing the outcome of the one set of values by the other the result will be an accessibility measure in the form of a weighted average distance for each origin site to all destination sites (Geertman and Ritsema van Eck, 1995).

Also in practice we see that, because of the ease with which potential values can be calculated within a raster-based GIS, the measure is often calculated by using just the geometric distances between cell centroids. As these distances are comparable to the simplest form of airline distances, the first criticism mentioned above regarding the buffer/overlay approach is in this case valid too. There is no satisfactory way in raster-based GIS to handle the effect of the discontinuous aspects of travel via a network, like multilevel overpasses and limited access to highways. Therefore, in our opinion, raster-based GIS are unsuitable for any realistic analysis involving calculations of effects of travel via transport networks.

There are some other criticisms of the potential value approach that are harder to overcome. In gravity modelling the distance decay function can be calibrated using the (log) mean trip length to represent distance behaviour correctly. A similar mechanism is not available when it comes to the calculation of potential values (often simply a power function is selected with distance decay parameter 2 in an unfounded analogy with Newton's Law of Gravity). Moreover, the results are highly sensitive to opportunities at extremely short distances (Ritsema van Eck and de Jong, 1996). As these particular distances are often arbitrary (intrazonal distance estimation or depending on the location of the centre point that represents a whole zone), this renders any outcome potentially unreliable.

12.2.5 The New Methodology of Accessibility Analysis

A comparative potential accessibility measure that overcomes most of the criticisms mentioned above can be developed. Moseley's schematic framework involving population linked to activities by a transport network can be redefined in GIS terms as origin locations linked to destination locations by transport network distances. Based on this adapted scheme, we can use GIS to calculate, for each destination location, which of the origin locations are within reach (and sum up the selected attribute values of those locations) and vice versa. This creates an accessibility measure called the proximity count or cumulative opportunity index. The proximity count is a simple count of locations that are within a predefined distance range. Instead of counting the number of locations, a weight variable for each location (such as the number of jobs) can be summed. For each site, all locations are counted that meet the distance requirement:

$$PCount(i) = \sum_{j^*} D_j$$
$$(j^* = \text{over all } j \text{ such that } C_{ij} < \text{Range}) \tag{12.2}$$

where $PCount(i)$ is the proximity count for origin site i.

A location or location related value is not uniquely allocated to any site. In fact, locations can be counted for more than one site. The proximity count therefore gives an indication of the potential (job) market not taking any competition effects into account. It can be used to determine which sites reach above certain (minimum) threshold values. Of course the choice of distance is critical: if it is set too large then all origins will be counted for all destinations and all proximity counts will end up equal. As an alternative, the threshold value can be preset and the threshold distance can be calculated as the minimum distance at which enough locations are to be reached (de Jong and Ritsema van Eck, 1997). Proximity counts and threshold distances are especially useful for determining whether or not the potential market size of a proposed site (service or retail) is large enough (de Jong *et al.*, 1991). In the next section, we exemplify this with the help of a real-world strategic planning question, the relocation of ambulance facilities.

12.3 The Relocation of Ambulance Facilities

In the Netherlands, as in many other countries in the western world, increasing the efficiency of public services is one of the main solutions for handling decreasing funds for public facilities. One of the areas in which the cutback in public funds is translated into a quest for improved efficiency is in the number and the location of ambulance service stations. The Dutch national government is striving to unify smaller service areas into larger service regions. This forces different ambulance services to collaborate, which in turn leads to a more efficient and effective use of ambulance provision, and a reduction in costs. One of the newly formed service regions is the ambulance service region of the Rotterdam Harbour area (Figure 12.1).

Ambulance provision is divided into three categories. The first category consists of the urgent journeys (so-called A1 journeys) where, according to the law, an ambulance has to arrive at its destination within 15 minutes of the Central Post for Ambulance (CPA) journeys receiving a call for help. The second category involves less urgent journeys (A2 journeys) where there is no strict time limit other than to arrive 'as quickly as possible'. The last category consists of so-called 'ordered' journeys (B journeys) consisting mainly of pre-arranged journeys between hospitals and pre-arranged journeys of patients from home to hospital and vice versa (e.g., for radiation therapy). In 1998, 74 478 ambulance journeys occurred in the study area of which 45% belonged to the A1 category and 41% to the B category.

The existing ambulance services and the CPA asked the Municipal Health Services of the Rotterdam Harbour area to investigate which ambulance stations in the Rotterdam Harbour area should be established within the new configuration and to determine how many ambulances would be needed in the area to fulfil the requested ambulance provision. To answer this question the Municipal Health Services contracted Nexpri to undertake an analysis of the effectiveness of current service provision and to recommend how ambulance services within the Rotterdam Harbour area might be improved.

The locations of the 16 existing ambulance stations and the classified total demand for A1 journeys in 1998 for each four-digit postal area in the Rotterdam Harbour

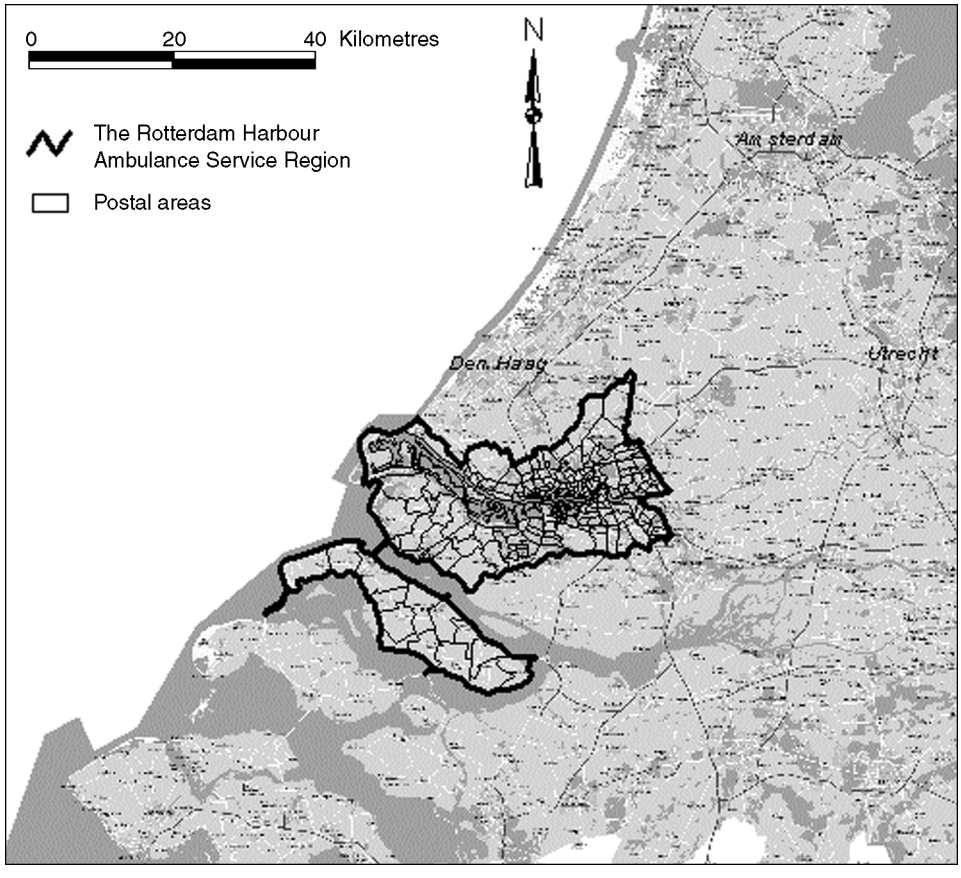

Figure 12.1 *Rotterdam Harbour ambulance service region*

area are shown in Figure 12.2, indicating the high demand intensity (counted number of calls for A1 journeys) in the centre of Rotterdam (the eastern part of the Rotterdam Harbour area) and decreasing towards the perimeter of the area.

Initially, a measure of the effectiveness of the existing ambulance services provided from the 16 stations was calculated with the help of ArcView and ArcView Network Analyst. The service area associated with each ambulance station was constructed by calculating an 8.5 minute travel time buffer based on the road network. To determine the required locations of stations to be able to reach patients within 15 minutes in response to an A1 call for assistance, a 95% confidence interval was calculated based on the Poisson distribution of A1 arrival times. The upper 95% confidence limit was assigned at the legal norm of 15 minutes. This resulted in a mean arrival time of 8.5 minutes within the confidence interval. The time period of 8.5 minutes takes into account the problem of congestion at peak hours as well as the average delay time (2 minutes) between the incoming call for assistance at the ambulance station and the moment the ambulance begins its journey.

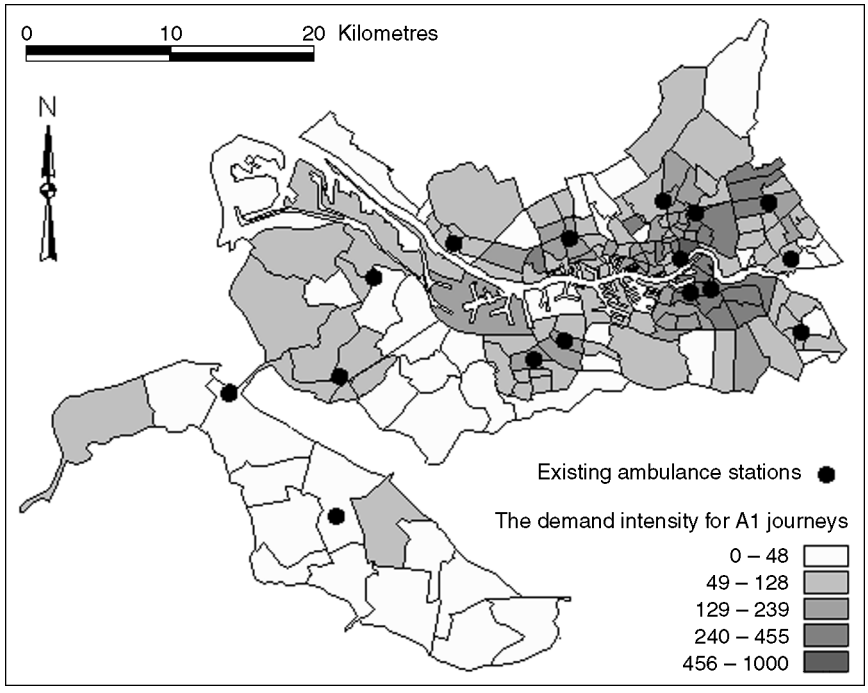

Figure 12.2 *Location of existing ambulance stations and the counted demand intensity for A1 journeys in 1998 per four-digit postal area*

Within the city centre of Rotterdam, the ambulance stations have overlapping service areas. Moreover, the travel time zones indicate that some areas in the more peripheral areas are not covered at all (Figure 12.3). The conclusion of this is that, when taking the threshold value of 15 minutes as a maximum for A1 journeys (8.5 minutes as an average), some parts of the Rotterdam Harbour area are in fact over-served by existing ambulance services and some are under-served. This implies that a more efficient distribution of ambulance services over the Rotterdam Harbour area might be identified.

As a starting point for this redistribution of ambulance station locations, four pre-requisites must be taken into account:

- each part of the Rotterdam Harbour area is potentially suitable as the location of a new ambulance station, so no areas are excluded initially;
- the new locations for the ambulance stations should be situated as close to demand as possible;
- the overlap of service areas of the ambulance stations should be minimised; and
- the total range of the new ambulance stations should cover at least all the urban areas within the Rotterdam Harbour area and preferably also the remaining rural areas within this region.

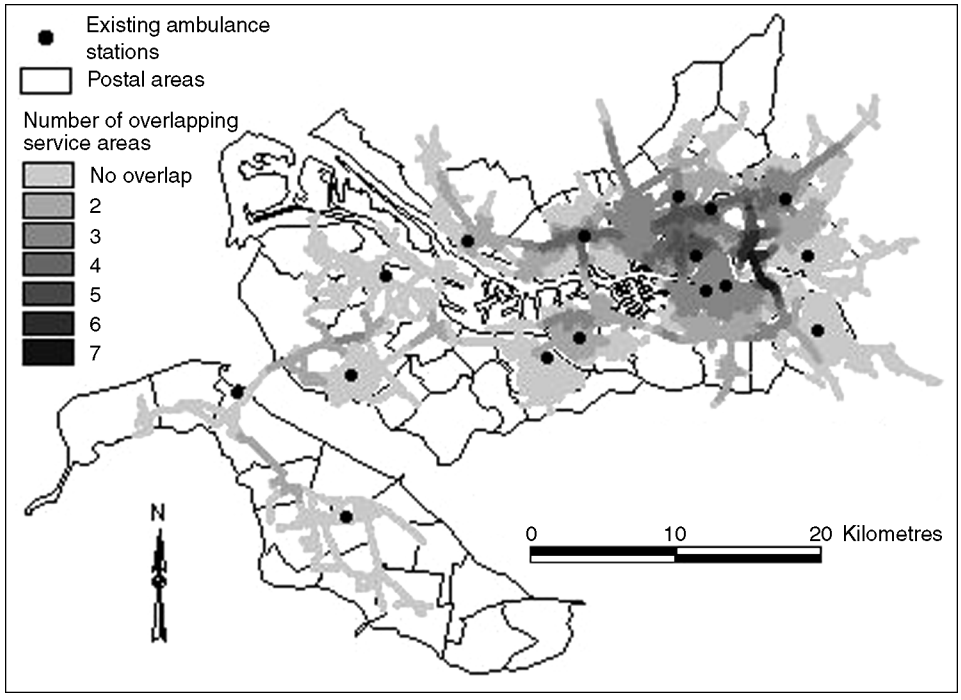

Figure 12.3 *Service areas for current ambulance stations*

Taking these prerequisites into account, network-based analyses have been performed with the help of ArcView and *Flowmap*. ArcView has been used primarily for database management, map-making, and the requisite analytical GIS functions of buffering and network analysis. *Flowmap*, on the other hand, has performed all the additional network calculations and measures that cannot be executed within the proprietary GIS (for additional information concerning *Flowmap*, see http://flowmap.geog.uu.nl). The demand for ambulance facilities is represented by the intensity of requests for ambulance service for each individual postal area. Moreover, use has been made of a hexagonal grid, corresponding in size with the average four-digit postal area. The grid cells represent potential new ambulance locations in the Rotterdam Harbour area. The choice for a hexagonal grid was made because the distance from the centroid of a square grid to the centroids of its neighbouring square grids is different (the diagonal is longer than the vertical or the horizontal), while with a hexagonal grid this distance is equal. In addition, a detailed road network has been used that links all the four-digit postal areas and hexagonal grid cells. Each of the component parts of the road network possesses a travel time, which also takes into consideration the delay time as a consequence of congestion.

Two accessibility measures, the proximity count and the proximity coefficient, have been computed for each of the hexagonal grid cells using *Flowmap*. The proximity count gives an indication of the demand for ambulance services within a user-defined

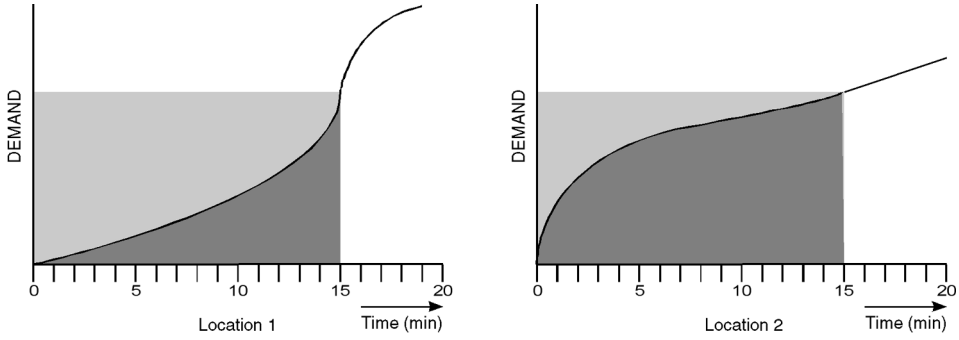

Figure 12.4 *The cumulative location profiles of two alternative sites*

travel time from each hexagonal cell. In this case, the proximity count indicates the intensity of requests for ambulance services within an average travel time of 8.5 minutes. This proximity count can be presented in a map, but also in a so-called location profile (Figure 12.4). A location profile for a potential ambulance station indicates the distance (in this case expressed in travel time) between that location (hexagonal cell) and the cumulative requests for the ambulance service. In fact, the shape of the location profile provides some information on the accessibility of each specific location. A convex profile (as shown in location 2 in Figure 12.4) indicates that the site is relatively close to the demand for ambulance services; a concave location profile (as shown in location 1) indicates that the site is relatively far away from the location of demand for the service.

This relationship can also be expressed in one measure, a so-called proximity coefficient, calculated by expressing the area under the graph (dark shaded area) as a percentage of the total area (dark and light shaded areas). Hexagonal grid cells with high proximity coefficients possess high accessibility to demand and are therefore very suitable sites to locate ambulance stations. The inverse is true for grid cells with low proximity coefficients. Figure 12.5 shows the proximity coefficients – classified on natural breaks – for each of the hexagonal grid cells within the Rotterdam Harbour area (in fact it appears that other classification methods in ArcView showed similar results).

Based on the proximity count maps and location profiles, the optimal future locations of ambulance stations were assigned by trial and error. The proximity coefficients were used to locate the ambulance stations so as to maximise accessibility and minimise the overlap between service areas. It appears that in and near the city centre of Rotterdam these coefficients possess a high value, so represent sites with good accessibility, as we would expect. The siting of ambulance stations in the (south) western part of the Rotterdam Harbour area is mainly driven by the achievement of the fourth prerequisite: that the range of the new ambulance stations should cover at least all the urban areas within the study area and preferably also the remaining rural areas within this region. Figure 12.6 illustrates the proposed sites for the ambulance stations.

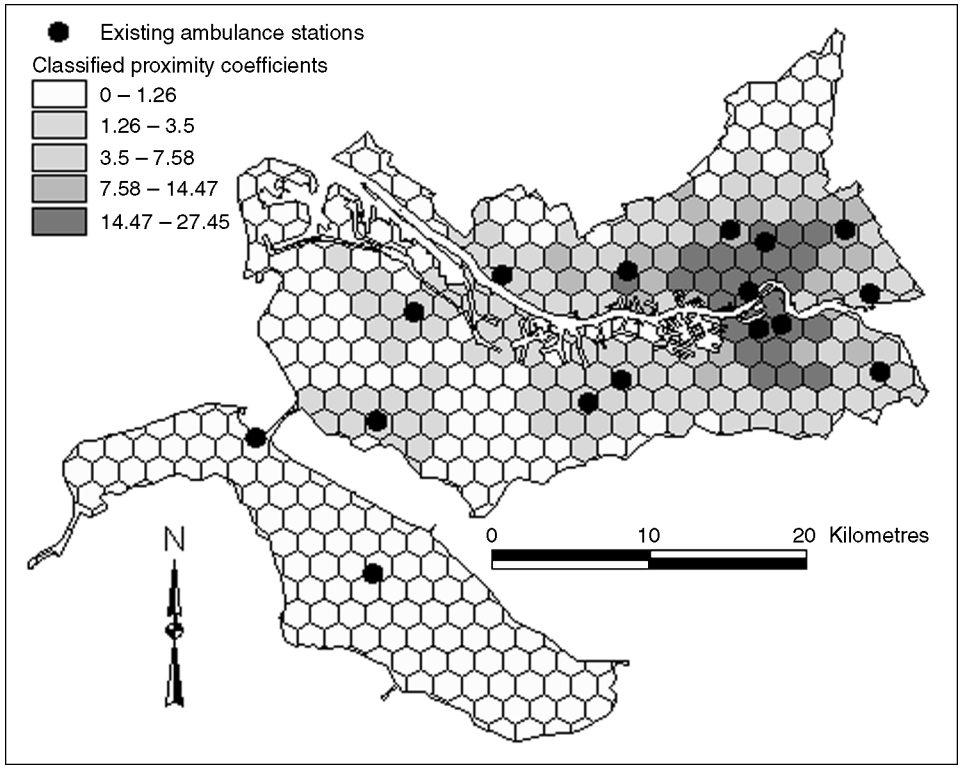

Figure 12.5 *Classified proximity coefficients for hexagonal grid cells in the study area*

This allocation process resulted in a total of 13 newly located stations (three stations less than the initial situation), with a reduction in the level of over-provision (less overlapping service areas) and an improvement in under-provision (fewer areas that do not fulfil the threshold of 15 minute A1 journeys) (Figure 12.7).

The results of this analysis were delivered to and accepted by the Municipal Health Services at the end of 2000. The existing ambulance services, the CPA and the Municipal Health Services of the Rotterdam Harbour accepted the results of the study. The political debate about the reconstruction of the ambulance service network is still in progress.

12.4 Further Developments

The analysis conducted for the client shows the solution of a real-world planning problem by applied geo-ICT research with the help of more fundamental research than had been required to create *Flowmap* in the first instance. Although acceptable to the Rotterdam Municipal Health Services, the research undertaken was not particularly innovative and begs the question of whether it is possible to improve on the proposed facility locations.

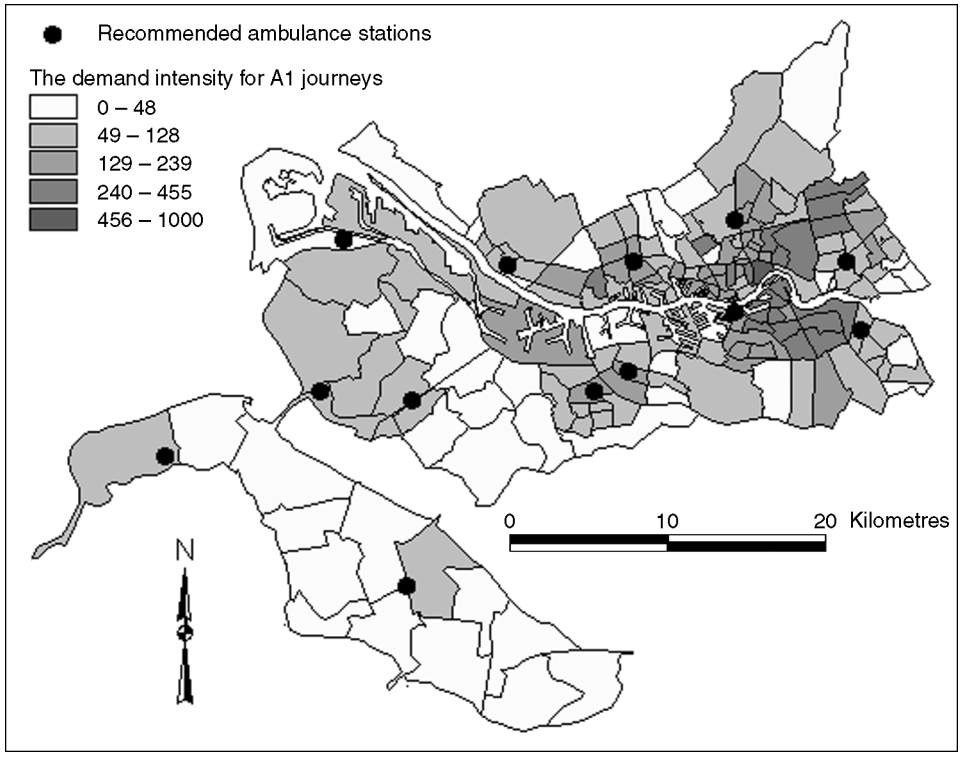

Figure 12.6 *The proposed sites for ambulance stations*

One development is to make use of the so-called 'alternate' algorithm to examine the distribution of ambulance stations. This alternate algorithm is an approach to optimisation that can be adapted to a GIS environment when dealing with the impedance associated with transport networks. As such it can be considered a combination of different approaches to the problem of facility siting. The basic principle of this adaptation is to 'tessellate' space into a large number of cells and to calculate the optimisation criterion for all the cells. The most extreme value found in a catchment area is the best location for a new site. Where the best site differs from the current site it replaces the current site. Thus, new catchment areas and best sites should be calculated until no more substitution takes place. This procedure does not guarantee a true optimal solution; there is some sensitivity to the MAUP problem and the procedure may end in a suboptimal solution. However, in general, it gives a good indication of what can be achieved through optimisation.

When performing an optimisation, it is necessary to be aware that there is not just one optimal solution, but there may be several solutions, depending on the 'target' function that is to be minimised. In the case of ambulance stations, for example, one can handle at least two different target functions. On the one hand, there is a good case for minimising the mean unweighted travel cost, ensuring the best accessibility for the whole area. On the other hand, one can minimise the mean travel cost

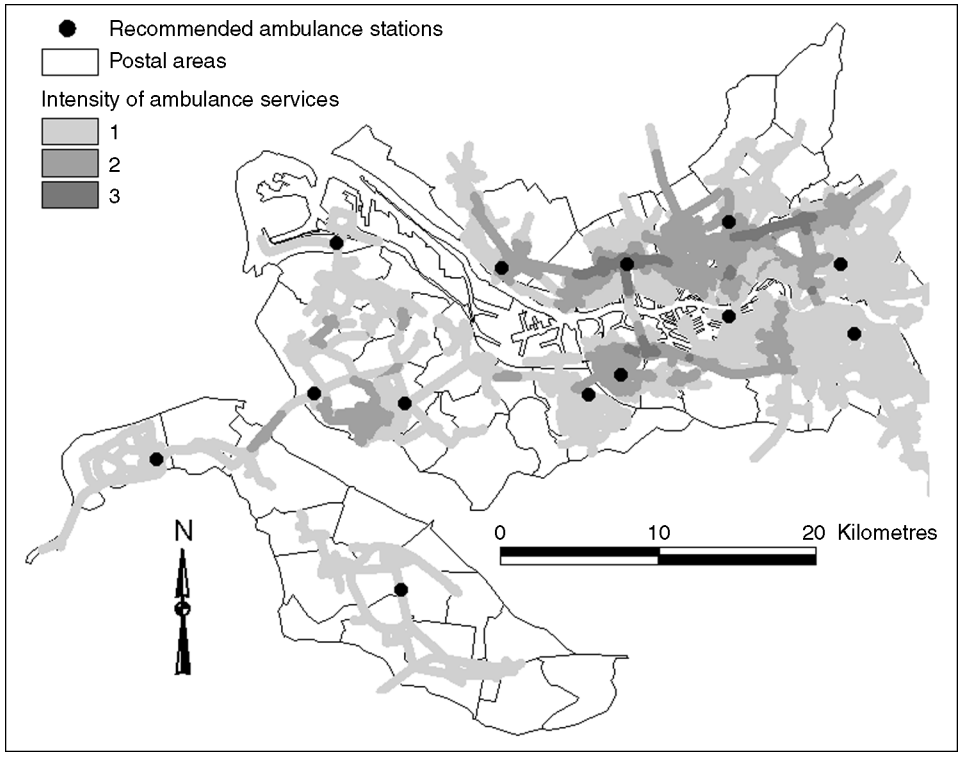

Figure 12.7 *Service areas of proposed ambulance stations*

weighted by the distribution of demand, ensuring the best accessibility where demand is highest. In the first case, sites tend to be found towards the centre of their catchment areas. In the second case, sites are more oriented towards the centre of gravity of demand within the catchment area. These two points may very well not overlap and as a consequence the choice of target functions can result in very different solutions.

The consequences of handling different target functions can be exemplified using the problem of siting ambulance stations. We have divided the study area into almost 1400 hexagonal cells each with a radius of 50 metres. Each hexagon has been allocated to the nearest of the proposed 13 ambulance stations. The study area is thus divided into 13 catchment areas as shown in Figure 12.8a.

Based on these initially proposed 13 catchment areas, some access time statistics have been calculated (Table 12.1). These statistics represent the base position shown in the second column. If the target criterion is to minimise the mean area access time without weighting, the catchment areas in Figure 12.8b are derived and the access times change accordingly. The mean area access time is reduced from 9.76 to 8.26 minutes by relocating 12 of the 13 proposed ambulance stations. This optimisation procedure can be repeated again but on this occasion under the criterion of minimising the mean travel cost weighted with the distribution of demand (Figure 12.8c).

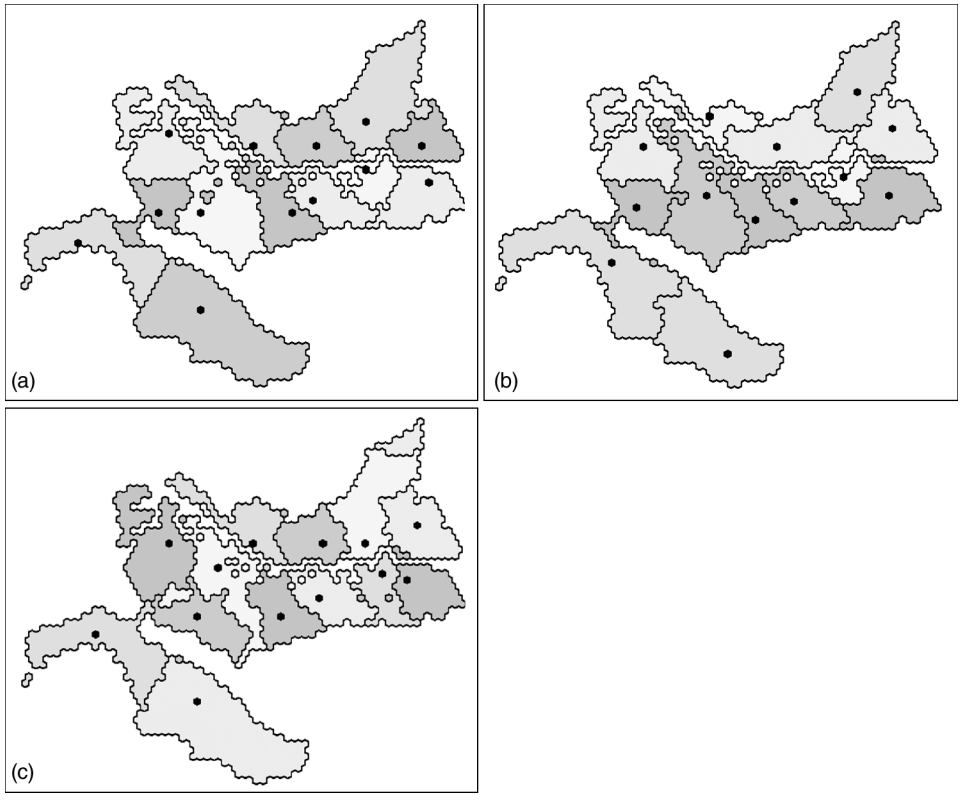

Figure 12.8 *Catchment areas: (a) proposed initially, (b) derived from minimising unweighted mean travel costs and (c) derived from minimising weighted mean travel costs*

Table 12.1 *Access times under different target criteria*

	Initial proposals (minutes)	Minimise mean area access time (minutes)	Minimise mean demand access time (minutes)
Mean area access time	9.76	8.26	9.29
Mean demand access time	7.09	6.70	5.62
Worst-case access time	43.22	38.24	34.59

This ensures the best accessibility where demand is highest. Based on the resulting catchment areas, the mean demand access time is reduced from 7.09 to 5.62 minutes by moving 12 of the proposed 13 ambulance stations.

This approach, using the alternate algorithm, can be applied in all cases where the relocation of service facilities, possibly in combination with an addition or reduction, is at stake. The added value of this kind of analysis is not so much the maps shown

in Figure 12.8, but primarily the statistics that go with these maps. Similar statistics can be calculated for all sorts of scenarios based on the relocation of fewer ambulance stations, in which case the optimal statistics provide a yardstick to measure the effect of each of the scenarios. Although of academic interest to continue such analysis until the optimal location has been found, it should be stressed that in practical situations accessibility rarely is the only factor playing a part in the decision-making process. As a consequence, the trend surface that can be constructed around the optimal location is of far greater importance as it can be combined in a multi-criteria fashion with other criteria to arrive at a decision space that provides the decision-maker with some direct insights.

12.5 Conclusions

This chapter has provided a particular example of the benefits of a reciprocal relationship between fundamental and applied research in the context of public service planning. An analytical tool (*Flowmap*) and a proprietary GIS have been used to generate a set of proposals for the relocation of ambulance stations in central Rotterdam. Some additional developments have been reported to show more state-of-the-art capabilities and possibilities.

In relation to the specific policy problem, efficiency has been improved by reducing the number of ambulance facilities from 16 to 13. Moreover, the effectiveness has been improved by a reduction of the areas experiencing either over-provision or under-provision of service. In this way the goals of the applied research have been achieved and have become input into the policy process. The outcome of the political process is still unclear, although the upcoming pressing financial situation undoubtedly will push in the direction of an efficiency operation in which the outcomes of this research will be of help.

As far as the interrelationship between fundamental and applied geo-ICT research is concerned, two final conclusions can be drawn. First, without the input of the former and its outcome (*Flowmap*), the research question would have had to be answered in a far more rudimentary way. In fact, *Flowmap* offered different tools that substantially improved our insight into the planning problem and the generation of a solution. Second, the research performed can only be attained by individuals working closely together on fundamental and applied research. It is the direct contact that is of additional value to both parties and which will result in novel solutions. This collaboration, the solution that has been produced and the insights generated through the research process, give impetus to undertake further applied work to support public service planning.

A Probability-based GIS Model for Identifying Focal Species Linkage Zones across Highways in the Canadian Rocky Mountains

Shelley M. Alexander, Nigel M. Waters and Paul C. Paquet

Abstract

Road fragmentation is a concern for the survival of sensitive species within and adjacent to protected areas in the Rocky Mountains of North America. The Idrisi Decision Support Module and Dempster–Shafer theory are used to establish potential linkage zones for lynx and wolves across the unmitigated sections of major highways in Alberta. Wolves and lynx acted as focal species for large and medium carnivore guilds, respectively. Linkage zones, derived from probability surfaces, showed minimal overlap between these two species. This suggests that the spatial requisites of crossing structures for wildlife are guild-specific at a minimum and mitigation should be designed to capture multiple guilds. Spatial probability modelling is a powerful method for representing habitat associations, determining ecologically important linkage zones and generating testable hypotheses. The uncertainty inherent in resource management and planning is reduced and managed by using such innovative spatial modelling tools.

13.1 Introduction

Road, rail, power and telecommunication networks create a grid upon landscapes commensurate with the extent of human endeavour. These networks are vital to our economy and provide a means to expand the human experience and improve travel

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

convenience. Associated with these 'benefits' is the ecological cost of habitat fragmentation, which occurs when contiguous patches of habitat are divided into smaller, isolated units (Andren, 1994). Most wildlife species have evolved resilience, to the extent that they can endure ecological change caused by natural fragmentation (e.g., floods, rockslides, rivers) (Weaver *et al.*, 1996). However, human fragmentation tends to occur with an intensity and extent unprecedented in natural systems, and some species fail to persist when confronted with this human disturbance.

Of the previously listed networks, roads carrying traffic may have the greatest cumulative disturbance effect. In addition to habitat loss and isolation, vehicular traffic can kill animals that attempt to cross between isolated habitats, and may cause others to avoid crossing roads for fear of detection. In ecology this phenomenon is termed 'the barrier effect' (Noss and Csuti, 1997). The barrier effect can alter animal community composition, create meta-populations, reduce biological diversity and increase the threat of extinction (Trombulak and Frissell, 2000; Spellerberg, 1998; Forman and Alexander, 1998; Bascompte and Solé, 1996).

In recent years, 'road ecology' has become more prominent in ecological investigations, as shown by conference series such as the International Conference on Wildlife Ecology and Transportation (Evink *et al.*, 1998a,b, 1999) and the 'Roads and Rails' workshop series (Columbia Mountain Institute of Applied Ecology, Revelstoke, British Columbia 1997–2001). Reducing wildlife mortality on roads has been one focus of previous studies, as roadkill can pose a serious threat to species with small populations or low resilience. Low resilience results from life history traits, which include, among others, late age of first reproduction, low reproductive rate, and low fecundity (Weaver *et al.*, 1996). For example, a species that cannot reproduce rapidly enough to offset road mortality will suffer population decline. Over time and across space, such a decline could force a population into extinction. Road fragmentation has been identified as an extinction concern for carnivores in and adjacent to protected areas in the Rocky Mountains (Noss *et al.*, 1996). Specifically, roadkill has been noted as one of the largest known sources of mortality for wolves within and outside of protected areas of the Canadian Rockies (Noss *et al.*, 1996; Banff-Bow Valley Study, 1996).

The creation of linkages between isolated patches of habitat is one method for improving biotic exchange across barriers (Forman and Alexander, 1998; Swart and Laws, 1996; Fahrig and Merriam, 1995). In the present study region (described below) few sources of empirical data document the effects of traffic on wildlife movement or the spatial design requisites for placing linkages (highway mitigation) across highways. The present research was designed to address these deficiencies in knowledge and understanding of landscape connectivity for multiple species in the Canadian Rocky Mountains.

In this study, wildlife movement was documented in four different road fragmented environments in the Rocky Mountains of Alberta. Wildlife movement was measured, using snow tracking surveys, across and adjacent to the Trans-Canada Highway (TCH) (14 000 vehicles: Annual Average Daily Traffic, AADT) and the 1A Highway (4000 AADT) in Banff National Park, and the Highway 40 (5000 vehicles: Summer Average Daily Traffic, SADT) and Smith Dorrien/Spray Trail (2500 SADT) in Kananaksis Country. In the study area (described subsequently), little empirical

Table 13.1 *Summary of objectives*

Objectives	General hypotheses/methods
Identify landscape attributes predicting wildlife movement for individual species	Species preferences are defined by a probability of relationship to habitat attributes
Test for species interactions	Species interactions will be analysed using GIS
Create a linkage zone model using evidential reasoning	Application of IDRISI GIS and D–S weight-of-evidence modelling

research exists on multiple-species crossing behaviour before road expansion, on the effects of traffic on wildlife movement or on the spatial requisites for crossing structures.

The modelling effort presented in this chapter is unique. This work provides an original application of Bayesian (Dempster–Shafer, D–S) inference to determine optimal road crossing sites (i.e., linkage zones across highways), generates additional working hypotheses about the efficacy of wolves and lynx as focal species, and creates a platform for the integration of spatial wildlife data in highway planning. The matrix in Table 13.1 specifies the objectives of the research relative to developing the linkage zone model, and presents the general hypotheses or methods by which objectives were met.

The following section explores the literature pertaining to road fragmentation effects, wildlife habitat preference, modelling habitat selection using GIS and the integration of Bayesian analysis in defining wildlife linkage zones across highways.

13.2 Background Literature

13.2.1 When Roads and Wildlife Corridors Collide

This research focused on the interface between wildlife movement corridors and highways, and the identification of optimal sites for placing wildlife crossing structures (i.e., mitigation). A number of key literature reviews have summarised research on road-related, ecological disturbance effects, including Trombulak and Frissell (2000), Jackson (1999), Spellerberg (1998) and Forman and Alexander (1998). *The Proceedings of the International Conferences on Wildlife Ecology and Transportation*, ICOWET (e.g., Evink *et al.*, 1998a,b, 1999) offer examples of recent advances. Research trends have focused on mortality, pollution/contamination effects, and mitigation.

Highway mitigation, which refers to the implementation of measures that reduce wildlife mortality and/or facilitate movement across highways, and spatial trends in mortality remain at the forefront of road fragmentation studies. Mitigation effectiveness, the barrier effect and placement requisites remain little studied (Spellerberg, 1998; Forman and Alexander, 1998). Community studies that address movement

requisites of multi-species are rare or non-existent, with the exception of the present study. The use of GIS has featured prominently in the recent *Proceedings of ICOWET* (Evink, 1999) and non-spatial decision support systems have become focal (Alexander and Waters, 1999; Smith, 1999; Maurer, 1999).

13.2.2 GIS Applications in Mitigating Road Effects

Habitat modelling has been advanced by the advent of geographic information systems (GIS), which greatly increase the scale, complexity and precision of spatial analysis. GIS is an excellent medium for predicting patterns of biological diversity, identifying areas of conservation significance and assessing the habitat potential of unstudied sites (Lenton *et al.*, 2000). In the region, studies have applied GIS in defining habitat selection by wildlife (e.g. Alexander and Waters, 2000a; Paquet, 1993). Relatively few have examined the spatial attributes of road crossing sites (Alexander and Waters, 2000b; Singleton and Lehmkuhl, 1999). Beyond the present research, no studies have examined multi-species interactions or predicted spatial linkages at a community level. GIS analysis has been used to identify mortality hotspots in determining placement of highway mitigation, although mortality hotspots have never been demonstrated to reflect crossing preferences. They simply measure mortality, not crossing attempts. Intuitively, these sites may reflect road alignment or curvature effects, rather than animal preferences. These road features may increase the likelihood of vehicle–wildlife collision and give the illusion that more animals cross at these sites.

Modelling the spatial requisites of movement corridors can be used to ameliorate the barrier effect, by confirming mitigation sites that have a high probability of selection for use by wildlife. Jackson (1999) summarises the types of mitigation popularly employed including modified drainage culverts, wildlife/drainage culverts, upland culverts, oversize stream culverts, expanded bridges, viaducts, wildlife underpasses, wildlife overpasses and fencing. Efficacy studies have demonstrated that species tolerances to structural design are highly variable (Jackson, 1999). Expanded bridges (open spans), viaducts and wildlife overpasses appear to be the most effective across communities in the Rocky Mountains of Banff National Park (Alexander and Waters, 1999). Placement of mitigation is argued as the most important component of mitigation success, followed by mitigation design. Jackson (1999 and all included references) lists the following efficacy criteria: size and openness, placement, human disturbance, substrate, vegetation cover, moisture, hydrology, temperature and light.

Barrier effects and mitigation efficacy vary by species (Trombulak and Frissell, 2000). For terrestrial mammals, GIS analysis helps identify the spatial attributes (habitat selection) likely to be suitable for movement corridors for individual species, guilds or community assemblages of species. Habitat selection is detailed in the next section and the use of GIS to infer habitat selection is presented in Section 13.3.3.

13.2.3 Habitat Selection: Spatial Attributes that Define Movement Corridors

Habitat selection modelling is predicated on the assumption that wildlife 'select', 'prefer' or 'avoid' specific habitat attributes (e.g., they may select closed vegetation for security or avoid roads). The selection of habitat may be inferred by examining use versus the availability of habitat. Peek (1986) identified 'ultimate factors' and 'proximate factors' as two facets of habitat selection. Ultimate factors include food, cover or shelter from enemies and adverse weather, nesting or denning sites and inter-specific competition. Proximate factors may include stimuli of landscape, terrain and competitors.

To exemplify, habitat selection by wolves was described as 'a complex interaction of physiography, security from harassment, positive reinforcement (e.g., easily obtained food), population density, available choice, and distribution theory' (Carroll *et al.*, 2000). In a multi-species environment, such selection must be explored for individual species. Alternatively, the interactions between species may be investigated to determine the degree to which a given focal species may act as a surrogate for others. In this study, relationships to habitat metrics and the spatial interaction of species were investigated for each study species. These results are the topic of a different paper (Alexander *et al.*, 2003, in prep). The latter analysis allowed inference on which species is the 'best surrogate species' and identified three focal species, representing three functional ecological scales: marten – micro-scale; lynx – meso-scale; and wolf – macro-scale.

13.2.4 Bayesian Approaches in Ecological Modelling

Ecologists are revisiting the use of classical statistics in the evaluation of ecological phenomena (Ellison, 1996). Ellison (1996) argues that this introspection is due to the fact that the central assumptions of classical statistics are violated in ecology: true randomisation is difficult, replication is often small, misidentified or nonexistent and ecological experiments rarely are repeated independently. Alternatives to classical statistical tests have been presented, and include variants on probability theory (e.g., Bayesian probability, Dempster–Shafer theory) and information theory (e.g., Bayesian information criterion, Akaike's information criterion) (Wade, 2000; Anderson *et al.*, 2000).

The application of information and Bayesian theory is neither new, nor confined to conservation biology, but is popular in current ecological research (Anderson *et al.*, 2000). For examples of relevant ecological applications, see Bartel (2000), Anderson *et al.* (2000), Dragicevic and Marceau (2000), Urbanski (1999), Ellison (1996) and Pearl (1987). The integration of Bayesian theory into GIS for use in wildlife management and ecosystem planning is far less developed. One notable example is the work of Lenton *et al.* (2000), which predicted species biodiversity in Africa.

A central assumption of these alternative approaches is that testing null hypotheses adds little to scientific understanding (Anderson *et al.*, 2000; Ellison, 1996). Ellison (1996) argued that 'we normally expect to accept a single ecological alternative hypothesis by rejecting a statistical Ho: otherwise we would not have done the

experiment in the first place'. Anderson *et al*. (2000) add that nearly all null-hypotheses are false on *a priori* grounds and that *p*-values are dependent on sample size (i.e., with a large enough sample one can always reject a null-hypothesis), even though such statements might be controversial. They argue that the former points to the difference between statistical significance and biological importance. Testing prior hypotheses (Ellison, 1996) or multiple working hypotheses (Anderson *et al*., 2000) has been suggested as an alternative to classical statistical approaches. Prior hypotheses are based on the current state of knowledge about underlying distributions of the data. These priors are compared with new information to see if the new information adds to the current knowledge. Multiple working hypotheses (Anderson *et al*., 2000) exhaust all possible combinations of explanatory variables for a given phenomena, such as species distribution. In this case, the range of hypotheses (i.e., combination of predictive variables) is compared using an information criterion, to provide a rank that indicates the optimal combination of variables.

13.2.5 Integrating Bayesian Theory and GIS in Habitat Assessment

Research on wolves in Banff National Park (BNP) indicated that landscape features, such as slope, aspect, elevation and vegetation type can influence movement (Paquet, 1993). For example, steeper slopes require greater energetic expenditure for an animal to cross and may result in the displacement of movement around a steep feature. Alternatively, dense vegetation may provide escape or hiding cover and may change a movement path when an animal fears detection or predation. A disproportionate use of physiographic attribute classes is assumed to reflect a 'preference' for those landscape elements. A 'preference' suggests that the animal is selecting a specific attribute class over another. Attribute classes are aggregated values within an attribute. For example, for the variable 'aspect', which ranges from 0 to 360 degrees, the 'aspect classes' are groupings of aspect values, such as those labelled north, which includes all aspect values between 337.5 and 22.5 degrees.

The statistical evaluation of preference is often handled with techniques, such as logistic regression, which treat species occurrence as a binary value representing presence as (1) or absence as (0) (Pearce and Ferrier, 2000; Bartel, 2000). Although there are variations in analytical procedures, often a site's presence and absence have been defined by stating a threshold count of 'wildlife sign' that indicates presence. Sites that have a number of observations of a species that exceed a threshold are considered 'presence' sites (1), those below the threshold are 'absence' sites (0). For instance, if the greatest number of species observed for all sites surveyed is 10, the analyst may specify that any sites with greater than five observations indicate presence (value 1) and any sites where there were fewer than five are discarded from the sample (value 0).

Binary data (1,0) are then subjected to techniques such as logistic regression. In this approach, the imposed threshold that defines the difference between presence and absence is arbitrarily defined: a value of 1 might be five tracks, 20 tracks or any number in between; a value of 0 might be assigned to any sites with fewer than five tracks. This assumption that sites with fewer than five tracks are not 'used' may be

an ecologically incorrect assumption. Moreover, Conroy and Noon (1996) argued that although presence provides affirmation of occurrence, absence does not provide any information – it could be an artefact of the sampling effort.

Binary approaches do not represent adequately the spectrum of preferences observed within landscape attributes, may needlessly discard information and are inherently indefensible because, in most cases, habitat attractiveness and preference for movement corridors exists as a continuum. For example, species may use sub-optimal habitat during regular foraging or movement (Tischendorf and Fahrig, 2000) because habitat is most often heterogeneous. In this study, highly suitable lynx habitat was spatially discontinuous and lynx traversed areas of low habitat suitability when moving between highly suitable patches. As an alternative to binary approaches, detailed above, we used a Bayesian classification approach that treats habitat use as a continuous probability. This approach considered relative track density by attribute classes and the probability of use was indicated by the weight-of-evidence of a trend in habitat use, based on the difference between observed and expected track counts for each attribute class. Thus, instead of specifying a threshold value, all track density values are considered important in predicting the presence of a species.

Fuzzy set theory is well suited to problems that deal with habitat analysis, where there is 'no clear separation between areas that are suitable and those that are not' (Bartel, 2000; Eastman, 1999; Zadeh, 1965). Although typically applied to spatial boundaries, such as problems related to soil classification (Dragicevic and Marceau, 2000), fuzzy set theory is extended easily to describe the fuzziness in species associations with habitat types. Fuzziness, as a measure of inconclusiveness (i.e., lack of exact separation in selection), is handled well with Bayesian probability or its variant D–S theory (Eastman, 1999). D–S theory was developed by Bayes' researchers to handle absence of information (Gordon and Shortliffe, 1985). The distinction between Bayesian probability theory and D–S theory is elaborated in the methods section below.

13.3 Study Area and Methodology

13.3.1 Introduction

Research was conducted in Banff National Park (BNP) and Kananaskis Country (KC), Alberta. Figure 13.1 shows the study area. BNP and KC are approximately 110 kilometres west of Calgary. BNP is 6640 square kilometres in area and is the most heavily visited national park in Canada with over 5 million visitors per year (Banff Bow Valley Study, 1996). KC is a 4250 square kilometres Forest Landuse Zone that is reserved for hunting, ranching, resource development, recreation and tourism activities. Peter Lougheed Provincial Park (PLPP) is a 514 square kilometres park in the northwestern corner of KC, where hunting and resource development are not permitted, with the exception of ongoing maintenance of existing hydro-electric projects. The study region is characterised by rugged mountainous terrain, steep valleys and narrow (2–5 kilometres), flat valley bottoms.

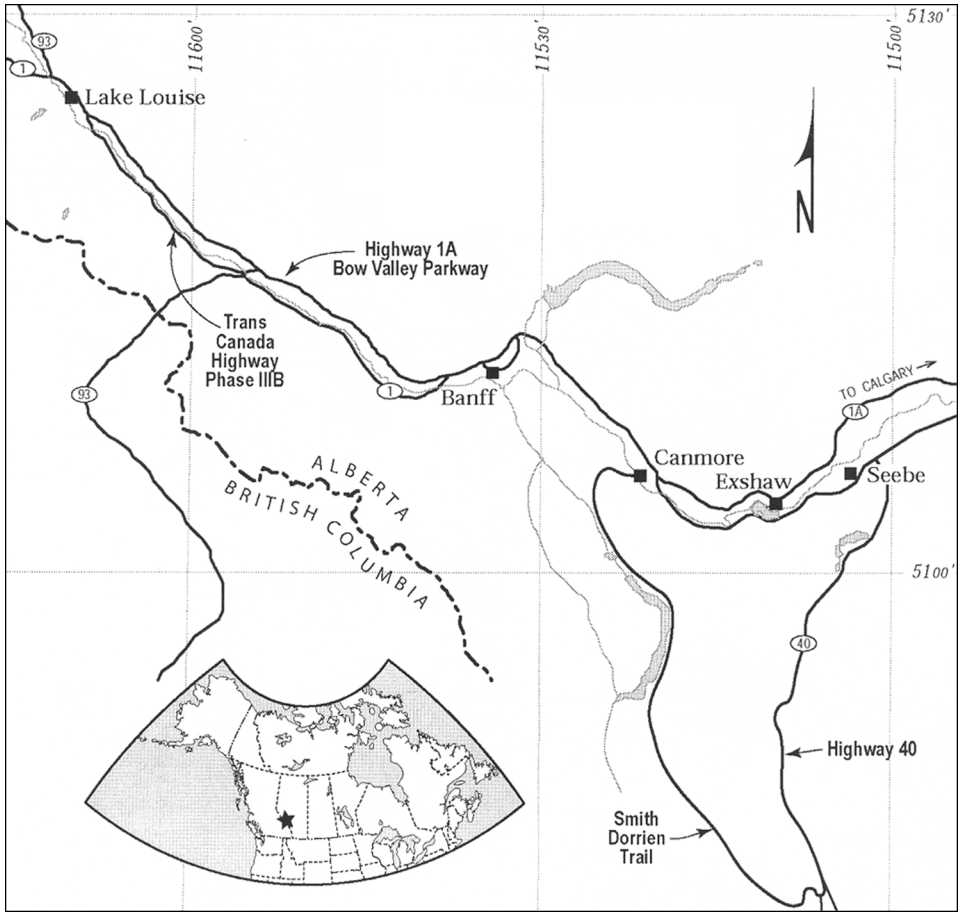

Figure 13.1 *Study area map for wildlife linkage zone model*

In BNP, track data were collected on the non-twinned (two lane), unfenced section of the Trans-Canada Highway (TCH) from Castle Junction to the British Columbia border, and along the entire length of the Bow Valley Parkway (1A). This section is termed Phase IIIB of the TCH 'twinning project' in BNP. Apart from the TCH and 1A the study area transportation corridor contains the Canadian Pacific Railway (CPR) main line, Trans-Alta power line, and a few seasonal campsites and tourism facilities. The BNP study roads do not have structures that facilitate the movement of wildlife over or under the highway or to reduce wildlife–vehicular collisions (i.e., it is not fenced). The previous structures are termed 'highway mitigation'.

In KC, research was conducted on Highway 40 (Hwy 40) and the Smith Dorrien/Spray Trail (Figure 13.1). Highway 40 is a paved two-lane highway with moderate traffic volumes, and the Spray Trail is a gravel two-lane road primarily offering access to primitive backcountry activities. The service areas of both

transportation routes are under pressure for recreation and tourism development, which will result in increased traffic volumes. With the exception of wildlife crossing signs, neither route is mitigated for wildlife.

13.3.2 Methodological Framework

Figure 13.2 shows the methodological framework for production of the final linkage zone model. This image is useful for understanding each of the following steps of model creation described below.

Research was conducted during the winter months (from November to April) over three years (1997–2000). Roads were surveyed between 18 and 48 hours after the end of a snowfall. Tracks in snow were observed from a field vehicle, while driving slowly (15–20 km/h) and verified on foot (Van Dyke *et al*., 1986). Tracks entering or exiting the road right of way were recorded for 13 terrestrial species, including the two focal species presented in this paper, wolf (*Canis lupus*) and lynx (*Felis lynx*). Tracks of other species were observed but not reported herein, for coyote (*Canis latrans*), fox (*Vulpes vulpes*), cougar (*Puma concolor*), bobcat (*Felis rufus*), marten (*Martes americana*), fisher (*Martes pennanti*), wolverine (*Gulo gulo*), elk (*Cervus elaphus*), moose (*Alces alces*), sheep (*Ovis canadensis*) and deer (*Odocoileus virginianus* and *Odocoileus hemionus*). Tracks were only observed in the right of way, as vegetation obscured tracks beyond this area. It was assumed that tracks entering this area were of animals attempting to cross the road.

Data collected at crossing sites included an Easting/Northing (UTM), which was collected with a handheld GPS (Garmin II, non-differentially corrected). Other data collected included species type, number of individuals and a range of behavioural parameters that are not analysed here. Repeat road surveys were conducted, as conditions permitted, approximately 3–4 days after initial surveys until the next new snowfall. Transects of one-kilometre length were fixed perpendicular to each road treatment and surveyed for tracks of the above study animals and in addition for hare, weasel and squirrel. Again, only the results of wolf and lynx are used for the probability mapping section in this chapter. Transects are straight survey lines across a study area, in this case marked every few metres with flagging tape on trees. Flagging tape was placed every 50 metres, which allowed researchers to repeat survey exactly the same area. Forty transects were surveyed randomly in Banff National Park and twenty in Kananaskis Country, between 18 and 108 hours after snow and immediately following each road survey (Thomson *et al*., 1988). Transects were surveyed on foot and required an extended survey period relative to the road survey. A one-metre resolution differential GPS (Trimble Pathfinder) was used to collect UTM coordinates for every 50 metre interval start point, for every transect. These data were used to geo-reference track counts for import into the Idrisi GIS (Eastman, 1999) for spatial modelling. Data were standardised by sampling effort, to minimise the effects of sampling bias. For example, if one site was surveyed five times and another three times, the total track count for each site was divided by the number of samples per site (i.e., five and three) to standardise between the transect sites.

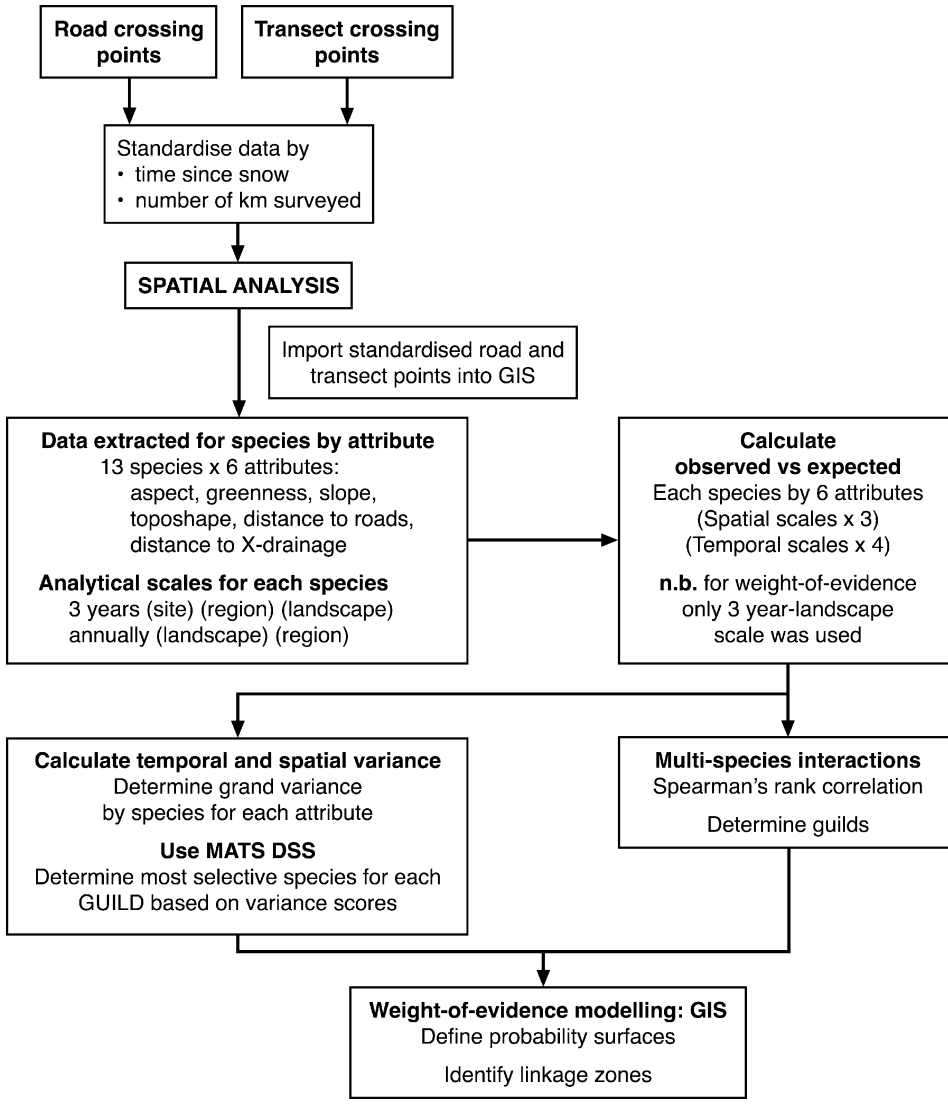

Figure 13.2 *Flowchart of model development*

13.3.3 Inferring Selection from Use Density

Density of tracks by attribute classes (i.e., track density in each aspect class) was determined by using the EXTRACT function in Idrisi (Eastman, 1999). With the EXTRACT function, the total track density by each attribute class is summarised in table format. These data tables were saved as text files and imported into Excel (MS Office 97).

A study frame (i.e., the spatial extent of area actually surveyed) was used to extract the distribution of class types within each attribute (e.g., north class or aspect). The study frame was a Boolean image, in which any site with a value of one (1) was an area that was sampled, any site with a zero (0) value was not sampled. The use of the frame is essential to avoid issues of 'framing bias' and 'ecological fallacy', which can yield incorrect results about habitat selection (Verbyla and Chang, 1994). The output from this operation provided a summary of total cell counts by attribute class. The extracted study frame values (i.e., the distribution of attributes samples) were used to determine the proportional representation of each attribute class in the sampling frame, which was then used to determine the expected number of tracks for each attribute class, as a proportion of total tracks observed. A value was then derived to indicate over- and under-use of attribute classes. This value was determined by subtracting the expected from the observed track density and dividing by the expected density (*N*) for each sub-class. Table 13.2 shows the distribution of marten points by aspect class for the three years. Column numbers are indicated at the top.

The first column of Table 13.2 indicates the attribute classes (here using the example of aspect classes). In this case, the aspect classes represent groupings of aspect values that are similar. For example see the row North (column one) in Table 13.2, where north aspect is defined as all slopes that face the directions 337.5 to 22.5 degrees around north (0 degrees); northeast is 22.5–47.5 degrees, and so on. Column two shows the total number of tracks observed by aspect class, as tabulated from the EXTRACT function in Idrisi. Column three is the expected track count, the derivation of which is discussed below. The fourth column shows the total sampled raster cells for each aspect class, followed by the proportional representation of the total number of cells (column five). The cells represent locations on the landscape that were sampled. The attribute value on any cell is an average over the cell (or pixel) resolution, which in this case is 30 metres. The proportion in column five was used to derive the expected track count (column three) by multiplying the proportion by the total number of marten tracks observed. Column five sums to 1.00 when the error

point (67 points in the Background class 0) are considered. The difference between observed and expected values appears in column six, and finally, the observed minus expected value is divided by the total expected (column three) in each class, to produce the values in the seventh column. This provides a relative index of observed versus expected use for comparison between scales of analysis and between species.

In Table 13.2, over-use is indicated in column seven by a positive value and under-use by a negative value. It was assumed that over or under-representation of tracks by attribute class has biological significance and represents a continuum of use by species of attribute classes. Column seven values were ranked by their relative level of over- and under-use. Over-use defines a greater amount of use of a habitat class than expected, based on its availability. Alternatively, under-use implies less use than expected, based on availability. To exemplify, in column eight, the highest rate of under-use (rank 9) is found in the class northwest, and the highest rate of over-use (rank 1) is found in class northeast. The rank scores in column eight provide a means to treat the nominal data as a linear variable, when determining the probability of detection for each attribute class and creating a probability surface in the GIS, for the aspect variable. This procedure was carried out for all 13 species sampled (refer to Section 13.3.2).

13.3.4 Dempster–Shafer Weight-of-Evidence Modelling

A univariate analysis of track occurrence by landscape attribute indicated that the probability of detecting carnivores is a function of slope, aspect, greenness and toposhape. Two other variables, distance to cross drainages and distance to roads were evaluated, but yielded no trend in selection or avoidance. Slope and aspect are surfaces derived from a DEM (30 metre resolution). Greenness was derived from a Landsat TM image using a Tasselled Cap (TC) analysis. TC is a simple linear index produced by taking the weighted average of the input bands from a TM Image (Richards and Jia, 1999). TC Greenness is proportional to vegetation productivity, where higher greenness values are assumed to represent better suitability. Toposhape is a measure of surface curvature that defines the landscape as a series of critical features, including peaks, ridges, saddles, flat areas, ravines, pits and five types of hillsides – convex, saddle, slope, concave and inflection (Eastman, 1999; Warntz and Waters, 1975).

Probability functions describing optimal conditions for habitat linkage zones were derived from the index of selection and avoidance. These are represented by the over-use and under-use observed for certain habitat classes, such as those shown in Table 13.2, previously. The decision rules and probability functions are described below.

Probability surfaces were constructed for wolves and lynx using the FUZZY module in Idrisi (Eastman, 1999). Although 13 species were studied in this research, only the probability surfaces for wolves and lynx are presented in this chapter. For habitat relationships and probability maps relating to other species, refer to Alexander (2001). An example of how decision rules are translated to probability curves is shown in Figure 13.3, which shows the aspect classes and ranks, which were identified previously in Table 13.2 (see also the discussion in Srinivasan and Richards,

Aspect	Rank	Sign
North	7	-
Northeast	1	+
East	3	+
Southeast	4	+
South	2	+
Southwest	5	+
West	8	-
Northwest	9	-
Flat	6	-

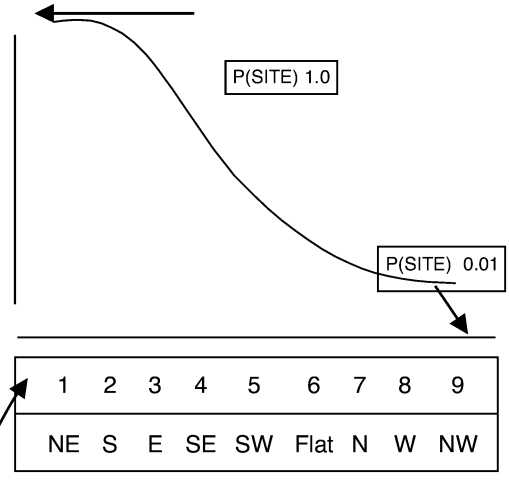

Figure 13.3 *Species use by aspect*

1990). The sign indicates the selection value (see description of Table 13.2), and the rank at which the sign changes may be used as an inflection point on the probability curve.

In the Idrisi GIS software, fuzzy sets can be expressed by sigmoidal, j-shaped, linear and user-defined probability curves. The curve indicated in Figure 13.3 is a monotonically decreasing sigmoidal function. For each probability curve, an associated hypothesis must be stated. From the curve, a hypothesis may be stated that the probability of detecting a marten site *p*(site) decreases with increase in rank.

The BELIEF module in Idrisi was used to aggregate all the 'lines of evidence' (slope, aspect, greenness and toposhape – as represented by their various hypotheses, e.g., species are more likely to be found on slopes with certain aspects as described in Figure 13.3). BELIEF aggregates these various 'lines of evidence by applying rules of combination based on Dempster–Shafer (D–S) Weight-of-Evidence modeling' (Eastman, 1999). D–S theory is a variant of Bayesian probability theory (Srinivasan and Richards, 1990), which allows us to decompose a large body of evidence into its component parts. The importance or influence of these component parts can then be assessed as probability statements that subsequently can be recombined to determine the probability of finding a particular species at a given location. If this species is then found in association with others, such as a guild of wildlife species, these locations, when adjacent to roads, may be especially attractive as sites for the mitigation of highway induced wildlife mortality. In this case, the evidence was aggregated using BELIEF, to create a linkage zone model, which indicates regions with the highest probability of detecting a given species. These high probability sites should indicate optimal locations for placing crossing structures.

D–S theory defines hypotheses in a hierarchical structure. For example, if the frame of discernment (Srinivasan and Richards, 1990), or decision frame using Eastman's

(1999) terminology, contains two hypotheses [A,B], the structure of the hypotheses for which D–S incorporates evidence includes all possible combinations of these hypotheses i.e. [A], [B], [A,B]. All three hypotheses are recognised because often evidence supports one or other of this combination of hypotheses. D–S theory employs the following rule of combination:

$$\begin{aligned} m(Z) &= \sum m_1(X) \times m_2(Y) \text{ when } X \cap Y = Z \\ &= 1 - \sum m_1(X) \times m_2(Y) \text{ when } X \cap Y = \Phi \end{aligned} \tag{13.1}$$

If

$$\sum m_1(X) \times m_2(Y) = 0 \text{ for } X \cap Y = \Phi \tag{13.2}$$

Then

$$m(Z) = \sum m_1(X) \times m_2(Y) \text{ when } X \cap Y = Z \tag{13.3}$$

where $m(Z)$ = basic probability assignment (the mass of support) for the hypothesis [Z] and X and Y are independent variables (Eastman, 1999; Gordon and Shortliffe, 1985).

D–S theory varies from Bayesian probability theory, in that it recognises the existence of ignorance due to incomplete information – as indicated by the previous non-site hypotheses. In Idrisi, D–S theory is 'able to determine the degree to which we, with our current state of knowledge (evidence), cannot distinguish among a subset of hypotheses (a condition known as ambiguity) or among all hypotheses (a condition known as ignorance)' (Eastman, 1999). For example, the mass of support for the probability of detecting wolves by slope is based on the empirical evidence that wolves prefer lower slopes. The weight of this evidence tends to support the non-use of steep slopes (>30 degrees), given the paucity of use in sites with higher slope steepness. Low slope alone, however, may not be enough to explain preference for shallow slopes, thus the hypothesis is expressed as a non-site (i.e., high slopes lack wolves) rather than as a site hypothesis that would state directly that low slopes have a high probability of being wolf sites. By contrast, all other lines of evidence, toposhape, greenness and aspect, were used to support the site hypothesis.

The BELIEF module is used to construct a knowledge base from the input data (i.e., all four predictive attributes for each species) and the hypothesis that each data layer supports (i.e., site or non-site, as discussed above). All four lines of evidence are integrated into a knowledge base by combining the various lines of evidence and producing basic probability assignments for each of the hypotheses. The BELIEF module will produce maps of the probability that an animal will be found at a given location based on the three lines of evidence that support the habitat hypothesis. The line of evidence, in this case slope, which supports the non-habitat hypothesis, produces a 'plausibility' map. The difference between the belief and plausibility maps produces the belief interval that may be useful for determining where to look for new sources of support for the habitat hypothesis. In the present chapter we are

primarily concerned with our existing evidence for species existence with respect to their habitat properties.

A first iteration of probability surfaces was constructed using four attributes (aspect, greenness, slope and toposhape). A lack of clear linkages was evident, and maps were re-analysed. A second iteration of probability maps was then developed without greenness (i.e. with three attributes: aspect, slope and toposhape). Greenness was removed because it is highly correlated for all species, and the initial probability image showed little variation in greenness within one kilometre of roads. Finally, data assimilation techniques were used to improve the identification of corridors (linkage zones) in a third iteration of maps. Data assimilation techniques involve using regional data to 'fine-tune' global models. Climatologists frequently use this method to enhance global weather models (Khattatov *et al*., 2000). In the third iteration of the linkage zone model, known species sites were 'assimilated' to calibrate the final model geographically. The assimilation was done by adding a layer depicting distance from known sites of the focal species, represented by a decay function where suitability of habitat decreases with distance from observed sites. This calibration was used because the first probability surface was generated using habitat associations from the three-year landscape scale analysis, a global model.

13.4 Results and Discussion

13.4.1 Introduction

In this section the results of three iterations of the linkage zone model are presented. The initial belief surface combined the four variables that showed non-uniform use by the focal species (i.e., slope, aspect, greenness and toposhape). A second surface was developed in response to an examination of the first surface. Specifically, conclusions regarding the lack of usefulness of 'Greenness' resulted in the development of iteration two, which included only slope, aspect and toposhape. In the final iteration (3), the model was enhanced by including known species occurrences. This is an assimilation approach that was investigated because there is a general understanding that, in movement, wildlife may be more inclined to use sites they have previously used more than those they have not. This was an exploratory iteration to determine the effect on the final model.

13.4.2 Iteration 1: Slope, Aspect, Greenness, Toposhape

In the first iteration of BELIEF maps, the valley bottoms showed uniformly high probability of detection for lynx and wolves. This probability was high for any areas below rock or cliff faces. Although a few sites of high probability could be identified crossing the valley (i.e., linkage zones), there was little visible separation between high and low classes in the valley bottom. This lack of separation was more pronounced in the wolf probability surface. Consequently, we reviewed the probability surfaces

and found that greenness was the only surface with extremely low geographic variability within 1 km of roads. Thus, the effect of adding greenness to the probability model appeared to be that of enhancing suitability of the entire image and reducing separation on the valley floor. This effect was not expected, but is reasonable given that all valley areas are highly productive, relative to the surrounding peaks. However, as the objective of the research was to identify suitable linkages across roads (i.e., the valley floor) the lack of separation in greenness at lower elevations is problematic. Greenness was removed from the calculation in the second set of map iterations and linkage zone separation was improved.

13.4.3 Iteration 2: Slope, Aspect, Toposhape

In this second iteration of the BELIEF module, non-suitable lynx habitat linkages were evident in the valley bottoms, illustrating the constrained movement opportunities for lynx at the interface with roads. Areas that exhibit low probability of detecting lynx were areas of flat slope and aspect. The region adjacent to the TCH Phase IIIA (southern side) showed enhanced suitability relative to other regions in the Bow Valley. Ground validation showed a combination of old-growth spruce and young, dense pine stands. In this unique situation, there is a spatial convergence of two habitat niche requirements for lynx, namely, denning and hunting. This type of spatial arrangement in forest types is not common in the Bow Valley study frame.

The second iteration of the wolf probability image reconfirms the topographic effect of the landscape on wolf habitat suitability (Weaver *et al.*, 1996). The highest probability of detection is limited to extreme valley bottoms. Lakes appear in the images as high probability sites for wolves, which is appropriate in winter only, when lakes are frozen and used as travel routes (Paquet, 1993). In some cases, glaciers were identified as high probability wolf sites, because they have low slope angle. This is a consideration for future research that may look at linkages outside the valley floor. The identification of glaciers, lakes and rivers as highly probable linkages between valleys is misleading, as they may be inhospitable for travel by wolves. A glacial and river hydrology overlay could be used to remove these areas, but is not necessary for the present research.

The limitation of wolves to the valley floor, as depicted in the probability image provides insight into the reasons why wolves have a difficult time persisting in road fragmented mountain terrain (Weaver *et al.*, 1996). In addition to finding the valley floors easier for movement, wolves are obligate predators of ungulates, which as a rule are human tolerant, valley bottom dwellers. These constraints placed on wolves increase their interaction with road surfaces in the valley and, consequently, increase their probability of being killed.

13.4.4 Iteration 3: Slope, Aspect, Toposhape, Observed Species-sites

In the third iteration of probability surfaces, shown in Figures 13.4 (lynx) and 13.5 (wolves), the data assimilation method was used. The probability of detection was

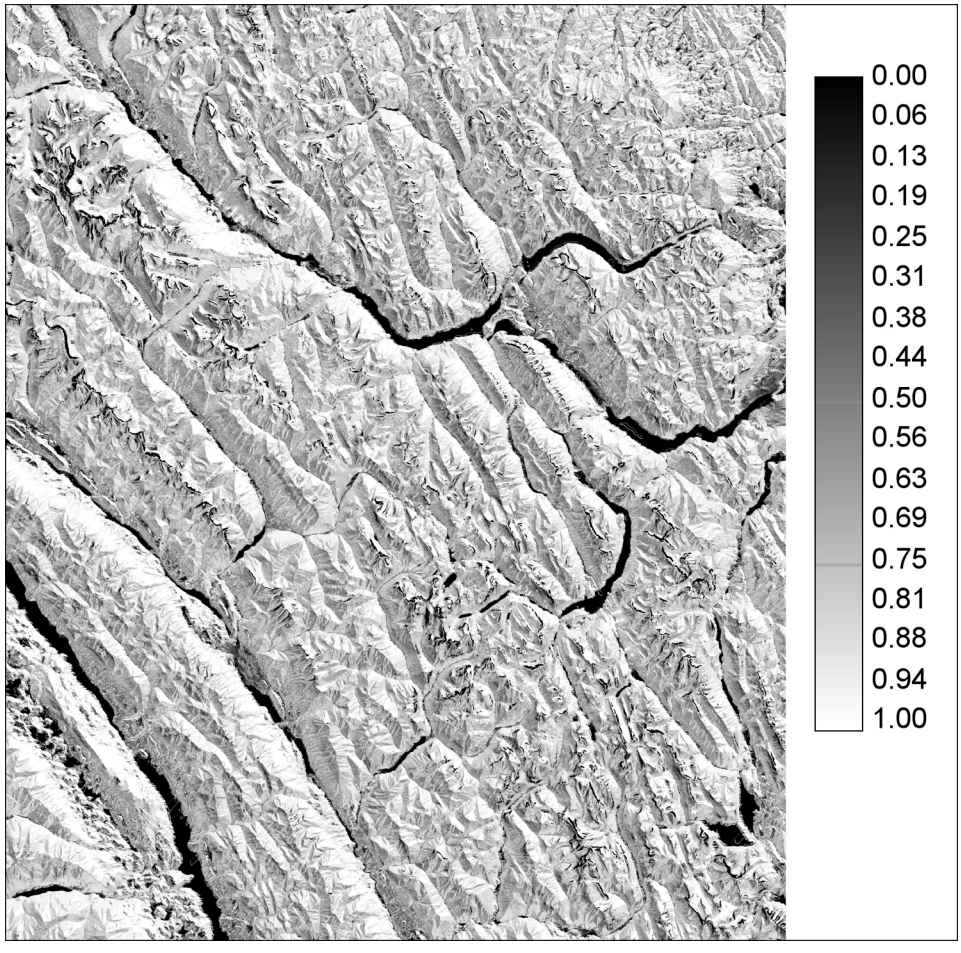

Figure 13.4 *Probability of lynx*

assumed to decline rapidly with distance from known (observed) points. Hence, the probability decayed over a distance from zero to 300 metres. The data assimilation created a more regionally specific (species-precise) predictive surface. However, the inclusion of this data enhanced sites within the existing linkages, but did not change the overall linkage zones.

Cross-valley linkages with higher than 95% probability (from Figures 13.4 and 13.5) were more frequent for lynx than for wolves, and crossing sites for wolves have wider spatial extent than lynx. By comparison Figure 13.4 (lynx probability) shows less contiguous highly suitable habitat for lynx than that for wolves, shown in Figure 13.5. The highest potential habitat for lynx is dispersed and is not confined to the valley floors. This offers lynx the benefit of not interacting with human disturbance on a continuous basis. However, lynx may be required to traverse very unsuitable patches of habitat (i.e., valley floors), in order to access other high quality habitat

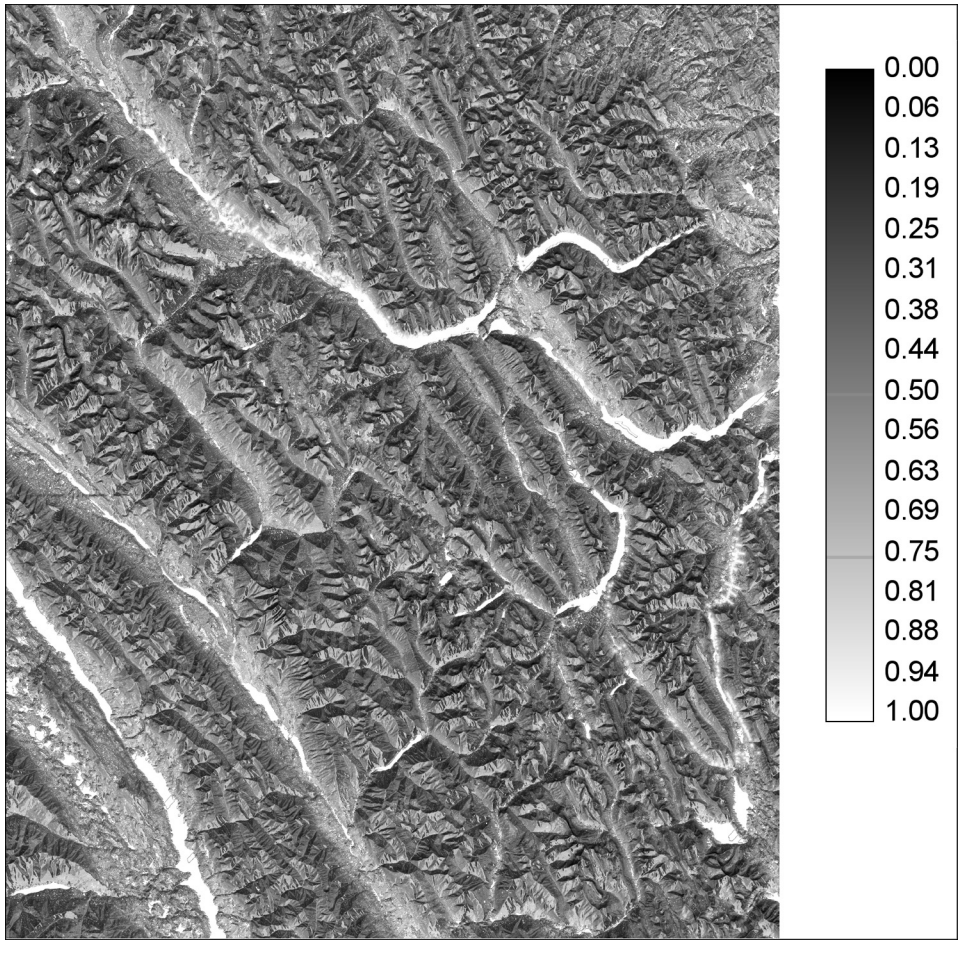

Figure 13.5 *Probability of wolves*

during dispersal or times when local prey abundance is low. Figure 13.5 also shows that wolves are highly constrained to the valley floors.

A comparison of Figures 13.4 and 13.5 also yields evidence that fewer connections are needed across highways for wolves, relative to lynx. The limited number of crossing opportunities suggests that the placement of mitigation will be critical to wolves. Lynx movement may be accommodated by placement of mitigation at a greater frequency. The suggestion to place lynx structures at higher frequency than wolves is grounded in the arguments of body size–home range and functional scale requirements (Holling, 1992). Lynx have smaller home ranges, thus, more may be accommodated in the same space as that required by wolves (assuming equal suitability for both species).

Plate 6 shows regions where there is >90% probability of detecting three focal species. Marten are included in this figure for demonstration purposes (i.e., how the

methodology may be extended to multiple species). Plate 6 was created by combining three Boolean images – one for each species. Marten were coded in Boolean as [1,0], wolves as [3,0] and lynx as [5,0]. This allows the images to be combined, such that the output may be used to detect sites for individual species (e.g., marten at zones with value 1), or to identify sites of various combinations of species. For example, if the user would like to identify a site where marten and wolves intersect in the landscape, then he/she would look for sites with the value 4 (i.e., 1 – marten + 3 – wolf). Likewise, sites where all three species may be detected have a value of 9 (1 + 3 + 5). This figure shows only the study region in Banff, west of Castle Junction. Evident in Plate 6 is the limited frequency and high dispersion of sites where all focal species have greater than 90% probability of crossing (i.e., the yellow sites). This suggests linkage zones must be species- or guild-specific, supporting previous arguments about connectivity requisites (Tischendorf and Fahrig, 2000; Conroy and Noon, 1996).

In major linkage zones where there exist fragmented regions of overlap, mitigation design might enhance the chances of both species crossing. For example, in the region directly west of Castle Junction there is some overlap between species. Mitigation design in this region should address the species-specific habitat needs that improve movement probability, such as maintaining a wide swath of land. Corridor width is one of the over-riding indicators of corridor success (Harrison and Bruna, 1999). Such design would increase the functional connectivity of the landscape (Tischendorf and Fahrig, 2000).

13.5 Policy Implications

As a result of the research findings, a number of policy implications have been presented to management agencies in the region, which are summarised in Table 13.3. These policy recommendations should serve as general guidelines for the spatial requisites of highway mitigation in the Rocky Mountain ecosystem.

Table 13.3 *Policy implications of the research*

1	Placement of mitigation should occur in high probability crossing areas, as defined on the GIS predictive model, herein.
2	Mitigation should be between 250 and 1000 metres in diameter (Alexander and Waters, 2000).
3	Using the above, mitigation should use elevated and buried highway sections, as often as possible. Exclusion fencing will be important in non-corridor areas.
4	Mitigation should be species- or guild-specific to maintain functional connectivity and ecosystem integrity.
5	Lynx and wolves may be used as focal species for mitigation (Alexander, 2001).
6	Higher resolution GIS images (e.g. <30 metres) are needed to manage appropriately for smaller functional levels (i.e. marten).
7	The adoption of GIS probability modelling and decision support is a cost-effective means of identifying crossing sites and provides a traceable process for decision makers.

13.6 Conclusion

This chapter examined the use of probability modelling in determining sites with the highest probability of detecting wildlife along four road systems in the Rocky Mountains of Alberta, Canada. The principal goal of the research was to locate optimal sites for placing mitigation structures (overpasses, underpasses or elevated highways) in order to restore structural and functional habitat connectivity for wildlife. Structural connectivity was addressed in this research by using spatial modelling and probability theory to find the optimal linkages in the landscape. Functional connectivity was addressed by identifying which species were good representatives of two levels of ecological organisation (i.e., meso- and macro-scales). Maintaining structural connectivity for two levels of ecological organisation alone will not achieve functional connectivity, if the design attributes of crossing structures are not appealing to the species involved (e.g., too narrow or too sparsely vegetated). This requires further examination of individual species' tolerances to habitat structure and geometry.

Biophysical attributes that predict movement were tested for non-uniform use by each of 13 study species. Attributes included aspect, greenness, slope, distance to drainages, distance to roads and toposhape (curvature). Strong evidence was found that aspect, greenness, slope and toposhape were useful predictors of habitat selection. It was observed that these preferences were well defined using probability functions. Moreover, in the analysis of track density estimates, this technique was argued to be superior to classical statistical approaches such as logistic regression or compositional analysis.

It was expected that greenness would be a useful predictor, based on work with grizzly bears (Mace *et al.*, 1999). However, in this case greenness was not suitable as a predictor because of the frame of analysis. There was little separation in greenness classes within the region of 1 kilometre from roads. Consequently, the inclusion of greenness obscured most linkage zones by applying an overwhelming 'greenness' suitability to habitat near roads. Therefore, greenness was removed from the analysis.

Structural connections were evident along the valley in BNP and these varied by species. Zones of overlap for both species that had high probability of use, were not abundant in the valley. This confirms the hypothesis that mitigation must be species-specific, or at least, guild-specific. Further tests should examine the periodicity of placement that may best suit each species/guild. In addition, design constraints should be examined. Other metrics should be tested for use in predicting species occurrence. For example, some species are known to associate with forests that have high structural complexity at the ground. Expert knowledge on relationships between metrics and finer scale predictors could be gleaned and incorporated into the weight-of-evidence model.

The strength of this modelling technique lies in its flexibility, its explicitness and its lack of assumptions associated with the more traditional statistical methods. Future data could be used to assess the predictive power of the model. Future analysis or evidence may suggest that other metrics are important, and these could be incorporated into the model. Moreover, if relationships within attributes (by class) are found to change, the associated probability functions can be modified. Human preferences could also be included in this model, at a later date. For example, highway

structural engineers may want to evaluate the costs of mitigating each identified linkage zone, based on the site criteria. The flexibility of this tool enhances its suitability for use in resource management, because it makes the tool practical. The model is explicit in its assumptions and rules. Explicitness is a desirable quality for resource management agencies, such as Parks Canada, who are subject to public scrutiny and who must be accountable for decisions, and for replication and adaptation of the scientific research.

Modelling Migration for Policy Analysis

Phil Rees, A. Stewart Fotheringham and Tony Champion

Abstract

This chapter reports on the development of an applied model of internal migration in the UK to support central government policy making. A two-stage modelling procedure was developed and parameters calibrated on a time series of historical data. Details of the data sets and the modelling are presented, together with illustration of the software package named MIGMOD that was constructed as a planning support system to assist government officials in predicting the impact of alternative scenarios.

14.1 Introduction

This chapter describes the results of a project carried out by a team (see Acknowledgements) based in the Universities of Newcastle upon Tyne and Leeds for the UK government during 2000 (Phase 1) and 2001 (Phase 2). Phase 1 was led by Tony Champion and Phase 2 by Stewart Fotheringham. The UK government department sponsoring the project (see Acknowledgements) changed its name and composition twice during the project and was known successively as the Department for Environment, Transport and the Regions (DETR), the Department of Transport, Local Government and the Regions (DTLR) and the Office of the Deputy Prime Minister (ODPM). For simplicity we will refer to the various organisations as 'the Department'. The chapter is published with the Department's permission but represents the views of the authors and not the Department.

The chapter describes the aims of the project, the type of spatial model constructed and calibrated and explains the choices in model design that were made during the course of the project. Exposing the choices explored and the different model designs used in Phase 1 and Phase 2 will, we hope, provide valuable guidance to other researchers seeking to model the flows of migrants over time between a large number of origin and destination areas. The main output of the project is a user-friendly software system known as MIGMOD (Migration Modeller) which we also describe. The original aim of the project was that it might help inform policy decisions, and we have undertaken simple policy scenarios. These are illustrative and indicative of the model's performance, rather than a true reflection of the effect of policy changes. This account of the work complements the overview provided by Champion *et al.* (2002).

The chapter is divided into a further seven main sections. Section 14.2 places migration within the UK in the broader context of population change and explains why the Department needed a model of migration. Section 14.3 explains the aims that the model was designed to achieve. Section 14.4 outlines the 'state space' of the model: what spatial units were used, what migrant groups were studied and what time periods were used in which to measure migration. Most of the choices were 'data-driven'. Section 14.5 describes the nature of the dependent variable being modelled and the set of determinant variables used in the two stages of the model (out-migration from origins, distribution from origins to destinations). Section 14.6 describes the model of out-migration used, known as the Stage 1 model, which is used to identify the factors that contribute to varying rates of out-migration from origins across England and Wales. Section 14.7 describes the Stage 2 model, a model of destination choice by migrants, which is used to determine the factors that lead to varying levels of destination attractiveness. In Section 14.8 we describe how the two models are integrated within a user-friendly software system for migration modelling termed MIGMOD. We also discuss the revisions to model design made between Phase 1 and Phase 2 of the project.

14.2 Context: The Role of Internal Migration in Population Change

Population change is often a good indicator of regional economic prosperity. Regional policy is often concerned with the direction of population shift: decline is a trend to be avoided because it leads to destruction of social and physical capital. Population change is also one of the main ingredients in household change, although the two are not necessarily highly correlated as evidenced by the decrease in average household size in recent decades in the UK leading to a greater household growth than population increase. Population change is driven by components which can have very different geographical patterns.

Table 14.1 presents estimated regional components of population change for Government Office regions of the United Kingdom in 1999–2000. Only three regions – Scotland, the North East and West Midlands – experienced such population decline, while London and the southern regions showed the highest rates of increase. The

Table 14.1 *Components of population change for Government Office regions (England) and countries, UK, 1999–2000*

Country and Government Office Region (England)	Rates (per 1000 population)				
	Natural increase	Net external migration	Net internal migration	Other changes	Total change
Wales	–1.0	2.0	2.1	0.0	3.1
Scotland	–1.2	0.8	–0.8	0.2	–1.0
Northern Ireland	4.1	0.5	–0.5	–0.6	3.5
North East	–0.8	0.9	–1.7	0.1	–1.6
NW & Merseyside	0.1	2.8	–1.1	0.1	1.9
Yorkshire & the Humber	0.6	1.2	–0.1	0.5	2.2
East Midlands	0.5	–0.6	3.8	0.3	4.0
West Midlands	1.1	0.2	–1.4	0.1	0.0
East	1.4	1.7	4.0	0.3	7.5
London	5.9	15.6	–9.1	–0.1	12.3
South East	1.1	1.5	2.1	0.0	4.6
South West	–1.2	3.2	6.2	–0.3	8.0
United Kingdom	1.0	3.2	0.0	0.1	4.3

Notes:

1. External migration includes asylum seekers and visitor switchers.
2. The components are based on mid-year population estimates current at the time of writing. The population estimates for mid-years from 1981 through 2000 will be revised in the light of the publication of the 2001 Census results. Prior to the 2001 Census the best estimate for the mid-2001 population was that in the 2000-based national projection (Shaw, 2002) at 59.987 millions. This compares with a 2001 mid-year estimate published in October 2002 of 58.837 millions based on the 2001 Census 'One Number' of 57.789 millions.

contributions of the three components of population change, natural increase (births minus deaths), net external migration (inflows from the rest of the world minus outflows to the rest of the world) and net internal migration (inflows from the rest of the UK minus outflows to the rest of UK) vary across the regions. Natural decrease characterises Wales, Scotland, the North East and the South West. Natural increase is low elsewhere except in Northern Ireland and London. Net external migration makes a positive contribution to population change in all but one region but a massive contribution to the growth of London's population. From Table 14.1 we can also see that internal migration is a vital component that shifts populations between regions because there are both gaining and losing regions. For example, Scotland, the North East, North West and West Midlands lost between 4000 and 8000 people through internal migration, while Northern Ireland and Yorkshire and the Humber had small losses. London lost substantially through internal migration though this was more than compensated for by its gain from overseas. The other regions, particularly the East, South West and East Midlands gained through internal migration.

If more balanced population growth is a policy goal, then this means improving survival chances in high mortality regions, encouraging couples to have more children in certain regions or spreading the influx of immigration across regions more evenly or reducing migration outflows from certain regions and decreasing migration inflows into others. Of these options, the latter would seem less controversial and more acceptable as a solution to population imbalances. In order to stem population losses from depressed regions, and to stem the increasing population pressures in economically successful regions, it is necessary first to understand how such migration imbalances arise. One of the best ways to achieve that understanding is to build a model of migration behaviour and to investigate the determinants of both out-migration and destination choice. Such a model is reviewed in this chapter.

14.3 Aims of the Project

14.3.1 Introduction

The primary aim of the project was to provide the Department with an initial migration model aimed at informing policy. The model was designed to enable the investigation of the first-round quantitative impacts of alternative economic and policy scenarios on gross flows of population between regions. For the longer term, the intention was that the model would be capable of further enhancement, notably in order to gain a better understanding of the role of migration in influencing household change. It was clear from the outset that there were insufficient reliable data for regions, counties or local authorities on the migration of whole or part households or individuals migrating between households to construct a model that would directly connect to the Department's Household Projection model. The Department was well aware that migration flows produced feedback effects on areas (spirals of decline resulting in out-migration sometimes create opportunities for renewal or heavy in-migration resulting in denser settlement which lowers the attractiveness of destinations) but the team and the Department agreed early on that such modelling was over-ambitious until simpler cross-sectional or time series models had been calibrated and verified.

The 'problems' to be solved were of two kinds. The first was to find ways of reducing heavy migration losses from northern and midland cities in the UK and from other areas with poor economic track records (former coalfields, the Thames Gateway region, rural Wales). Heavy out-migration from these regions means shrinking demand for housing and other consumption goods, leading to a downward spiral of economic and social development, and loss of valuable social capital (Walker, 2002). However, we should also recognise that inter-area migration is also a means of shifting people to areas of economic opportunity. The second problem was to avoid the consequences of over-stimulation of successful regional economies. High in-migration might put pressure on house prices and make housing unaffordable to workers outside the dynamic sector, as is very much in evidence in and around London currently.

14.3.2 Detailed Objectives

The principal objectives were to develop an initial policy model which:

- was capable of handling gross migration flows between regions;
- could be used to examine the impact of alternative scenarios;
- could provide advice on urban–rural shifts;
- was compatible with household projections methodology;[1]
- was flexible, easy to use and transparent; and
- was capable of further enhancement, especially at a finer spatial scale.

It was agreed at the outset that, in developing this initial model, there was a need for pragmatism, notably in relation to data availability and feedback effects. In particular, this initial model would not attempt to incorporate the impacts of migration or other changes on the determinant variables. *Phase 1* of the modelling work established the framework, set up the database, developed a prototype working model and produced a standalone version for use by the Department. *Phase 2* reviewed model robustness, conducted a full range of diagnostic tests of determinants and investigated some counterintuitive results from the prototype model in detail. The overall model structure remained the same in both phases but different model forms were adopted in Phase 2 after extensive winnowing of the very large determinant dataset and after experimentation with multiplicative or additive equations linking dependent migration and independent determinant variables and with linear and quadratic and exponential functions of the determinant variables.

14.3.3 The Modelling Framework

The central features of the approach were:

- the modelling of out-migration from each area by reference to a set of determinant variables (Stage 1 of the model);
- the use of a model to distribute migrants between destinations (Stage 2 of the model);
- the development of an operational, user-friendly combination of Stages 1 and 2 that enables the model user quickly to set up and run a range of 'what if?' scenarios and to view the large volume of inputs and outputs (Stage 3 of the model); and
- the development of a selection of scenarios of determinant variables reflecting desired policy options (Stage 4 of the model).

[1] The ODPM household and ONS population subnational projections use local authority (LA) zones, whereas the migration model described here uses FHSAs. FHSAs are aggregations of LAs for most of the 1983–98 period, though from 1996 Health Authority reorganisation meant small inconsistencies in the aggregation. Changes in Health Service organisation since 1998 mean that the data series will not extend and future work will need to employ the New Patient Migration data series (ONS, 2002). These new data are available directly for the LAs used in subnational projections.

The modelling team discussed and agreed this framework with the Department very early on in the project. In fact, the rationale for this two-stage approach was reviewed in Champion *et al.* (1998). The main argument for modelling the out-migration flow separately from the destination choice is that different data sets were available for the two types of decisions. In order to model out-migration determinants, the team had available to it 15 years of annual out-migration data which allowed some time effects to enter the modelling framework (see below). In order to model the determinants of destination choices, an origin–destination matrix of migration flows was needed and this was only available for seven time periods which was not sufficient to allow time-related variables to enter the model. There is also evidence that migrants often conceive of migration as a two-stage process with worsening conditions at an origin eventually reaching a threshold level at which people decide to leave and then conditions at various locations being examined in order to decide on a destination. The model structure adopted conforms to the consistency principles for spatial interaction models first defined by Wilson (1967, 1972). The equation structures used in Phase 1 and Phase 2 versions of the migration model are discussed below in Section 14.4.

The calibration and testing of the model has embraced several dimensions of space, time, age and gender. Decisions needed to be taken on the zones to employ in the model, the time horizon over which the model would be calibrated and the disaggregation of migration into sub-categories for which different models were fitted. These decisions are discussed in the next section of the chapter.

14.3.4 Additional Investigations

In the development of the initial migration model, the project included three discrete modules of optional work. These were (i) improving the treatment of international migration, (ii) providing a population projection framework and (iii) examining the household dimension of migration. Details of this additional work can be found in the Phase 1 Final Report (Champion *et al.*, 2002).

14.4 The State Space

14.4.1 Spatial Units

For which areas should a migration model be developed? This is really two questions: what scale of spatial unit should be used and what collection of units should the model be calibrated for? Because the Department wished to know how migration affected household change, the ideal zone to have chosen would have been the local authority (LA). However, the UK did not have an annual time series of migration data at the LA scale until 1998 when migration data based on the patient registers came on stream. Data are available in the decennial censuses (1971, 1981, 1991 and soon 2001) at LA scale though the number and definition of LAs differs between

1971 and 1981 and between 1991 and 2001. The time period between the censuses is too long to allow any great understanding of the temporal influences on migration patterns.

An alternative is to use migration data available on an annual basis from the National Health Service Central Register (NHSCR). The zone system used in this series are the Family Health Service Authority (FHSA) areas as defined between 1983 and 1998 (see Figure 15.2 in Champion *et al.*, 2002) in England and equivalent authorities in Wales, Scotland and North Ireland. FHSAs were coincident with shire counties (England and Wales), metropolitan districts (England), groups of London boroughs, Area Health Boards (Scotland) and Health Boards (Northern Ireland). Ideally, the migration model would have been constructed using all of these areas which cover the whole of the United Kingdom. Unfortunately, there are gaps in the flow statistics between areas in Scotland for a number of years and between areas in Northern Ireland and in Great Britain. In Phase 1 of the model construction, therefore, it was decided to treat Scotland and Northern Ireland as two zones only. FHSAs in Wales were included as separate zones in the analysis. Results for Wales were not required directly by the Department because Wales was not its responsibility but the team argued strongly that migration links between places in England and places in Wales were strong and their exclusion would bias results for a good part of England. The flows between England, Scotland and Northern Ireland were much weaker and use of single zones for these countries would not seriously bias model results. The system to be modelled at the outset consisted of migration flows from 100 origins to 100 destinations disaggregated by age and sex.

In the event, one or two changes to this set of origins and destinations were necessary because of difficulties in estimating determinant variables for Scotland and Northern Ireland comparable to those for England and Wales. The statistics available for Scotland and Northern Ireland did not match sufficiently well to merit inclusion of these zones in Stage 1 of the model, so that only 98 zones were used. For Stage 2 there were fewer difficulties because the variables were cross-sectional in nature and only needed for 1996–97. However, major difficulties arose in the prediction of migration flows to Northern Ireland. With the set of determinant variables used in Stage 2 of the model, we consistently and massively overpredicted flows to Northern Ireland and therefore underpredicted flows to other zones. Missing from the model were variables that measured the relative attractiveness of zones based on perceptions of their political history and threat of external violence. In the absence of such measures, we confined the Stage 2 distribution model to 99 zones. In Phase 2 of the work these decisions were reviewed and the number of zones reduced to 98 in both stages of the model.

The effect of excluding some sub-national areas from the model calibration could not be tested with the data sets we were using but is an issue that could be addressed using 2001 Census data when they are available, as the 2001 Census Origin-Destination Statistics will provide comparable and comprehensive flow statistics between all LAs in the UK. There is also the question about what effect does immigration from, and emigration to, external zones have on migration between internal zones (whether those external zones fall within the UK or without). We did include

estimated measures of external immigration and emigration (Stillwell *et al.*, 2001) in the internal migration model but their close correlation with variables measuring 'urbanness' meant their exclusion from the final determinant set to avoid problems of collinearity. The results of the model calibrations of immigration rates to destination zones suggest that previous immigrant stocks, the numbers of term-time students and population size of zone were the main attractors and that immigration and internal migration operated in different 'worlds'.

14.4.2 Time Series

For which years should the migration model be calibrated? Should we use as many years as the available information allow or strive to calibrate for particular periods? NHSCR flow data by origin, destination, age and sex are available for the 98-zone system from 1975–76 (mid-year to mid-year) until 1998–99 (at the time that the work was carried out). However, there are two major discontinuities in the series that make it necessary to confine analysis to the years 1983–84 to 1997–98. Prior to 1983–84, the data were published only as aggregations of the full origin–destination–age–sex (ODAS) array of flows, namely as three sub-arrays of migration flows by origin–destination (OD), by origin–age–sex (OAS) and by destination–age–sex (DAS). Between 1983–84 and 1997–98 the data were supplied as frequency counts classified by origin–destination–age–sex (ODAS). The age classification was by single years of age, whereas prior to then it had been by five-year age group. In the years 1996–98 local governments were reorganised successively in Scotland, Wales and parts of England. After 1 April 1998 the migration data are recorded for these new LAs (see Wilson and Rees, 1998, for details of the links between pre- and post-1998 LA geographies). So there were available 15 mid-year to mid-year counts of ODAS-classified migration flows. How could these data be used and with what kind of migration models?

The first idea was to model the out-migration flows or rates as a time series. All the advice of our econometric colleagues (Barmby, Tremayne – see acknowledgements) was against that approach: at least 40 years of data were necessary. A decision was therefore made to pool the data for the different years into one set of observations for model calibration purposes. However, because we decided after experimentation that it was best to have a one-year lag between the migration outcome and the time reference of the determinant variable, the time series of observations used dropped to 14 (1984–85 to 1997–98) for Stage 1 of the model (the origin prediction model). In Phase 1 of the model fitting we did not use a time trend as one of the explanatory variables but subsequent examination of the time series of out-migration rates for ages 16–19 and 20–24 revealed that a steady rise in out-migration took place from 1990–91 onwards, due primarily to the expansion of higher education in the 1990s. A linear time trend was therefore introduced to Stage 1 of the model in the Phase 2 work.

One argument that was put to us after several presentations of the model was that we should have explored the possibility that the determinants of migration

would behave differently in times of economic boom and bust, and that different outcomes would result. Some analysts have interpreted the influence of the economic cycle on migration as follows: regions enter booms and busts at different times and the cyclic effects spread outwards from inception points. So, for example, the recession of 1981–3 saw downsizing of manufacturing industry and job losses first in the northern regions and then spread south increasing north to south transfers. The boom of 1988–1990 stimulated house price rises and outward migration in the South East which spread to the rest of the country tipping the north into positive migration gains for a year or so before the traditional pattern of north to south losses reasserted itself. These effects are ones we did not explore, given the need to develop a robust and operational model in a short time frame for the Department.

For Stage 2 of the model, time is less critical an issue. We calibrated the distribution model for a single year only but checks on alternative years indicated that the structure of migration distribution from origins to destinations is very stable, being dominated by the 'competing destinations' variables of distance (with a contribution from contiguity), destination accessibility and population size (Fotheringham, 1986, 1991). The year chosen for the final calibration was 1996–97 rather than 1997–98 because boundary changes were beginning to affect some migration flows in 1997–98.

14.4.3 Age Groups

The review of knowledge about the patterns of migration and the reasons for moving suggested that these would vary significantly with a person's position in the life course. It is not usually possible with aggregate data to place migrants into exact life course stages (e.g., retired from work or still working) but usually information is available on the age of migrants. Ages can then be grouped into approximate life-course stages. How many should there be and where should the boundaries be drawn between stages?

Since the NHSCR data were available for single years of age up to age 85+, it would theoretically have been possible to fit 86 different models, one per age group. However, previous empirical work (Stillwell *et al.*, 1992) had established that most of the variation between ages could be described using a small number of grouped ages. Initially, some eight age groups were proposed: 0–16, 17–19, 20–24, 25–29, 30–44, 45–59, 60–69 and 70+. These correspond to childhood/schooling ages, the ages at which adolescents leave home for higher education, the ages at which students leave higher education for their working and partnership careers, the ages when they look for career advancement, the family formation ages, the later working ages (quiescent in terms of migration), the ages of retirement when locations are reassessed and the older ages when events such as loss of spouse/partner or increasing infirmity precipitate migration. We examined the correlations between the flow matrices at ages around the bounds of these life-course stages and moved 16 year olds into the late adolescents group. We also amalgamated the last two ages as the flow matrix for the

70+ age group was too sparse for reliable calibration. The final age groups chosen for the model were therefore seven in number: 0–15, 16–19, 20–24, 25–29, 30–44, 45–59 and 60+.

14.4.4 Gender

There is a growing interest in the differences between men and women in their migration behaviour, though the differences are only expressed when they are not in marriage, partnership or in families. The Government Statistical Service now requires all analyses to include a gender dimension and this we did in the migration model, though the differences in results are generally not great.

14.4.5 Summary

Choosing the state space that we did meant that we would be calibrating the Stage 1 and Stage 2 parts of the migration model for seven age groups and two genders or 14 migrant groups in total. However, there were further choices to be made. Should the out-migration model be calibrated for each origin separately or for all origins together or for groups of origins?

The option of calibrating the Stage 1 model for each origin was ruled out first: there were too few observations (14) per origin to produce reliable parameter estimates. We calibrated models in Phase 1 with grouped origins using Government Office Regions as the grouping criterion and compared the results with a model calibrated on all origins collectively. As would be expected, the former produced more accurate predictions of out-migration rates but a lot of the improved predictive performance came from the ability to estimate separate intercept terms for each zone. How should the variation of these intercepts be interpreted? It appeared that much of the variation in the intercepts was masking variation in some of the relationships between out-migration rates and origin attributes which was thus misleading. It appeared that some origin attributes had little effect on out-migration rates but this was simply because the effect of differential levels of those origin attributes was subsumed within the varying intercept values. Hence we opted for an 'all zones together' calibration for the 14 migrant groups and somewhat reluctantly dropped the idea of separate models for different clusters of origins.

The situation for the Stage 2 destination choice model was different. Here we had, for each origin, 97 destination flows upon which to calibrate the distribution model. By selecting origin-specific distribution models we could allow the determinants to have different influences on the outcomes for each origin. For example, we found that house prices (in the Phase 2 model) had coefficients that were both negative and positive depending on origin (other things being equal), while distance has negative coefficients in all cases (no origin had migrants who preferred to move to distant places). For Stage 2, therefore, it was possible to calibrate 98×14 or 1372 separate models (for just one year).

14.5 Data

14.5.1 Database Assembly

The major element of the work in Phase I of the project was the assembly of the data needed for calibrating the Stage 1 and Stage 2 models. Three broad types of data were required: (i) data on migration flows, (ii) data on the distance between each pair of the 100 'zones' and (iii) data on the characteristics of the 100 'zones' and their populations. We were guided in selection of determinant variables by the review undertaken in Champion *et al.* (1998), paying particular attention to the inclusion of variables that were directly or indirectly connected to the Department's policies for urban, rural and regional development.

In practice, several obstacles were encountered. Few datasets are published for all four countries of the United Kingdom, so data either had to be obtained as a series of separate tasks or had to be estimated. No datasets present statistics for the 100 zones used, so either data had to be aggregated from smaller units or values imputed from larger areas containing the zones. Data sources did not always provide information for all years. Some variables were found to need denominator data from a separate source, thus doubling the task (e.g. for crime rate defined as total number of offences per household).

Despite these problems, data were obtained for 139 potential determinants of out-migration and 69 potential determinants of migration destination choice. Much of this achievement was due to the valuable assistance given by a considerable number of persons and agencies (see Acknowledgements). Even so, it proved necessary to resort to estimation in order to complete the data series for all 98 FHSAs of England and Wales and for all relevant years. The data series for Scotland and, even more so, those for Northern Ireland were less comprehensive. In Phase 2 of the project, the initial 139 determinant variables were reduced through careful qualitative review and examination of multicollinearity to 49 potential determinants for Stage 1 of the model and the 69 potential determinants of destination choice were reduced to 23. The variables in the two datasets are listed in Table 14.2, which also gives the source of the data collected on each variable. Both data sets represent a huge increase in size from those normally used in migration models.

14.5.2 Within-UK Migration

As outlined in Section 14.4, the migration data are derived from the NHSCR and made available by Office of National Statistics (ONS). For the purpose of this study, data files have been constructed for the 100 zones for the 14 age–sex groups for mid-year to mid-year periods as follows:

- the numbers of out-migrations and in-migrations for 15 years 1983–84 through to 1997–98 are converted to rates based on the respective population groups of each zone; and

Table 14.2 *List of variables used in the (Phase 2) Stage 1 model*

Variable name	S1	S2	Meaning	Source
AIR	✓		Principal component of no2nox, ozone (high values associated with areas of poor quality)	AEA Technology. Values taken dataset point nearest to FHSA population-weighted centroid
AIRPORTS		✓	Access to scheduled flights to non-domestic destinations in 1997	Input data from CAA.
ASDIVRT	✓		% divorced – age-specific	1991 Census
ASUNEM		✓	Age-specific unemployment rate	NOMIS database; ONS mid-year estimates
ASUNEM_L	✓		Age-specific unemployment rate lagged	As ASUNEM
ASUNEM_L_Y	✓		Y variable for age-specific unemployment rate lagged	ASUNEM & DIJNETW
CTAX		✓	Average council tax for households	DETR Local Government website
CLIMATE	✓	✓	Principal component of frosty days, sunny days, rainfall, July temperature (high values associated with warmer drier areas)	University of East Anglia. Values taken dataset point nearest to FHSA population-weighted centroid
COMMUT	✓		% long distance commuters	1991 Census
CONTIG		✓	Contiguity dummy, equals 1 for pairs of zones sharing a boundary, otherwise 0	Derived from map of zones
CRIME	✓	✓	Principal component of household insurance premiums, index of crime a serious problem, total rates of offences recorded by police (high values associated with high crime areas)	Insurance companies, police records
DESTACC		✓	Sum of alternative destination populations divided by network distance from origin	ONS population estimates and DIJNETW
DIJNETW		✓	Network distance between each pair of zones	Computed from district level map by Duke-Williams and Alvanides
EMPGRO		✓	Employment growth	1991 Census and Survey of Employment
EMPGRO_L	✓		Employment growth lagged	As EMPGRO
EMPR		✓	Employment rate	As EMPGRO
EMPR_L	✓		Employment rate lagged	As EMPGRO
EMPR_L_Y	✓		Y variable for employment growth lagged	EMPR & DIJNETW
GCSE_L	✓		% 16 year olds obtaining 5+ GCSEs at Grade C or above lagged	DfEE, Scottish Office, DENI
HHINC		✓	Household income	Estimated by Bramley & Smart 1996, Bramley 1996
HHINC_L	✓		Household income lagged	As HHINC
HHINC_L_Y	✓		Y variable for household income lagged	HHINC & DIJNETW

HPRICE		✓	House price	Nationwide Building Society & CURDS, University of Newcastle
HPRICE_L	✓		House price lagged	As HPRICE
HPRICE_L_Y	✓		Y variable for house price lagged	HPRICE & DIJNETW
LISTED	✓	✓	Listed buildings (divided by dwellings 1998)	National built heritage organisations
LISTED_Y	✓		Y variable for listed buildings	LISTED
LOWI_L	✓		Index of relative share of low earners lagged	Estimated from New Earnings Survey
LOWI_L_Y	✓		Y variable for index of relative share of low earners lagged	LOWI_L & DIJNETW
MGINTR_Z_L	✓		Building Society mortgage interest rate lagged	Building Societies average
NOCENT	✓		% no central heating	1991 Census
NOCENT_Y	✓		Y variable for % no central heating	NOCENT & DIJNETW
NONWH	✓		% non-white	1991 Census
NONWH_Y	✓		Y variable for % non-white	NONWH & DIJNETW
OCCMIG	✓		Occupational migration index (predicted number of migrants based on occupation divided by residents – age-specific	Based on analysis of 2% SAR, then applied to 1991 Census LBS.
PARDOM	✓	✓	Students at parental domicile divided by number of residents, average of start and end mid-year estimates	HESA, UCAS and 1991 Census (Bailey and Rees 2001)
PNBU	✓	✓	New housing development (units) on land in former urban use divided by total new housing development	DETR & Ordnance Survey Land Use Change Statistics (LUCS)
PNRL		✓	% net relets social sector	DETR HIP1 series
PNRL_L	✓		% net relets social sector lagged	DETR HIP1 series
POPN		✓	Number of residents, average of mid-year estimates	ONS Population estimates
PQPR		✓	% new build completions private sector	DETR HIP1 series
PQPR_L	✓		% new build completions private sector lagged	DETR HIP1 series
PQPR_Y_L	✓		Y variable for % new build completions private sector	PQPR & DIJNETW
PQSR		✓	% new build completions social sector	DETR HIP1 series
PQSR_L	✓	✓	% new build completions social sector lagged	DETR HIP1 series
PQSR_Y_L	✓		Y variable for % new build completions social sector lagged	PQSR & DIJNETW
PVAC		✓	% vacant all sectors	DETR HIP1 series
PVAC_L	✓		% vacant all sectors lagged	DETR HIP1 series
PVAC_Y_L	✓		Y variable for % vacant all sectors lagged	PVAC & DIJNETW
RGDPCH_Z_L	✓		Real GDP annual % change lagged	ONS Economic Trends, Wilcox Housing Finance Review
RGURB	✓	✓	Land area subject to urban development of all types divided by population	DETR & Ordnance Survey Land Use Change Statistics (LUCS), and ONS mid-year estimates
RGURB_Y	✓		Y variable for land area subject to urban development	RGURB & DIJNETW

Table 14.2 *Continued*

Variable name	S1	S2	Meaning	Source
RLAPSC	✓	✓	Index of private sector stock in poor condition	Index used in HNI system, based on EHCS and proxies. England only.
RLASC	✓	✓	Index of local authority stock in poor condition	Index used in GNI system by DETR, based on stock profile and EHCS. England only
RLASC_Y	✓		Y variable for index of Local Authority stock in poor condition	RLASC & DIJNETW
SCENIC	✓	✓	Access to National Parks, Areas of Outstanding Natural Beauty and Heritage Coasts	Provided by DETR. Weighted averages of ward values.
SINGELD	✓		Proportion of single elderly households	1991 Census
SINGLE	✓		% single	1991 Census
TER	✓		% housing terraced	1991 Census
TERMT		✓	Students at term-time address divided by number of residents, average of start and end mid-year estimates	HESA, UCAS and 1991 Census (Bailey and Rees 2001)
TERMT_L	✓		Students at term-time address divided by number of residents, average of start and end mid-year estimates, lagged	HESA, UCAS and 1991 Census (Bailey and Rees 2001)
TIME_Z	✓		Time trend (year counter)	1 = 1984, 2 = 1985 etc.
TPOPN_Y_L	✓		Y variable for total population lagged	ONS Population estimate, TPOPN & DIJNETW
UNEMP_Z_L	✓		National claimant unemployment rate % lagged	DfEE, ONS population estimates
UNIVPL_Z_L	✓		Total number of students in England and Wales lagged	HESA Statistics
URBAN_L	✓		Principal component of bright lights indicator, % flats, % shared dwellings, population weighted average ward density of population, immigration rate, persons per room, HWCH, urbanisation factor (high values indicate more urbanised areas)	See text and Champion *et al.* (2001)
VACDRL	✓	✓	Vacant and derelict land divided by Total dwellings 1998 (HIP1)	Based on new National Land Use Database. Covers England only.
VACDRL_Y	✓		Y variable for all vacant and derelict land	VACDRL & DIJNETW
VISITS		✓	Visitor numbers to tourist attractions in 1996 divided by 1991 Census population	British Tourism Authority
WIDOW	✓		% widowed	1991 Census

Notes:
1. The suffix _L indicates a lagged variable. The suffix _Y indicates a regional variable. The suffix _Z indicates a national variable.
2. S1 = Stage 1 of the model: out-migration from origins. S2 = Stage 2 of the model: destination choice.

- the numbers of out-migrations from each of the 100 zones moving to each of the other 99 zones for each of the seven years 1990–91 through to 1996–97.

This NHSCR migration dataset is derived from the re-registration of individuals with family doctors (GPs) in another FHSA area. It therefore has the advantage of providing a continuous record of migration within the UK. As such, it has for many years been the main source of within-UK migration data used by ONS for its official population estimates for England and Wales. This is not to say that the NHSCR data provide a full and perfect record of migration. There is a well-recognised undercount of young adult males in the NHSCR datasets caused by this group of migrants being relatively less likely to re-register with their local GP. This causes the measured total out-migration values for these cohorts from many FHSAs to be smaller than they should be. If not corrected, this will lead to biased model calibrations if the undercount is not uniform across all FHSAs (which it is not).

To appreciate the nature of the problem, consider the comparison in Table 14.3 of the ratios of males/females in the SMS (Special Migration Statistics compiled as part of the 1991 Census) and the 1990/91 NHSCR for four sample FHSAs. These figures support the suspicion that young males have a tendency to postpone re-registering with a GP until later years: the ratios of males/females are much lower in the NHSCR dataset than in the SMS for the age groups 16–19, 20–24 and 25–29. The undercount, however, is not spatially stable and varies considerably across the FHSAs. Consequently, a model of out-migration totals for each migrant group will have problems predicting values for males in the age groups 16–19, 20–24 and 25–29 given the problems in the recorded values. There might be an associated problem of males re-registering at a destination after several years and hence inflating the figures in later age groups. There is some evidence for this in the Table 14.3 for Newcastle and North Tyneside, for example. Can we use the information on sex ratios in the SMS (which are presumed to be unbiased) to produce better migration matrices from the NHSCR data?

To achieve better estimates of migration from the NHSCR data, we assume that there is little or no bias in the recording of female migration in the NHSCR and that the ratio of total out-migrations by males/females for each origin in the NHSCR

Table 14.3 *Male/female ratios in migration outflows by age in Census and NHSCR data for 1990–91 for four FHSAs*

FHSA	Dataset 1990–91	Ages 0–15	16–19	20–24	25–29	30–44	45–59	60+
Newcastle	SMS	.92	.98	.99	1.12	1.18	1.16	.58
	NHSCR	.97	.65	.75	1.03	1.3	1.31	.67
North Tyneside	SMS	.93	.90	.87	1.12	1.23	1.14	.64
	NHSCR	1.02	.70	.67	.91	1.36	1.08	.68
Barnet	SMS	1.08	.75	.78	1.02	1.16	1.11	.65
	NHSCR	1.09	.61	.65	.76	1.07	1.00	.71
Kensington & Chelsea	SMS	1.06	.87	.73	.86	1.17	1.38	.76
	NHSCR	1.10	.69	.50	.60	.93	1.21	.81

should be the same as that observed in the SMS. This means that for each age group and for each FHSA the following equality holds:

$$M(n)/F(n) = M(s)/F(s) \tag{14.1}$$

where $M(n)$ and $F(n)$ are the numbers of male and female out-migrants, respectively, from the NHSCR and $M(s)$ and $F(s)$ are the respective values from the SMS. Consequently, we can construct a better estimate of $M(n)$, $M(n)^*$, by deriving separately for each origin the revised number of male out-migrants:

$$M(n)^* = [M(s)/F(s)]F(n) \tag{14.2}$$

For example, in the case of Newcastle, the 1990/91 NHSCR records a total of 214 male out-migrants. Using the above adjustment, the new total would be 0.98×330 (the number of 16–19 female movers from Newcastle recorded in the NHSCR) giving a value of 323. In a similar way, the total number of males 20–24 leaving Newcastle would rise from 1416 to 1869. This process was repeated for each origin for all seven age groups of migrants and across all 15 periods of the NHSCR. The assumption is made that the ratios of males/females is relatively constant through time and is recorded relatively accurately via the SMS.

These adjusted matrices were then used in the Stage 1 modelling procedure described below. To examine the impact of the adjustment, we calibrated a version of the Stage 1 out-migration model with the two sets of out-migrations (unadjusted and adjusted). Although the results are broadly similar, there are some differences in the estimated parameters and in seven cases different conclusions would be reached about the effect of individual variables on out-migration. In five of these seven cases the parameters change in terms of being significant at the 95% level and in the other two the sign of the parameter changes.

14.5.3 Migration Determinants

The data on the determinants of migration, both out-migration and destination choice, fall into three broad groups: (i) a relatively small set of *national* economic indicators; (ii) a much larger set of purely cross-sectional *zonal* variables; and (iii) a set of variables that are measured both over space and over time. The selection of many of the variables was informed by the findings of the review *The Determinants of Migration Flows in England* (Champion *et al.*, 1998), which identified seven factors influencing migration rates and places' attractiveness to migrants. These were demographic, cultural and social, labour market, housing, environmental, public policy and impedance. Below we provide a brief justification for seeking variables to represent each of these categories in the models.

14.5.4 Types of Determinant Variables

The two most important distinguishing features of the data assembled to represent the determinants of migration are whether the variable is national or local, and

whether the observation is in the form of a time series or a single point in time. For any cross-sectional variable we can also compute a *regional* version of the variable (see below) which measures the incidence of that variable in regions other than the one from which out-migration rates are measured. In this way, in order to model out-migration rates, we can capture the pull effects of conditions in other regions as well as the conditions from which out-migration takes place.

All the national-level variables are time-series, with observations for each of the 14 years being modelled in Stage 1. In Table 14.2 these are denoted with the suffix 'Z'. A number of the local-level variables are also time-series in nature. Where this is the case, we have used a one-year time lag for the equivalent variable in the Stage 1 modelling to avoid problems of circularity. Lagged variables are denoted with the suffix 'L'. For the remainder of the local variables, there is only one observation time point. The most common reason for this is that the data are taken from the Population Census and therefore relate to 1991. Fortunately, most of the variables affected are ones that change only rather slowly and the year 1991 is around the mid-point of the Stage 1 modelling period.

Regional variables (labelled with Y suffix) are calculated for the Stage 1 out-migration model. These variables are meant to capture the possible pull effects on out-migration caused by conditions elsewhere in the country. After experimentation with alternatives, the following formula was used for the regional variables:

$$Y_i = \left[\sum_{j\,j\neq i}(X_j/X_i)d_{ij}^{\beta} \Big/ \sum_{j\,j\neq i} d_{ij}^{\beta}\right] \tag{14.3}$$

where X_i is the value of X at location i and X_j represents the value of X at one of the other FHSAs. The formula produces a distance-weighted average ratio of X_j to X_i where nearby locations are weighted more heavily in the calculation than more distant ones. The value of β was taken as –2 which, from experience, gives a reasonably differentiated surface of Y values. Values of β less negative than this give a surface which is smoother; values of β more negative will give a spikier surface. Values of $Y_i > 1$ indicate that X_i is generally *smaller* than its neighbours. Values of $Y_i = 1$ indicate that X_i is generally very similar to its neighbours. Values of $Y_i < 1$ indicate that X_i is generally *larger* than its neighbours. One point to note with the formula for the regionalised variables is that the value of Y will tend to infinity as X_i tends to zero. In the few instances where this occurred, small values were substituted for zero. Also, the formula should not be used if the X values take both negative and positive signs.

14.5.5 National Indicators

A number of factors can be considered to affect the overall volume of migration taking place in the UK. These are time-series variables that are used only in the Stage 1 (migration generation) modelling. They are primarily related to the state of the economy: although we considered a wider set in Phase 1 of the work. The national variables that survived for input to the Stage 1 model in Phase 2 were GDP change (RGDPCH_Z), unemployment rate (UNEMP_Z_L), mortgage interest rate

(MGINTR_Z) and the number of university places (UNIVPL_Z_L), together with a time trend indicator (TIME_Z). These variables influence people's willingness and ability to move house or to set up home independently.

14.5.6 Demographic Variables

These variables are area-specific, with each zone being potentially able to take a different value. To varying extents, most of them are considered relevant to both model stages, because they are considered to influence both the extent to which people are likely to leave a zone and, for these migrants, the choice of one destination zone over another. The most important demographic factor influencing the propensity to move house – the age of a zone's population, with its linkage to stage in the life course – is already accounted for by out-migration being modelled for the 14 separate age–sex groups.

It was, however, considered important to have a direct measure of students in higher education, because of their high level of longer-distance mobility. Considerable effort was therefore put into generating two variables for students (Bailey and Rees, 2001). One variable, PARDOM, measures their presence at their parental/vacation address (from which most would be leaving for university and to which many might be expected to return). The other, TERMT, is for their term-time address (to serve initially as destination and then, at the end of their studies, as origin). Note that such special treatment does not need to be given to Armed Forces personnel, the other distinctive high-mobility subgroup, because their movements are not covered by the NHSCR.

The other specifically demographic variables included in the model relate to total population size (POPN), rate of immigration from outside the UK (incorporated in the URBAN composite variable), incidence of divorce (ASDIVRT), distribution of the population by marital status (SINGLE, WIDOW) and composition by household type (SINGELD).

14.5.7 Socioeconomic and Cultural Variables

The likelihood of people moving house, and therefore possibly leaving an area, is strongly related to their socioeconomic and cultural attributes. In particular, past research has highlighted the migration differentials between groups based on ethnicity, occupation/social class and income. One key variable presented under this heading, therefore, is the proportion of the population that is non-white in ethnic origin (NONWH, NONWH_Y), used in the Stage 1 model. Several measures were assembled to represent occupation/social class including the proportions in groupings by Social Class and by Socioeconomic Group, but after a data reduction exercise just one was used for the Stage 1 (migration generation) modelling. An age–gender specific index (OCCMIG) has been generated to represent the relative chances of out-migration from each zone based on the occupational structure of its population. Several measures of income were assembled and, after investigation

for multicollinearity, measures of average household income (HHINC_L and HHINC_Y_L) and the concentration of those on low incomes (LOW_L, LOWI_Y_L) were input to the Stage 1 model calibration and HINC was used in the Stage 2 model. We also included an educational measure, GCSE_L, in the Stage 1 model inputs.

14.5.8 Labour Market Variables

Labour market factors are seen as potentially important both in prompting out-migration from an area and in influencing people's destination choices. They would normally be interpreted as measures of the overall economic environment of the area, but some can also stand as factors affecting the propensity of individuals to move away from an area. A few variables were assembled to represent directly the labour market situation, including levels of employment (EMPR_L and EMPR_Y_L at Stage 1 and EMPR at Stage 2) and changes in jobs (EMPGRO_L at Stage 1, EMPGRO at Stage 2) and unemployment (ASUNEM_L and ASUNEM_Y_L at Stage 1 and ASUNEM at Stage 2). Beyond this, a number of the variables included above (under the 'social and cultural' heading), particularly those related to occupation and income, can also serve as indicators of the economic performance of areas, as can measures of the tightness of the housing market.

14.5.9 Housing Variables

Housing factors form a critical element underlying migration patterns in the UK, but they have complex interactions with migration and need especially careful treatment. On the one hand, some housing measures such as high house prices and low vacancy rates can reflect the strong economic performance of an area and indeed of neighbouring areas within commuting distance. On the other hand, these factors can directly influence the opportunities for in-migration, with high house prices acting as a deterrent and high vacancy rates as an attraction. Even here, however, the effect may not be as simple, as high house prices may lead to more rapid in-migration in anticipation of future price rises and very high vacancy rates may serve to undermine confidence in an area and deter people from moving there. The size, composition and quality of the housing stock can also influence both the level and the type of migration. Housing tenure, besides being a reflection of the social composition of an area, is also known to affect migration patterns, most notably the well-documented problems that people moving between local authority areas have in accessing council housing. A large number of housing variables were therefore assembled for the model. House prices are measured by HPRICE_L and HPRICE_Y_L at Stage 1 and by HPRICE at Stage 2. Vacancy rates are captured by PNRL_L, PVAC_L, PVAC_Y_L at Stage 1 and by PNRL, PVAC at Stage 2. House building is represented by PQPR_L, PQPR_Y_L, PQSR_L, PQSR_Y_L at Stage 1 and PQPR and PQSR at Stage 2. Housing condition is measured by NOCENT, NOCENT_Y,

RLAPSC, RLASC and RLASC_Y at Stage 1 and RLAPSC, RLASC at Stage 2. Housing tenure is input through TER at Stage 1.

14.5.10 Environmental Variables

In the current era within advanced economies, environmental factors play a major role in people's residential moves, both in prompting exits from areas and in acting as 'pull' factors. The term is used here in its broadest sense, covering all the physical, economic, social and political aspects that affect both the everyday quality of life and the longer term trends in life chances. This heading can therefore be considered to include most of the factors mentioned under the other headings above, insofar as they bear upon the overall quality of an area and of the neighbourhoods that it comprises.

Among those not specifically considered above are variables relating to derelict and vacant land (VACDRL and VACDRL_Y at Stage 1 and VACDRL at Stage 2), variables relating to the pattern of development, such as the proportion of new housing on brownfield land (PNBU at Stages 1 and 2), variables relating to population density, settlement size and level of urbanisation (combined into a composite variable URBAN), variables relating to crime (CRIME at Stages 1 and 2), variables relating to climate (CLIMATE at Stages 1 and 2) and air quality (AIR at Stage 1). Also included under the environment theme are variables relating to physical attractiveness, such as accessibility to scenic areas (SCENIC at Stages 1 and 2), and listed buildings (LISTED at Stages 1 and 2 and LISTED_Y at Stage 1), number of visitors (VISITS at Stage 2), the extent to which an area acts as a dormitory for commuters to relatively distant jobs (COMMUT at Stage 1) and accessibility to international air passenger connections (AIRPORTS at Stage 2). A 'bright lights' indicator measuring access to theatres and concert halls was incorporated into the URBAN composite.

14.5.11 Public Policy Variables

Public policy variables relevant to migration behaviour include not only direct interventions such as migration incentives and immigration policy but also indirect influences through the uneven effects of government grants, local taxes, defence spending, higher education expansion and the amount and location of land approved for house building. Two variables relating to expenditure on local government services, namely overall expenditure per capita and expenditure relative to the Standard Spending Assessment, were explored in Phase 1 but dropped because of multicollinearity. Level of council tax (CTAX) was included in the Stage 2 model.

In general, it was believed more satisfactory to estimate the role of public policy, past or anticipated, by reference to variables representing the aspects that public policy seeks to alter. For instance, the migration impact of a regional development initiative can be assessed by reference to, for instance, the number of extra jobs, while the impact of a policy that alters the availability of land for

housebuilding can be studied via changes to the number of housing completions. This is the approach adopted for assessing the consequences for migration of alternative policy scenarios.

14.5.12 Impedance Variables

The term 'impedance' is used here to refer broadly to the friction of distance, which is the single most important factor affecting movers' choice of destination. For a whole set of reasons, people changing address tend to move over short distances; indeed, three-fifths of movers recorded by the 1991 Population Census moved less than 5 kilometres. All other things being equal, places that are further apart therefore tend to have less to do with each other than places that are close together. Secondly, areas that share a boundary tend to have more migration between them, because this migration will include a proportion of short-distance moves from one side of the boundary to the other. Thirdly, areas situated in high population-density regions are likely to be less attractive to migrants, everything else being equal, because of increased spatial competition between destinations.

These three spatial processes are allowed for in the Stage 2 (migration distribution) component of the model, using respectively:

- a network-weighted distance variable, DIJNETW, based on distances between the population 'centroids' of pairs of zones, calculated on the basis of shortest surface route rather than straight-line distance, so as to take account of the effect of estuaries;
- a contiguity variable, CONTIG, taking the value of 1 for zones that share boundaries with each other, 0 for other pairs of zones;
- a destination accessibility variable, DESTACC, which measures the degree of spatial competition faced by a destination from nearby destinations.

The distance variable was used indirectly in the Stage 1 model as it is used in the computation of all regional variables.

14.6 Stage 1: A Model to Predict Total Out-migration from Each Origin

The model consists of two stages which recognise that migration results from two factors: the desire to leave an origin and the choice of destination. The model therefore consists, firstly, of a model to predict migration outflows from each area and, secondly, of a model to allocate the flows of migrants from each origin area to each of the alternative destinations. This section outlines the Stage 1 model. The volume of results from this exercise is substantial and beyond the limitations of this chapter. They are left for detailed discussion elsewhere. However, the end product of the project was the combination of both the Stage 1 and the Stage 2 model results into a user-friendly software package. We describe some sample results from this software to show how the overall package operates. We also describe the changes in both the

Stage 1 and Stage 2 modelling procedures as we moved from the prototype in Phase 1 to the final product in Phase 2.

14.6.1 The Phase 1 Out-migration Model

The volume of out-migration from an origin zone i is predicted as

$$O_{it}^{m} = omr_{it}^{m} P_{it}^{m} \tag{14.4}$$

where O_{it}^{m} is the total out-migration of migrant group m from zone i in time interval t, omr_{it}^{m} is the out-migration rate from origin i in time unit t for migrant group m (one of the 14 age–sex groups) and P_{it}^{m} is the population of migrant group m at risk of migrating from origin i during time interval t (usually estimated as the mid-interval population or the average of start of interval and end of interval populations). The out-migration rate is in turn modelled, in general form as

$$omr_{it}^{m} = f\left(X_{it/t-1}^{m}, Y_{it/t-1}^{m}, Z_{t-1}\right) \tag{14.5}$$

where omr_{it}^{m} is the out-migration rate for migrant group m from zone i in time interval t, $X_{it/t-1}^{m}$ is a vector of origin attributes in either year t or $t-1$ (lagged by one year); $Y_{it/t-1}^{m}$ is a vector of distance-weighted attributes describing the situation in other areas in either year t or $t-1$ and Z_{t-1} is a vector of attributes describing the national economic situation as it affects the overall volume of migration in year $t-1$ (lagged by one year).

In total, 14 models were calibrated, one for each migrant group defined on the basis of seven age groups and the two sexes. The models were calibrated using NHSCR data on total outflows from each of the 98 FHSA areas in England and Wales. Once calibrated, the Stage 1 model allows the total volume of out-migration from each area to be predicted, given conditions of that area, of surrounding areas and of the national economy.

What specific form should equation (14.5) take? Should the form be multiplicative or additive? Should we use logged functions of the variables (the multiplicative option) or leave them unlogged? Should non-linear forms of the variables such as quadratic forms be considered? In Phase 1, we adopted a multiplicative model with the specific form:

$$omr_{it}^{m} = \exp(K^{m}) A^{m} V_{1}^{alm} \ldots V_{53}^{a53m} \exp(a_{54}^{m} V_{54}) \ldots \exp(a_{58}^{m} V_{58}) \tag{14.6}$$

where the term $\exp(K^{m})$ is the intercept in the log–log regression, specific to each age and sex group. The age and sex specific adjustment factor A^{m} is necessary because of a statistical bias in the intercept estimate in a log–log regression. The adjustment factor is obtained by constraining the total predicted out-migration of a specific migrant group for all 98 origins to equal its observed value for the 1996/97 time period. The model contained 58 explanatory variables. The variables V_{1i} to V_{53i} were

explanatory variables which became log functions in the log–log regression, while the variables V_{54i} to V_{58i} could not be logged due to negative values and were represented in the exponential form. The regression parameters, represented by power coefficients, a_v^m, are specific to each variable v, and to each migrant group m.

The Stage 1 model developed in Phase 1 has a number of drawbacks, which were addressed in Phase 2 of the project. The first was the strong possibility of multicollinearity between determinant variables. This was addressed by both qualitative and quantitative means resulting in a much-reduced set of potential explanatory variables and a small set of composite indices constructed using principal components analysis. The second difficulty was the rather awkward combination of power and exponential relationships. This was addressed by switching to a straightforward linear model. The third problem was the assumption that a monotonic relationship existed between a dependent variable and determinant variables. This was addressed by introducing quadratic forms of each variable entered into the models. The fourth drawback of the Phase 1 model was a tendency for out-migration from London FHSAs to be underpredicted. This was handled through the introduction of a London dummy variable. The London effect we think results from the different nature of internal migration in London, with migration flows being within a labour/housing market area rather than between such market areas. The fifth was that the model form made no allowance for possible time trends in migration (not accounted for by the set of time varying determinants used). A time trend was introduced to address this problem. The sixth difficulty was the arbitrary way variables were selected for inclusion in the model. In Phase 1, we had aimed at a common model across all migrant groups and selected the variables based on a majority of migrant group models reporting significance for particular variables. In Phase 2, stepwise inclusion based on significance of parameters was used for each age–sex group to determine a set of 14 age–sex-specific final models.

14.6.2 Investigations of the Phase 1 Out-migration Model Problems

Modelling Time Trends

To gain an understanding of the level of variation in out-migration volumes both across space and over time, we graphed out-migration volumes over time for each of the seven age groups (males and females combined) for all 98 FHSAs. Figure 14.1 illustrates trends in out-migration by the age groups used in the model for one FHSA, Newcastle. The main findings from the 98 graphs are as follows.

- There is a great deal of stability over time in the out-migration rates for the age groups 0–15; 30–44; 45–59; and 60+. This is true across the country and for many FHSAs the relationships are essentially flat. The main variations in the rates for these age groups are cross-sectional.
- Migration rates tend to be highest for the age groups 20–24, 25–29 and 16–19 and lowest for the age groups 60+ and 45–59.

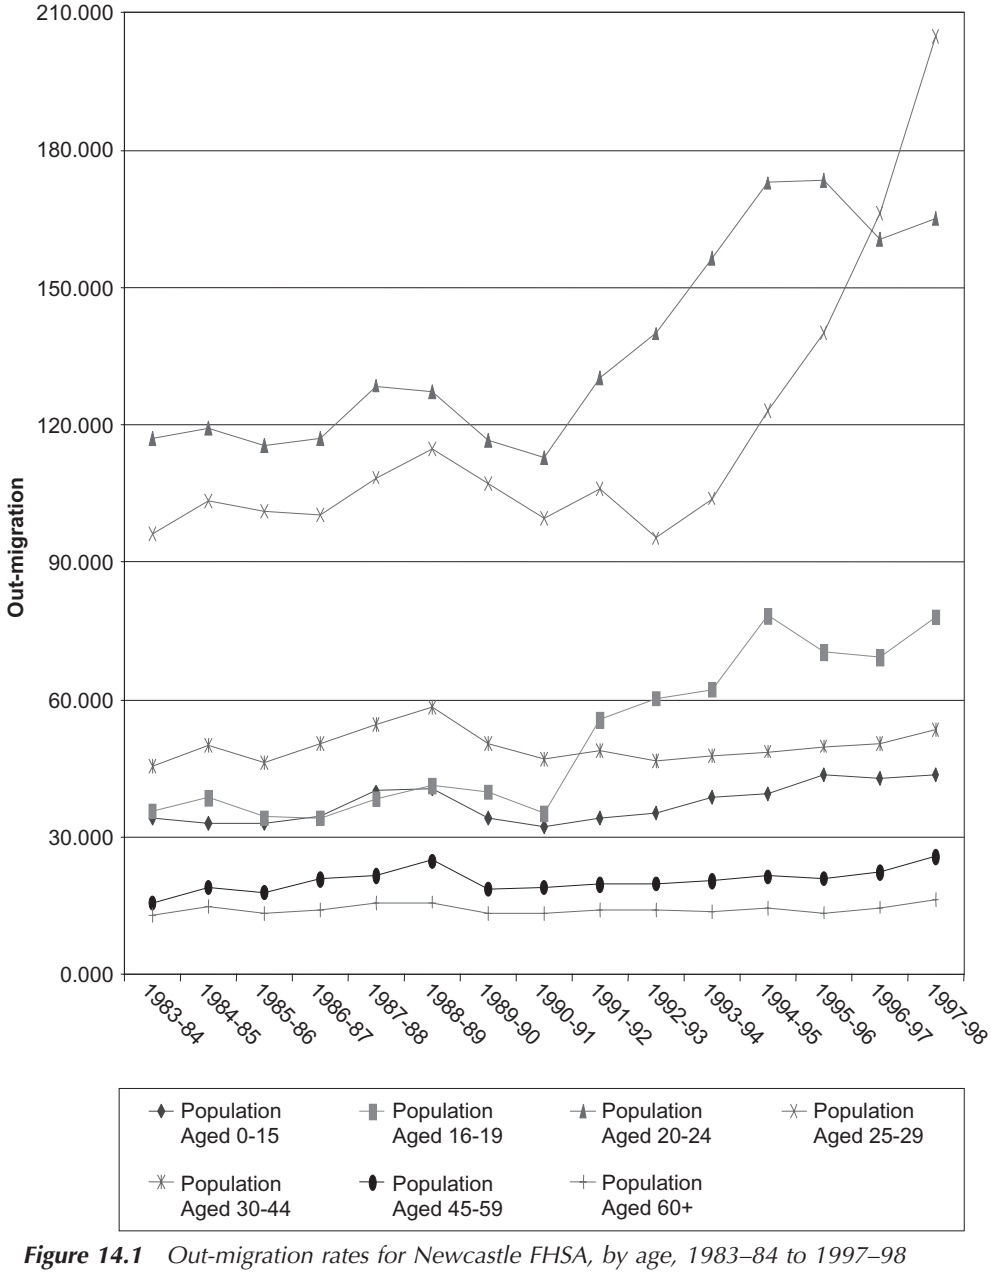

Figure 14.1 *Out-migration rates for Newcastle FHSA, by age, 1983–84 to 1997–98*

- There has been a rapid and strongly linear rise for almost all FHSAs in out-migrations by the 16–19 age group since 1990. Before this date, the level of out-migration for 16–19 year olds was relatively constant. The rise is due to the rapid expansion of higher education in the 1990s. We therefore added a variable to the Stage 1 model, UNIVPL_Z, the total number of university places available in a year.
- For FHSAs with relatively large student populations, such as Newcastle, concomitant with the rise in out-migration by the 16–19 age group through the 1990s, has been a rise in out-migration by the 20–24 and the 25–29 age groups. This is highly likely to be due to graduated students leaving university.
- There is little evidence to support any particular time trend otherwise in out-migration rates over time.

As well as plotting out-migration rates over time, all the other time-varying variables were also plotted over time to get a better 'feel' for the data. Many trends appeared to be highly erratic over time which, to anticipate the results of the Stage 1 model calibrations, probably explains the lack of explanatory power in some of these variables. The Stage 1 model contains some time series variables that might need special treatment in the model because of trends in some of the observations and some of the determinants. In Phase 1, no special treatment was given to these variables.

There are different strategies, of varying degrees of complexity, for handling time series variables in regression. To a large extent, the choice of a particular strategy depends on asymptotic properties of the time series variables, both dependent and independent, that are difficult to assess, especially in the case here with only 15 different time periods. Basically, the issue is whether any trends that are observed are stochastic or deterministic. Different strategies need to be followed depending on the answer to this question: stochastic trends are better handled using a differencing approach; deterministic trends are better handled using a de-trending approach. Although there is a vast literature on this subject, there is no real consensus on how to proceed in our situation where we have only 15 time periods and no real way of assessing the nature of any time-dependency. This severely limits what we can do. It should also be noted that although we are using 15 years of data to estimate certain relationships in the out-migration model, the majority of determinants are cross-sectional. However, despite these caveats, we conducted the following experiment.

- We added a linear trend to the out-migration model. This is the simplest and perhaps most effective way to account for time trends in both the dependent and independent variables. A non-linear trend, such as a quadratic, could be added if the data suggest such a trend exists although there is no real evidence for such a function.
- We transformed all time-varying variables into first differences by subtracting the value in time $t - 1$ from the value in time t. One obvious result of this procedure is that we were left with only 14 time periods. Variables that are constant over time were not first differenced.

A 'plausible' Stage 1 model was constructed and the experiment run with males 30–44 migrants (the largest volume of migrants). The following calibrations of this model were then undertaken:

- a 'baseline' model with no time trends taken into account;
- a model with a linear time trend added; and
- a model using first differences.

The results demonstrated the superiority of using a linear time trend. The use of first differences gave a very poor model fit and most of the cross-sectional variables were statistically insignificant. There was a modest improvement in goodness-of-fit in using a linear time trend over using no time trend. As anticipated, the two models yield broadly similar results for the parameter estimates of the cross-sectional variables but there are some variations in parameter estimates for the time-varying variables, which are more accurately estimated in the model including the time trend. Several other forms of the Stage 1 model were calibrated with and without the time trend and all the results supported the conclusion that adding a linear time trend provided slightly better results. Consequently, the Stage 1 models results used in the MIGMOD software were obtained from models containing a linear time trend.

OLS or WLS?

In Phase I, the Stage 1 models were calibrated with WLS with extra weight given to data pertaining to health areas with large populations. The justification for this was that the dependent variable in the regressions is migration rate which might be less reliable for origins with small populations. However, the justification may not be particularly strong in this case as the FHSAs all have fairly large populations. Consequently, we examined the efficacy of WLS compared with OLS on a sample of models. The results of applying the two calibration techniques were virtually identical so that there is little rationale for using WLS over OLS. Consequently, we employed OLS for the Stage 1 model calibrations, which avoids the need for a somewhat speculative definition of the weighting variable.

Unlogged or Log–Log Format?

In Phase I, the Stage 1 models were calibrated in log–log format. This had the disadvantage of producing a biased estimate of the intercept which had to be corrected after the calibration had taken place by the addition of an adjustment factor to the model format. This was done originally because the log–log format appeared to give slightly better predictions of out-migration. To examine whether this advantage still held, given the change in the Stage 1 models, we performed the following experiment.

Two plausible Stage 1 models were identified that contained the variables listed in Table 14.2. These models differed only in that one contained a linear time trend and the other did not. Both models were then calibrated by unlogged regression and then

Table 14.4 *Goodness of fit (R^2) for model tests*

Model	Unlogged	Log–Log
Without time trend	0.924	0.907
With time trend	0.928	0.918

again in a log–log format. The adjusted R^2 values from the four calibrations are shown in Table 14.4. These results suggest that an unlogged regression is superior to a log–log format. This also has the added advantage of producing an unbiased estimate of the intercept so that an adjustment factor is not needed in Stage 3 (the front-end) to balance the predicted values. Results from the calibrated models in the form of scatterplots of the standardised residual against the standardised predicted value confirmed the validity of the unlogged form of the model. The plots exhibit no evidence of heteroscedasticity and no evidence of any non-linearity.

Lagged or Unlagged Time-Varying Variables?

Some of the variables in the Stage 1 dataset vary over time. It is an issue as to whether these variables are entered in the model with their current year values (unlagged) or the previous year's values (lagged). The answer relates to whether migrants respond more to current conditions or to conditions in the previous year (the justification for the latter being a time lag between the stimulus to move and the move itself). It is difficult, if not impossible, to argue convincingly for either approach and so the question then becomes an empirical one – which form of the variables generates the more accurate model?

To answer this question a plausible Stage 1 model was calibrated for Males 30–44 using the variables described in Table 14.2. In one version of the model the time-varying variables were lagged; in another they were unlagged. The lagged model produced an adjusted R^2 value of 0.952, while the unlagged model R^2 value was 0.935. It was therefore decided to use lagged versions of the time-varying variables.

14.6.3 The Phase 2 Out-migration Model

From the resolution of the set of issues discussed above, the final form of Stage 1 of the model was defined. The Stage 1 model relates the adjusted out-migration rate for migrant group m in FHSA i at time t to a series of independent variables which describe the economic, social and geographic conditions of i. The independent variables are of three types: cross-sectional variables (some of which also vary over time); regional variables; and national time series variables. The linear model of out-migration rates has the basic form:

$$omr_{it}^{m} = \kappa^{m} + \sum_{p} \alpha_{p}^{m} X_{pit}^{m} + \sum_{q} \beta_{q}^{m} Y_{qit}^{m} + \sum_{r} \gamma_{r}^{m} Z_{r}^{m} + \varepsilon_{it}^{m} \qquad (14.7)$$

To this were added quadratic terms, a linear time trend and a London dummy:

$$\begin{aligned} omr_{it}^{m} = {} & \kappa^{m} + \sum\nolimits_{p} \alpha_{p}^{m} X_{pit/t-1}^{m} + \sum\nolimits_{q} \beta_{q}^{m} Y_{qit/t-1}^{m} + \sum\nolimits_{r} \gamma_{r}^{m} Z_{rt-1}^{m} \\ & + \sum\nolimits_{p} \delta_{p}^{m} \left(X_{pit/t-1}^{m} \right)^{2} + \sum\nolimits_{q} \eta_{q}^{m} \left(Y_{qit/t-1}^{m} \right)^{2} + \sum\nolimits_{r} \theta_{r}^{m} \left(Z_{rt-1}^{m} \right)^{2} \\ & + \psi^{m} T_{t} + \zeta^{m} LD_{i} + \varepsilon_{it}^{m} \end{aligned} \tag{14.8}$$

where omr_{it}^{m} is the predicted out-migration rate for migrant group m in FHSA i in time interval t, X represents a cross-sectional variable (some of which can also be time-varying); Y represents a regional variable; and Z represents a national time-varying variable, T is a time counter and LD stands for London dummy (= 1 if the FHSA is in London, = 0 otherwise). The regressions coefficients are denoted by Greek letters and ε_{it}^{m} is the error term for each zone, time and migrant group combination. The model is calibrated separately for each of 14 migrant groups (males and females in each of seven age groups).

14.7 Stage 2: A Model of Destination Choice

14.7.1 The Model

The Stage 2 model is a migration destination model that distributes the total number of out-migrants from FHSA i to each of the 97 destination FHSAs based on the characteristics of each destination FHSA and the separation between the origin and each destination. It is a spatial choice model of the destinations chosen by migrants from an origin. The model to be calibrated has the general form:

$$M_{ij}^{m} = O_{i}^{m} \prod\nolimits_{p} X_{pj}^{\alpha pim} d_{ij}^{\beta im} \Big/ \sum\nolimits_{j} \prod\nolimits_{p} X_{pj}^{\alpha pim} d_{ij}^{\beta im} \tag{14.9}$$

where O_{i}^{m} is the volume of out-migration of type m from origin FHSA i (known when the model is calibrated, predicted by the Stage 1 model when predictions are being made at Stage 3); X_{pj} represents an attribute of FHSA j that affects the choice of j by migrants from i; and d_{ij} is the distance between i and j. The X variables are raised to powers, α_{pim}, specific to each variable p, origin i and migrant group m, while the distance variable is raised to the power β_{im} specific to each origin i and migrant group m. The parameters of this model indicate the sensitivity of migration flows to particular destination characteristics: in essence they indicate what features of a destination make it attractive to migrants and which features make it unattractive. For example, a relatively large score on an attribute with a positive parameter estimate would make a destination attractive to migrants, *ceteris paribus*, while a relatively large score on an attribute with a negative parameter estimate would make a destination unattractive to migrants, other things being equal. This model has a long history in the analysis of spatial interaction patterns (see *inter alia*, Fotheringham and O'Kelly, 1989, and Fotheringham *et al.*, 2000, Chapter 9).

The model is calibrated separately for each of the 98 origins and each of the 14 migrant groups. For any origin, $O_i^m/\Sigma_j \Pi_p X_{pj}^{\alpha pim} d_{ij}^{\beta im}$ will be a constant (k_i^m) so that the origin-specific model is then simply,

$$M_{ij}^m = k_i^m \prod_p X_{pj}^{\alpha pim} d_{ij}^{\beta im} \tag{14.10}$$

Note that there will be $98 \times 14 = 1372$ sets of model parameters to be calibrated in this highly specific spatial interaction model.

14.7.2 Poisson Regression or OLS?

In Phase 1, we calibrated the Stage 2 model by Ordinary Least Squares regression by taking logs of both sides of the equation to make it linear-in-parameters. Although convenient, this has two problems:

- The dependent variable M_{ij}^m is a count of migrants and therefore is likely to be Poisson distributed rather than normally distributed. This means that one of the key assumption of OLS is probably not met. This is particularly a problem where the migration matrices contain lots of small flows as is the case here.
- A practical problem arises in taking logs of both sides of the model when M_{ij}^m is zero (as are many of the recorded flows). Taking the log of 0 yields negative infinity. The solution to this used in Phase 1 was to add a small increment (0.5) to all flows before taking logs. Although tests showed this does not appear to bias the results greatly, nevertheless it is a somewhat arbitrary procedure.

An alternative, and perhaps superior method of calibration, is to use Poisson regression which assumes the conditional mean of the variable we are trying to model has a Poisson distribution and avoids the need for making some approximation to zero flows. The use of Poisson regression for calibrating migration distribution models has been demonstrated in a number of papers (*inter alia*, Flowerdew and Aitkin, 1982; Flowerdew, 1991).

In order to compare the performances of Poisson and OLS regression for migration destination choice models, we conducted a series of experiments comparing Poisson and OLS calibration results on the same datasets. A relatively simple, but quite plausible, Stage 2 model was postulated containing the following explanatory variables (the model was constructed from the original set of variables from Phase 1): Population, Destination accessibility, Distance, Contiguity, Urban, Beach, Rain, Council Tax and Household Income. This model was calibrated separately for each of the 98 origins using migration data for males 30–44. The performance of the calibrated models in replicating migration flows was assessed using the modified psi statistic, ψ (Knudsen and Fotheringham, 1986), which demonstrated the superiority of Poisson regression in terms of goodness-of-fit to the observed data. Consequently, all the Stage 2 models were calibrated with Poisson regression.

14.7.3 Variables for Stage 2

In Phase 1, the Stage 2 dataset contained 69 variables. This set was greatly reduced following a qualitative assessment of each of the variables in the dataset and an examination of multicollinearity amongst the independent variables. This left a final set of 27 variables in the Stage 2 model which are listed in Table 14.2.

14.7.4 Migration Data

As with Phase 1, the migration data used in all calibrations of the Stage 2 model were for the 1996/97 time period. Previous results in Phase 1 suggested that the calibration results were either stable over time or that the 96/97 period provided a good average of the years since 1990 (see Champion *et al.*, 2001).

14.7.5 Modelling Procedure

The procedure for variable selection was different from that employed in Phase 1. In Phase 1 initially, a separate model was calibrated for all origins for each migrant group using all 69 explanatory variables. Then, to determine the final model form for each migrant group, variables were selected from the 69 if they were significant for >9 origins and the model containing only those variables was re-calibrated. Instead of this largely *ad hoc* procedure, in Phase 2 we calibrated the model containing the 27 variables in the Stage 2 dataset for each of the 98 origins and for each migrant group. This avoids the need for any *ad hoc* selection procedure and allows us to make comparisons of the parameter estimates across the 14 migrant groups.

One final note should be mentioned on how the Stage 2 modelling procedure differed from that in Phase 1. It was agreed with the Department that we should drop the modelling of migration flows from Scotland so that we had only 98 origins for which migration flows are estimated endogenously in Stage 3 of the procedure.

14.8 Stage 3: The MIGMOD Software

The out-migration and destination choice models described above (Stages 1 and 2) are combined within a user-friendly software package termed MIGMOD built around the GeoTools mapping software developed at the University of Leeds. MIGMOD contains all the data described above as well as the estimated parameters from the calibrations of the Stage 1 and 2 models. As shown below, the user has access to these in both tabular and, where feasible, mapped form at the click of a button. We now describe some of the features of the MIGMOD software.

The parameters from the calibrated Stage 1 model in equation (14.8) and the calibrated Stage 2 model in equation (14.10) were entered into MIGMOD along with

data on observed migrations and the determinants of both out-migration and destination choice. Within MIGMOD the level of out-migration from each origin is then computed by first estimating the out-migration rate from each origin and for each migrant group within that origin and then multiplying these rates by the relevant population size. This produces estimates of out-migration volumes for each migrant group within each origin. These out-migration numbers are then allocated across the destinations on the basis of the attributes of these destinations according to the Stage 2 model. The user can then alter conditions in any origin or set of origins and/or in any destination or set of destinations and examine the impact such changes have on the resulting migration patterns.

The starting point of MIGMOD is the initial menu as shown in Figure 14.2. This gives the user four options:

- view any of the coefficients from either the Stage 1 or the Stage 2 models;
- examine various aspects of the observed and predicted migration matrices;
- develop policy-related scenarios in which some combination of the independent variables in the Stage 1 and 2 models is changed and a new set of predicted migration flows is obtained which can then be compared with the original set of flows; and
- view any of the time-varying variables in a series of graphs over time.

For instance, selecting 'View Coefficients' produces a set of options on which coefficients you want to view. The user has a choice of a table of Stage 1 parameter estimates, as shown in Figure 14.3, or a matrix of origin-specific Stage 2 parameter estimates for any one of the 14 migrant groups as shown in Figure 14.4 for the

Figure 14.3 *Stage 1 parameter estimates viewed through MIGMOD*

migrant group 'Males 30–44'. A very useful feature of MIGMOD is that if any column of data or parameter estimates relates to a set of regions, as the Stage 2 parameter estimates do, then simply double clicking on the column heading automatically generates a map of the data or parameter estimates. For example, a map of the spatial distribution of the house price parameter in the Stage 2 model for Males 30–44 is shown in Figure 14.5. This shows the interesting pattern that migrants from relatively wealthier origins primarily in the south of England view high house prices at a destination as an attractive feature whereas migrants from relatively poorer origins view high house prices as a deterrent. More information on such parameter variations is given in a future publication and can be found in the government report on this project (Fotheringham *et al.*, 2002).

Rather than viewing the calibration results, the user can select the option of viewing the original migration data, in which case the window shown in Figure 14.6 appears. This allows the user several options to view different facets of the migration data. Basically the user establishes two migration data sets termed 'Observed' and 'Baseline'. The 'Baseline' button is used to define one migration set which will henceforth be referred to as 'The Baseline'. The user is given a set of options ranging from the observed data, the predicted migration matrix from the baseline model and the predicted migration matrix from other runs of the model using different scenarios of

Figure 14.4 *Stage 2 parameter estimates viewed through MIGMOD*

explanatory variables. The 'Observed' button is used in a similar manner to define a different set of migration data to that defined as 'The Baseline' and this is termed 'The Observed'. The 'Operation' bar then allows the following matrices to be displayed:

- View the 'Observed' Matrix;
- View the 'Baseline' matrix;
- View the 'Observed' – 'Baseline' matrix;
- View the absolute differences between 'Observed' and 'Baseline'; and
- View the percentage differences between the 'Observed' and 'Baseline'.

To this point all the operations are based on the cells of the full matrix. The button labelled 'Matrix' gives the user the option of viewing outflow totals, inflow totals and net flows for any of the migration matrices. The button labelled 'All Ages' allows the user to define which of the seven age groups should be displayed and one option here is to use 'All Persons'. The final option entitled 'Persons' allows the user to define whether the migration data displayed are for males or females or both. The use of MIGMOD for developing scenarios for policy evaluation is described elsewhere (Champion *et al.*, 2002; Fotheringham *et al.*, 2002).

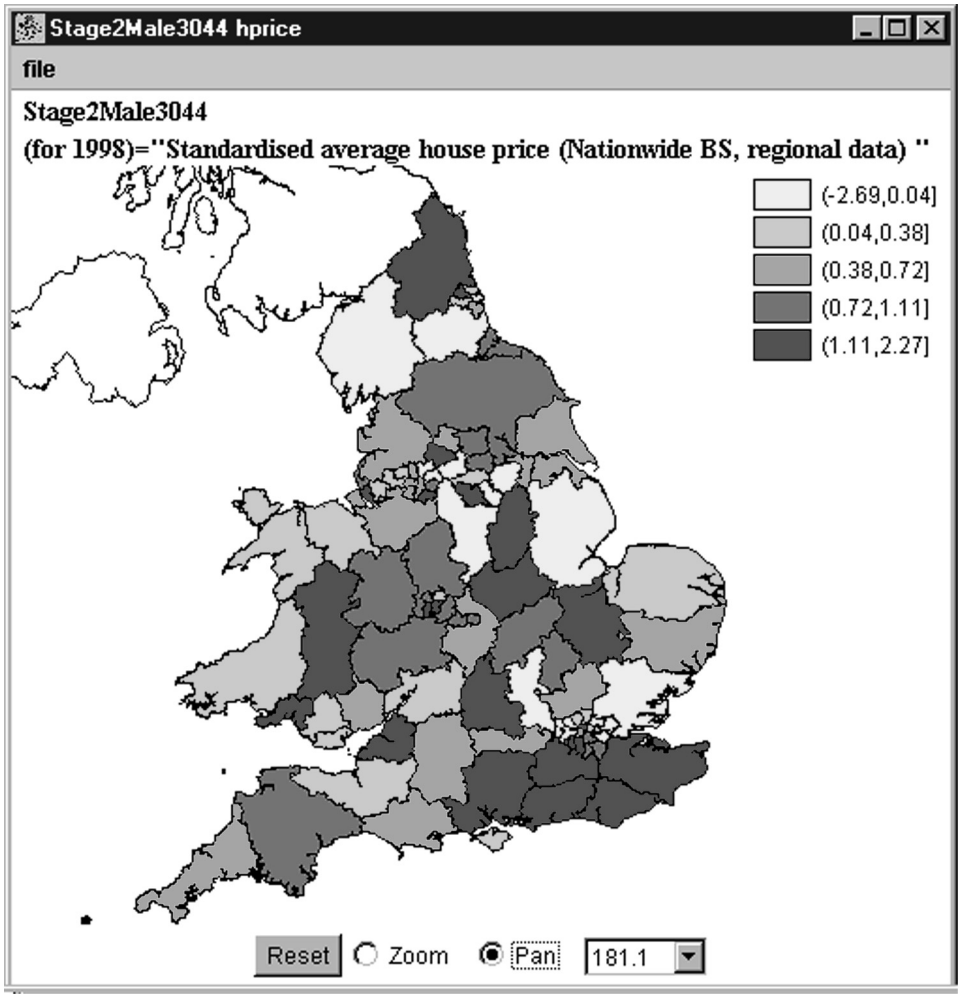

Figure 14.5 *The spatial distribution of the house price parameter in the Stage 2 model*

14.9 Summary

This chapter has described the structure of a very large spatial interaction model, constructed to explain the flows of migrants between 98 zones in England and Wales. The model was constructed in two phases and many changes were made in the second phase to overcome difficulties present in the first phase model. The two model stages, prediction of out-migration flows from origins and their distribution to destinations, were combined in Stage 3 into an operational model for the sponsoring Department so that scenarios related to policy could be implemented. Full details are provided in the Final Reports to the Department (Champion *et al.*, 2001; Fotheringham *et al.*, 2002) and in Champion *et al.* (2002). The authors believe that the model of

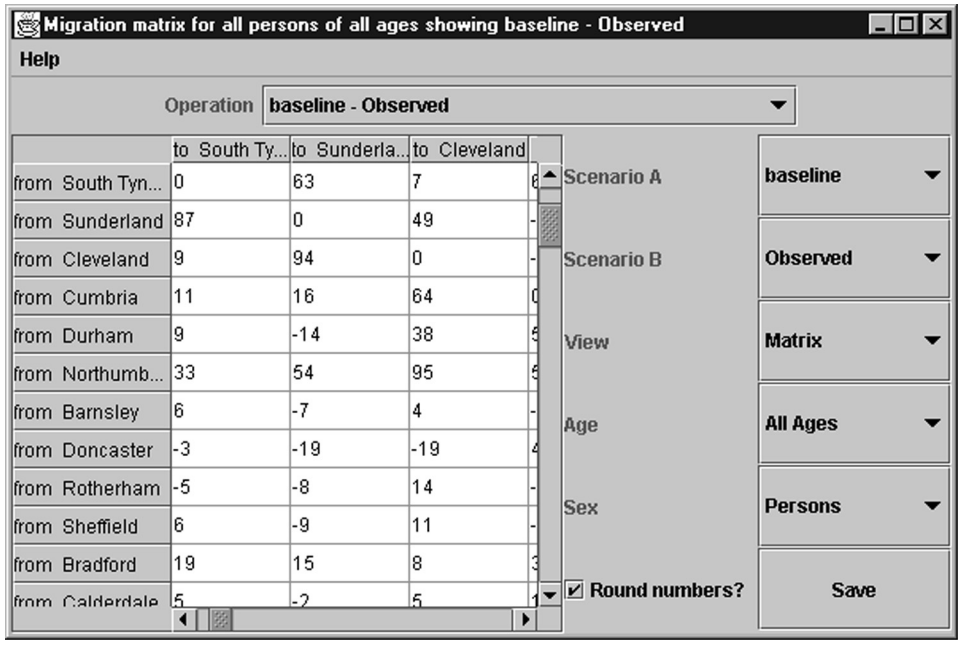

Figure 14.6 *The migration data viewer in MIGMOD*

migration constructed here to be one of the most comprehensive and meticulously researched such endeavours, which we hope will find utility in the formulation of English regional development and housing development policy in the future.

Acknowledgements

The Team

The migration model was constructed by a research team from four organisations: the University of Newcastle upon Tyne, University of Leeds, Heriot-Watt University/Edinburgh College of Art and Greater London Authority (formerly London Research Centre). The authors were supported in their work by other members of the team in data assembly, modelling and scenario development: *Newcastle* – Tony Champion (who led Phase 1), Seraphim Alvanides, Tim Barmby, Chris Brunsdon, Martin Charlton, Mike Coombes, Simon Raybould, Andy Tremayne; *Leeds* – Adrian Bailey, Oliver Duke-Williams, Heather Eyre (now with Education Leeds), James Macgill, John Stillwell; *Edinburgh* – Glen Bramley (who was responsible for scenario development), Hilary Anderson, Tania Ford; *Greater London Authority* – John Hollis and *University of Southampton* – Tom Wilson (now at the University of Queensland, Brisbane). The authors would also like to thank DETR's steering group led by Andrew Parfitt in 2000 and DLTR's steering group led by Stephen Rosevear in 2001,

who managed the contract so efficiently, and members Dorothy Anderson and Jenny Wood (ONS) who were helpful in identifying and supplying data.

The Sponsor

This chapter describes work carried out for the Department of the Environment, Transport and the Regions (DETR), restructured and renamed Department of Transport, Local Government and the Regions (DTLR) in June 2001 under contract RADS 5/9/22 (2000) and a variation (2001). The full report on Phase 1 and Phase 2 has been published by the Office of the Deputy Prime Minister (ODPM, 2002).

The Operational Model (MIGMOD, version 2.0)

An interface to the model was developed at the University of Leeds, primarily by James Macgill of the Centre for Computational Geography with help from Heather Eyre and Phil Rees and delivered to the Department on CD as a self-install and standalone software suite with accompanying observed migration datasets, the determinant variables, the model parameters, a set of predicted migrations and a system for developing alternative scenarios. MIGMOD is the intellectual property of the Department (currently ODPM). Readers who would like a copy of the operational model should seek permission from the ODPM.

Data Contributors

The research team is indebted to the many individuals and organisations that provided advice and help in the assembly of data. We are especially grateful to those at the Department who played a facilitating role in putting us in touch with data holders: Andrew Parfitt, Dominic Bryant, Russell Harris, Stephen Rosevear. In addition to those listed below against individual variables, Kerrick Macafee (the Department) and Glenn Everett (DTI) were also very helpful. We would also like to acknowledge the help and advice provided by members of the national statistical offices, especially in relation to data on international migration: *ONS*: Roma Chappell, Lucy Vickers, Alastair Davies, Denise Anderson, Brett Leeming; *GRO-Scotland*: Francis Hay; *NISRA*: Robert Beatty, Maire Rodgers, Maureen Ferguson. The following persons helped with particular variables. They are listed by variable with affiliation and name: agric, ONS (AES/ACE), Notice Ref 195R, via NOMIS (DETR), Carole Sutton, Simon Connell; air, AEA Technology, Emma Linehan; asunem, Employment Service/LFS via NOMIS, Andrew Craven (NOMIS); bank, ONS (AES/ACE), Notice Ref 195R, via NOMIS (DETR), Carole Sutton, Simon Connell; cars, DETR, Andrew Ledger; climat, Hadley Centre (UEA), David Viner; constr, ONS (AES/ACE), Notice Ref 195R, via NOMIS (DETR), Carole Sutton, Simon Connell; divrate, ONS, John Haskey; dlgexp, DETR, Welsh Office, Scottish Executive, Somerset CC, CIPFA, Stephen Greenhill, Ade Akinfolajimi, Justin Vetta, Stuart

Modelling Regional Economic Growth by Means of Carrying Capacity

Leo van Wissen

Abstract

In this chapter a new model of spatial economic growth is proposed. It is based on the ecological concept of *carrying capacity*, defined for a geographical system of regions. The use of ecological concepts refers to the dynamic evolution of populations over time. Here, we view the development of economic markets as an ecological process of growth towards the carrying capacity level. The carrying capacity is given an economic interpretation, and is equal to the market demand for a product. In addition, a spatial dimension is introduced that gives, for each location in a spatial system, the disequilibrium between carrying capacity (demand) and supply. The chapter shows a number of characteristics of the model and demonstrates how the model may be used empirically. Some empirical results are given from an application of the model in the field of industrial demography.

15.1 Introduction

Regional economic growth can be modelled in many ways. The question why certain regions grow faster than others has attracted many geographers and economists in the past. Amstrong and Taylor (2000) give a concise overview of a number of these models and methods, such as the regional input–output model, the neoclassical regional growth model, the regional multiplier model, or the economic base method. Most existing models share one common characteristic: they are essentially

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

macro-economic models, applied at the meso-scale of the region. As a result, they share many of the characteristics of macro-economic models: in particular they are either implicitly or explicitly based on the notion of equilibrium. This equilibrium view of the world has been challenged in recent years from different viewpoints. After all, it seems more logical that regional models of economic growth should focus on change instead of equibrium and structure. Change in these models is a necessary but short episode between two states of equilibrium, or can only be deduced from the difference between two equilibrium states.

One of the most important criticisms against this essentially neo-classical view of the world was raised by Nelson and Winter (1983), who advocated a new evolutionary paradigm in economics. Their models were based on an evolutionary concept of economic change. It emphasises change instead of equilibrium, process, instead of structure. Important economic processes are selection, adaptation, inertia and competition. Within sociology, a somewhat similar field has developed, which focuses on processes of change in populations of organisations. This field is called organisational ecology, or simply demography of firms or industrial demography (Hannan and Freeman, 1989; Carroll and Hannan, 2000), in which populations of firms evolve through selective processes of entry and exit.

Demography of firms is also becoming more widespread in economic geography (van Dijk and Pellenbarg, 2002; van Wissen, 2002). In principle it may offer an alternative view on regional economic growth, based on regional variations in birth, death, migration and firm growth processes. In the past it has been used largely as a descriptive tool for regional employment change (see e.g., Gudgin, 1978), but more recently analytical models of regional economic growth have been developed as well (van Wissen, 2000).

In analytical models of firm population evolution in a regional economic setting, there are a number of problems that have to be solved. These problems derive from (1) the translation of demographic processes to the level of firm populations; (2) the introduction of economic mechanisms of demand and supply in demographic processes; and (3) introducing the spatial dimension in firm demographic models (van Wissen, 2002). The first problem involves issues such as definitions, model structure, the modelling of firm birth, death and other demographic components, and the impact of age, period and cohort, or other primary variables on demographic events. Many of these issues have been treated in van Wissen (2000). This chapter deals with a possible solution to the second and third problems.

The second problem deals with the notion of the market. Even if equilibrium is not taken as the starting point, there is still the impact of the 'invisible hand of the market' on firm founding and failure, and growth. One of the most important differences between human and firm demography is the existence of demand and supply interactions or, in ecological terms, a feedback mechanism between the number of firms in a population and population growth. In short, the larger the population of firms and the larger the supply of products in the market, the fiercer the competition and the lower the population growth. Population ecologists call this feedback between population size and growth the density dependence model (Carroll and Hannan, 2000). The ecological notion of *carrying capacity* is a fruitful starting point for introducing an invisible market hand into these models. *Carrying capacity* is an

ecological concept. In an ecological framework a population (generally of animals) will grow if its current size is smaller than the carrying capacity for that population. If the actual size is larger than the carrying capacity, the population will decrease in size. We will build upon this ecological concept and extend it to apply to a multi-sector economy.

The third problem involves introducing the spatial dimension into the model. In most regional economic models, as well as in most population ecology models, the notion of space is not very well developed. In the simplest case, regions are small-scale variants of nations, with only imports and exports as signs of life outside of the region. In other cases, such as in the multi-regional input–output table, a limited number of regions interact, but the influence of distance remains implicit in the model. In recent years, Krugman and colleagues developed a series of economic models that take the spatial dimension seriously (Krugman, 1995; for an introduction see Neary, 2001). Although these models have many attractive theoretical properties, it is difficult to apply them other than in a highly stylised world, where only two regions exist, or which has a linear or circular form. The ecological model to be developed also contains an explicit spatial dimension. In population ecology, populations interact with each other. These interactions occur between different populations as well as between different regions. The spatial dimension essentially implies that nearby populations have higher propensities to interact than others.

In short, this chapter proposes a model of regional economic change, based on the ecological concept of *carrying capacity*. It also contains elements of regional input–output models, thus establishing a link with more traditional regional economic growth models. Thirdly, the model involves inter-sectoral as well as spatial interactions. Ironically this resulting model has a much larger applicability than the field of firm demography. Although its structure is based on an ecological concept, the resulting model can be used in a population ecology or evolutionary framework, but it may also be used as a regional economic model of change without reference to these fields.

This chapter is organised as follows. First, in Section 15.2, we introduce the basic concept of *carrying capacity*. In the following sections, we extend this concept to a multi-sector economy (Section 15.3) and include a spatial dimension (Section 15.4). In Section 15.5 a general matrix notation is given. A number of model characteristics are investigated in Section 15.6 using a simulation framework. The concept of spatial carrying capacity is not only relevant from a theoretical point of view. On the contrary, it can be applied in an empirical setting as well. Section 15.7 contains empirical evidence of the usefulness of this approach. Section 15.8 concludes.

15.2 The Concept of Carrying Capacity

Carrying capacity denotes the maximum number of users that can be sustained by a given set of resources in a specified territorial unit. In organisational ecology it is defined as the maximum number of organisations of a specified type that the market, or society, can sustain (Hannan and Freeman, 1989). The term can be given a clear

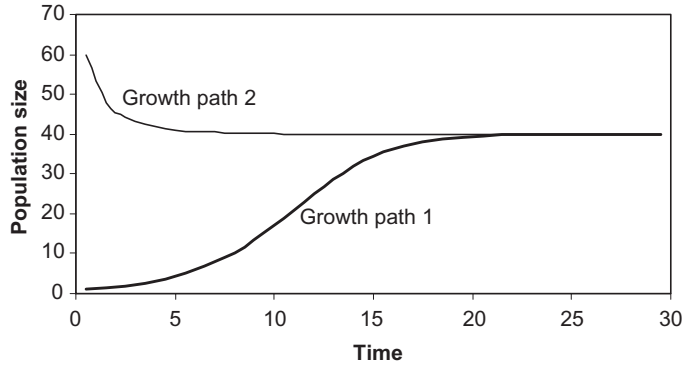

Figure 15.1 *Population growth following a logistic growth curve towards the level of the carrying capacity, starting from two different initial values*

mathematical interpretation, most notably in the example of the logistic growth curve describing the temporal growth path of the number of members of a population in a closed environment; for instance, the number of rabbits on an island. If natural growth of a population in discrete time between time t and $(t + 1)$: $X(t + 1) - X(t)$, denoted as $\dot{X}(t)$ is proportional to the size of that population then we have geometric growth:

$$\dot{X} = g(X(t)) \tag{15.1}$$

where g is the growth rate of the population.[1] If growth is positive this leads to an ever-increasing size of the population. It is clear that this growth curve is not realistic for most, if not all, species. A population cannot grow with a fixed growth rate g indefinitely. Given its dependence upon external resources, such as food or living space, a population is limited to a certain maximum, the level of which is conditional on the level of the resources and the technological level of the population to exploit these resources. Let the maximum size of the population be K, then the geometric growth model may be modified to the logistic growth model by making the growth rate not only dependent on the intrinsic growth parameter g but also dependent on the difference between the actual size of the population, X, and the maximum size, or carrying capacity, K:

$$\dot{X}(t) = gv(K - X(t))X(t) \tag{15.2}$$

The additional parameter v is the adjustment speed of the process. Figure 15.1 depicts two possible growth logistic paths resulting from this equation for fixed g. If $X(t)$ is very small compared with K then $K - X(t)$ is large and growth is high. With increasing size of the population over time, the gap between the maximum and actual size

[1] Formally the growth rate should be multiplied by the average size of the population between t and $t + 1$: $\frac{1}{2}(X(t) + X(t + 1))$, but for simplicity we use the initial population.

of the population narrows and consequently the growth rate $g(K - X(t))$ becomes smaller. If $X(t)$ is equal to K then growth is equal to zero. If, for some reason, the actual size of the population is larger than the carrying capacity, $K - X(t)$ is negative and the growth rate is negative as well.

Hannan and Freeman (1989) applied this logistic growth model (15.2) to longitudinal data on growth in the number of units of organisations. In their approach they included a number of explanatory variables in their model but, at the same time, they circumvented the problem of modelling the carrying capacity K explicitly. Instead, they estimated a second-degree polynomial to longitudinal growth data in order to find an empirical estimate of the maximum level of the population. This can easily be shown to be possible if we rewrite equation (15.2) as follows:

$$\dot{X}(t) = gvKX(t) - gvX(t)^2 = aX(t) - bX(t)^2 \tag{15.3}$$

The value of K may be found as $K = a/b$. Its precision depends on the precision of the coefficients a and b and the estimate is therefore in general not very reliable. But even if the value of the carrying capacity could be estimated precisely, there are a number of objections to model equation (15.3). First, the level of the carrying capacity is not static, but conditional on the size of resources and the level of technology. These change over time and therefore the size of the carrying capacity cannot be treated as static either. In other words: K should be $K(t)$. Secondly, there is no explicit content in this interpretation of the carrying capacity. It is simply a coefficient to be estimated from observed growth curves. Instead, an explicit model of carrying capacity is necessary that captures the essential underlying factors. More specifically, we require a model of carrying capacity based on economic notions.

15.3 An Economic Interpretetion of Carrying Capacity

The starting point is the population growth function equation (15.2). Firms operate in a multi-sector economy where they interact with each other. Interactions occur between industries in the form of intermediate supply and demand relationships, other interactions involving information, transfer of knowledge, and so on. Interactions also occur between industries and consumers. The latter type of relationship is self-evident but the inter-industry linkages are important as well. Each firm, as a member of a certain industry, has a potential network of linkages with other industries. Some linkages are beneficial for the firm: for instance, when these linkages are deliveries from one firm to the other. Some linkages are of the competitive type: the same firms compete in one market. The existence of other industries in the neighbourhood with whom it may interact is therefore a significant growth stimulating or inhibiting factor for this firm. At the same time, the growth of this particular firm is in itself again a potential growth-enhancing factor for other industries with inter-industry linkages with this firm, or a growth-limiting factor for similar firms who are in competition with this particular firm in the same market. In short, the size and composition of the population of firms in the neighbourhood is a determining factor for the growth potential for an individual firm. The effect of the population of firms

in the neighbourhood upon the individual firm is realised through interaction linkages between firms. The concept of carrying capacity, as defined here, captures this growth potential of a local population of firms due to the size and composition of firm populations in the neighbourhood.

The concept of carrying capacity is here defined formally as the level of demand exerted by intermediate and final demand categories in the market. This notion is close to the economic interpretation of the concept as given by Carree and Thurik (1999). They propose a model of entry and exit of firms in markets as adjustments to a disequilibrium situation. The equilibrium situation is called the carrying capacity (Carree and Thurik, 1999, pp. 986–7). It is the benchmark number of firms which drives the direction of the change in the actual number of firms. Carree and Thurik relate the carrying capacity in a local market to the level of consumer demand. Here we use a specification, which is close to an input–output model, involving both intermediate and final demand. First, we present the situation involving only one region.

The actual level of supply will adjust to market demand. If supply is less than demand, there is an opportunity for increased production: birth rates go up, death rates go down, and incumbent firms will grow. If supply exceeds market demand, then the level of production will decrease: firm birth levels will drop, death rates will increase and incumbent firms will diminish in size. The relation between change and the level of production, $\dot{X}(t)$ and $K(t)$ is then given by equation (15.2) above. However, in a multi-sector economy the carrying capacity is specific for each sector s ($s = 1, \ldots, S$). Thus, the level of $K_s(t)$ is determined by both intermediate and final demand in the region:

$$K_s(t) = \sum_{r=1}^{S} a_{sr} X_r(t) + c_s B(t) \tag{15.4}$$

where a_{sr} is the technical coefficient in the input–output table of sector r on sector s, c_s is the per capita final consumption of goods produced by sector s, and $B(t)$ is the size of the population at time t. Equation (15.4) is an elementary input–output equation without investments and exports, that specifies the interrelations among producers and between producers and consumers in the national economy. Note that here final consumption is explicitly related to the size of the population B using the consumption coefficients c. Equation (15.4) does not include exports and investments. They might be added as additional terms. Note that imports are implicit in the input–output specification. Sectors that rely partially on imports will have technical coefficients that do not add up to 1: the demand for this sector will only partially be met by internal supply.

The parameters of the demand equations of the input–output model may be derived from the national input–output table and the national accounts. So, equation (15.4) gives the level of the carrying capacity as a function of intermediate and final demand. Since the input–output model is an equilibrium model, $K(t)$ and $X(t)$ are equal to each other, and small changes in $B(t)$ will lead to a new equilibrium value for the $X_s(t)$. Here, we allow both $B(t)$ and the $X_r(t)$ to change, and specify a

logistic adjustment function of $X_s(t)$ to its equilibrium value (carrying capacity) $K_s(t)$:

$$\dot{X}_s(t) = g_s v_s (K_s(t) - X_s(t)) X_s(t) \tag{15.5}$$

Note that the growth rate g and the speed of adjustment v are sector-specific.

15.4 Introducing Spatial Interactions into Carrying Capacity

There is another source of disequilibrium in the market. In a multi-regional economy, local variations may exist in supply and demand. The input–output model is generally used to determine levels of production given an increase in one of the final demand categories. For economic demography with a spatial dimension, we need an instrument to determine demand–supply ratios at the local level. Of course we cannot assume that each region or local area is an island without interactions with other zones. Producers will deliver their goods to retailers and other producers in other regions; consumers will make shopping trips to retailers in other zones as well; in other words, there exist complicated spatial patterns of transport flows of goods between producers and other producers (inter-industry linkages), and between producers and consumers. In order to deal with these spatial demand–supply interactions, we introduce the notion of the *spatial demand field*. A spatial demand field defined at location j ($j = 1, \ldots, I$) is a probability density function that gives, for every location i ($i = 1, \ldots, I$) in the neighbourhood of j, the probability that the good m, that is required at location j as either an intermediate input by a producer or as final input by a consumer, is produced at location i. This conditional probability $p_m(i|j)$ is not uniform over all production locations i, but decreases with distance between i and j. In other words, the form of the demand field is in general not flat but a dome with its top in the centre located at the demand origin j and decreasing with increasing distance from the centre. In addition, since the good is produced somewhere, it holds that $\Sigma_i p_m(i|j) = 1$. A function that is often used for modelling probability functions is the logit function. Used as a spatial interaction function with distance as its only argument, it has the following form:

$$P_m(i|j) = \frac{\exp -\beta_m d_{ij}}{\sum_k \exp -\beta_m d_{kj}} \tag{15.6}$$

where d_{ij} is the distance between locations i and j, and β_m is a distance deterrence parameter which is specific to the good m being demanded. If instead of the linear distance the log of the distance is used, the exponent in both nominator and denominator is replaced by $d_{ij}^{-\beta_m}$. A high value of β_m indicates a strong distance decay effect and a steep slope of the spatial demand field, implying that with increasing distance it soon becomes highly unlikely that the required good m is produced at i. A small value of β indicates a small distance decay effect and thus a relatively flat spatial demand field: even at larger distances between i and j it is still likely that goods

demanded by producers and consumers at j are produced in i. A value of $\beta = 0$ implies a perfectly flat spatial demand field and the absence of any distance effect: at every location i it is equally likely that the good m demanded in j is produced in i. It should be clear that β is specific for every economic good m, since the form of the demand field varies with the character of the good. The spatial demand field of grocery products is very small (high β), whereas the demand for specialised services is often exerted at the national or even international market (β is very small or zero). Note that this system, just like the input–output model, is demand-driven. Firms and households require inputs or consumer goods m, and look around for suppliers to meet their demand. In which locations they look around for producers in alternative locations i is specified by the demand field $p_m(i|j)$. For practical reasons we do not work with individual goods m, but with goods produced by the aggregate sector s.[2]

How does this relate to the model of carrying capacity introduced here? First we note that the concept of carrying capacity refers to production capacity. In the spatial framework just introduced we make a distinction between locations i, where production takes place, and locations j, where goods are demanded or consumed. Of course in the recursive structure of the input–output framework producers are at the same time demanding intermediate goods as well, so each location may belong to both categories. In order to distinguish between production and consumption characteristics of locations, we introduce the total level of demand exerted by consumers and firms in location j:

$$D_s(j,t) = \sum_{r}^{S} a_{sr} X_r(j,t) + c_s B(j,t) \tag{15.7}$$

Note that this is quite similar in form to equation (15.4). There is one important difference, however. In the spatial framework of equation (15.7) we make a distinction between the level of demand and the level of production in each region, because, unlike the closed system of equation (15.4), they are not equal. The link between demand $D_s(j,t)$ and production capacity $K_s(i,t)$ is a spatial interaction relation, as given by the spatial demand field (15.6). The carrying capacity $K_s(t)$ introduced in equation (15.4) is the aggregate market demand, summed over all intermediate and final consumers. Thus, in a spatial setting, if we sum over all locations j, where these intermediate and final demanders are located, we arrive at the total market demand for goods produced by sector s in location i. The required production capacity of sector s at location i for intermediate and final demand in j at time t is given by:

$$K_s(i,j,t) = p_s(i|j) D_s(j,t) \tag{15.8}$$

and the total required production capacity, or carrying capacity at location i is the sum over all locations j:

$$K_s(i,t) = \sum_{j}^{I} p_s(i|j) D_s(j,t) \tag{15.9}$$

[2] Formally: s is the index of the class of goods Ω_s to which the single good m belongs: $m \in \Omega_s$.

By comparing the carrying capacity $K_s(i,t)$ with the actual level of production $X_s(i,t)$ in region i at time t the likely direction of local economic development of sector s located in i may be derived. The direction and size of growth can be modelled in terms of a logistic growth path as follows:

$$\dot{X}_s(i,t) = g_s v_s (K_s(i,t) - X_s(i,t)) X_s(i,t) \tag{15.10}$$

This equation states that growth in production in sector s in location i in the unit time interval t, $\dot{X}_s(i,t)$, is determined by the intrinsic growth rate g_s of sector s, multiplied by the overall speed of adjustment of the process, v_s, and modified by the effect of the gap between carrying capacity $K_s(i,t)$ and actual level of production $X_s(i,t)$.

The inter-sectoral and spatial interaction linkages developed here reflect a specific form of spatial agglomeration effect. A certain mix of production in a region may increase the level of the carrying capacity of the region and therefore the growth rate of the regional economy. Other mixes will only increase the actual level of production, while keeping the carrying capacity level constant, which results in lower growth rates in the region. The model therefore produces local variations in growth rates.

In summary, the advantages of this definition of spatial carrying capacity for economic demography are the following:

- the spatial input–output representation is consistent with the national input–output table;
- if the national input–output table represents an equilibrium situation, then the spatial input–output model gives for each location i the local disequilibrium in demand and supply for each sector. Since the system is consistent with the national input–output table, excess demand in some locations will be mediated by excess supply in other locations;
- inter-sectoral linkages as well as spatial interaction linkages between sectors are included in the model;
- the model presents a link between spatial economic disequilibrium on the one hand and macro-economic indicators of the national economy on the other;
- the information concerning $K(i,t)$ and $X(i,t)$ is of interest, since it describes the spatial distribution of demand and supply, as well as local market disequilibrium for each economic sector;
- in addition K and X are instrumental in driving the local spatial economic development for each sector, as hypothesised in equation (15.10); and
- the combination of inter-sectoral and spatial interaction linkages reflects the mechanisms of spatial agglomeration effects. As a result of this, local variations in economic growth rates will occur as an endogenous process.

We will test some of these ideas in Sections 15.6 and 15.7 below. First, however, the dynamic concept introduced in equation (15.10) will be discussed a little further in the next section, since it can be reformulated in other terms, giving it a more familiar structure.

15.5 The Model as a Dynamic Difference Equation for its Subpopulations

Equation (15.10) is a specific example of a system of logistic growth equations for interacting populations (Wilson, 1981, pp. 54–5). The system may be formulated in matrix terms as a set of difference equations. For convenience we make no explicit distinction between intermediate and final demand. In matrix terms, the system has the following form:

$$\dot{\mathbf{X}}(t) = \mathbf{G}[\mathbf{K}(t) - \mathbf{X}(t)]\mathbf{X}(t) \tag{15.11}$$

where $\dot{\mathbf{X}}(t)$ is an $S \times I$ growth matrix with elements $\dot{\mathbf{X}}_s(i,t)$ and $\mathbf{G}$ is an $S \times S$ diagonal matrix of sector-specific relative growth rates and adjustment speeds $g'(s,s) = g_s v_s$. The matrix of carrying capacity $\mathbf{K}(t)$ with dimensions $S \times I$ is calculated as:

$$\mathbf{K}(t) = [\mathbf{AX}(t) + \mathbf{cb}(t)]\mathbf{M} \tag{15.12}$$

Here, $\mathbf{A}$ is an $S \times S$ matrix of technical coefficients a_{sr} from the input–output table, $\mathbf{c}$ is an $S \times 1$ vector of consumption coefficients, and $\mathbf{b}(t)$ is a $1 \times I$ population distribution vector. The elements of the $I \times I$ matrix of spatial discounting factors $\mathbf{M}$ are calculated as:

$$m(i, j) = p(j|i) \tag{15.13}$$

where $p(j|i)$ is the probability that a good demanded in j is produced in i; the functional form is given in equation (15.6). The interpretation of equations (15.11)–(15.13) is similar to (15.6)–(15.10). Note, however, that in this matrix formulation the distance deterrence function is generic for all economic sectors. In more realistic formulations this is not tenable. Equation (15.11) is the logistic growth equation for S $\times$ I submarkets. Equation (15.12) is the model for carrying capacity. $\mathbf{AX}(t) + \mathbf{cb}(t)$ is the demand exerted by firms and consumers, located in j, for goods produced by sector s. The matrix $\mathbf{M}$ defines the spatial demand field around j. The row elements of $\mathbf{M}$ sum to 1.

Difference equation systems of the form of (15.11) have been studied extensively in the sphere of organisational ecology (see, for example, Tuma and Hannan, 1984). Although each equation is linear, the resulting behaviour of the system is intrinsically non-linear and not always stable. A complete treatment of all properties of this system will not be given here. General accounts of coupled difference equations involving spatial interactions are provided in Wilson (1981). A number of features of the model should be discussed here, since they are related to the nature of sectoral and spatial interactions and the consequences for overall system stability. From equation (15.11) it is clear that equilibrium occurs whenever the carrying capacity is equal to supply: $[\mathbf{AX}(t) + \mathbf{cb}(t)]\mathbf{M} = \mathbf{X}(t)$. Unfortunately analytical solutions cannot be found for this system of equations, except for trivial cases. In the next section some results of a series of computer simulations with varying characteristics of intersectoral and spatial interactions will be given and discussed. The simulation results are illustrative for the structural characteristics of the model.

15.6 Computer Simulations of the Model

For the computer simulations we used a three-sector economy plus population for 16 regions, configured in a four by four square regional pattern. Interregional distances were calculated using Euclidean distance. The input parameters for the system are given in Table 15.1. We will focus on the following key parameters: ν is the speed of the system, the sectoral interactions a_{sr}, and the spatial interactions, determined from the logit function (15.6), where the β_s coefficient determines the demand field.

Figure 15.2 gives the initial distribution of the population and each of the three sectors over the 16 zones. Figure 15.3 presents the equilibrium configuration after 300 iterations. If the evolution of the system is smooth, the equilibrium distribution does not reflect the initial distribution of the sectors. Using the speed of adjustment as given in Table 15.1, the evolution of the system is indeed smooth, and the initial highly skewed spatial distribution of the sectors is replaced by a more balanced distribution that reflects the combined effects of different parameters. A number of conclusions may be drawn from the equilibrium distribution. First, the distance effect favours economic development in more centrally located zones over peripheral zones. Second, the equilibrium configuration of each sector reflects, to a certain extent, the population distribution or final demand. The population impact is stronger for sector 3 than for the other two, since this sector is more dependent on final demand. The correlation between the population and sector 3 distribution is 0.78, against values around 0.69 for the other two sectors. The final distributions of each of the sectors are very similar, although the level is different, with correlations around 0.98. Formally, the spatial distribution of each of the sectors is a weighed average of the distribution of the other sectors, with weight matrix **A**.

As can be observed from Figures 15.2 and 15.3, the chosen input parameters have resulted in a model that has evolved to a steady state. This steady state is equal to the level of the carrying capacity for each (i,s) combination. However, if the speed of adjustment is increased (or, equivalently, the intrinsic growth rate of sectors), the

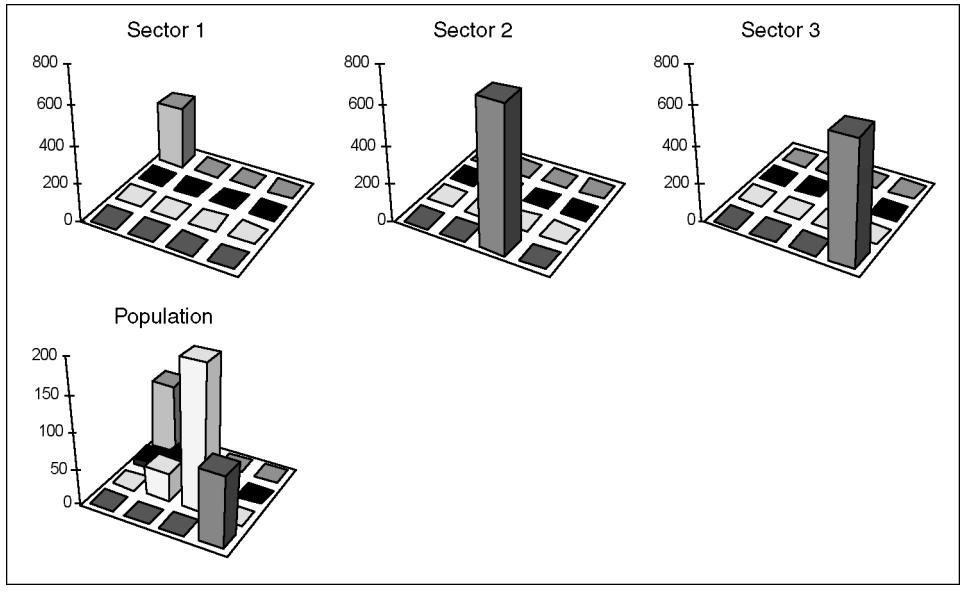

Figure 15.2 *Initial distribution of sectors and population*

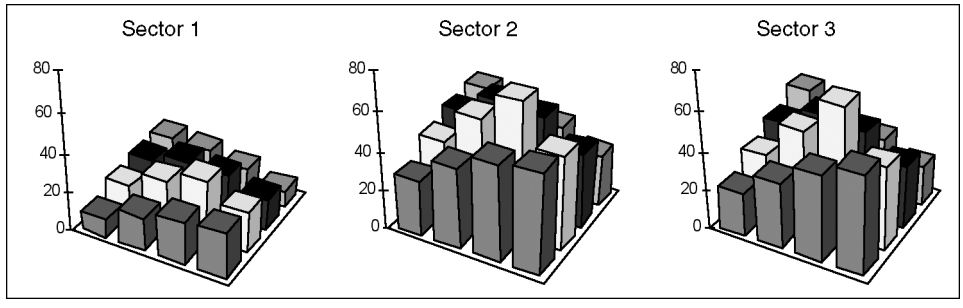

Figure 15.3 *Equilibrium configurations of sectors*

resulting growth of each sector is no longer guaranteed. Figure 15.4 shows an interesting example for one region. In the slow mode with a system speed of 0.02 the region develops from an initial value of 0.5 to the equilibrium value of 60. Increasing the speed to 0.10 results initially in smooth but fast growth up to size 50. At this point, growth decreases substantially and small oscillations set in that become larger after reaching the slow mode equilibrium of 60. After this point, growth oscillates around the value of 60. With speeds higher than 0.10, oscillations set in from the start and are much larger. Oscillations may also occur in a regular pattern; for instance with a certain periodicity. These oscillations are the result of an overreaction of the subsector to a large carrying capacity. This overreaction leads to a growth

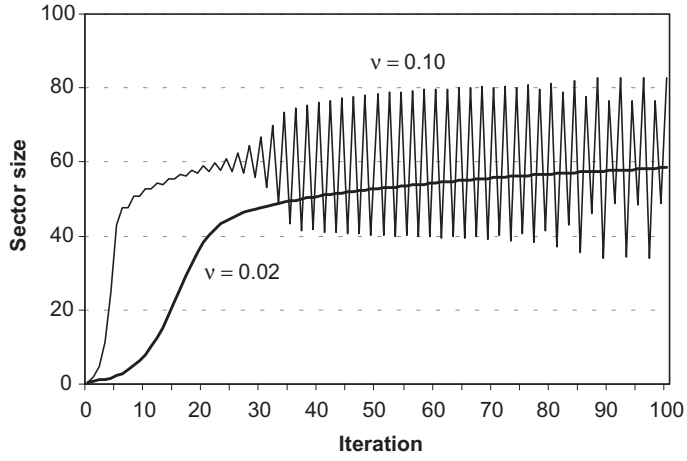

Figure 15.4 *Development towards a steady state and oscillatory behaviour using different speeds of adjustment*

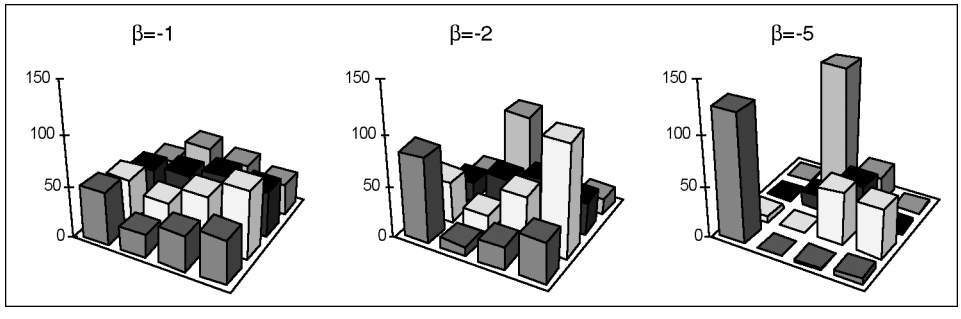

Figure 15.5 *The effect of distance friction on the equilibrium configuration of sector 3*

of the subsector above the carrying capacity. In the next period this has to be compensated by a large negative growth, and so on. Thus, the growth speed of a sector may have serious impacts upon the stability of the regional economic system as a whole.

Increasing the effect of distance will result in the emergence of a few locations where most of the activities are concentrated (Figure 15.5). Interestingly, the regions where concentration takes place are not the regions where initially activities were concentrated. Moreover, with increasing distance friction, the system no longer converges towards the steady state, but starts to oscillate. The configuration shown for the case of $\beta = -5$ in Figure 15.5 is not an equilibrium state. Conversely, interactions without distance friction will result in a completely flat surface and smooth behaviour towards the steady state.

From Table 15.1, which shows the technical coefficients used in the simulations and per capita final consumption, it is clear that sector 3 is most directly related to

final demand, whereas sector 1 is the most independent sector of the three. Sector 2 is dependent on sector 1 for deliveries but also dependent on population. The effect of a change in technology will change the spatial distribution. For instance, a change of the technical coefficient $a(2,1)$ from 0.45 to 0.10, implying that for the production of one unit of good 1 much less input of good 2 is needed than before, has the result that the equilibrium value of sector 1 increases on average by 30%, whereas the equilibrium value of sector 2 decreases on average by 20 per cent. The effect on sector 3 is modest: a slight increase in equilibrium value of 7%.

These examples show that a spatial equilibrium of a multi-sectoral economy depends crucially upon the key interaction parameters of the economic system: speed of adjustment and intrinsic growth speed, sectoral interactions, and spatial interactions. The speed of adjustment of economic activities and the spatial deterrence effect have potentially highly disturbing effects, including non-equilibrium situations. In the next section we will relate some of these findings to empirical observations of individual firm dynamics.

15.7 Empirical Implementation of the Model

The concept of carrying capacity as developed in the previous sections may be implemented in empirical modelling. The required amount of information is only limited. The parameters necessary for calculation of the spatial carrying capacity are:

- the technical coefficients of the input–output table a_{sr} collected in the matrix **A**;
- per capita consumption coefficients c_s, collected in the row vector **c**; and
- sector-specific distance parameters β_s.

In order to calculate the level of the carrying capacity $\mathbf{K}(t)$ we also need:

- the matrix $\mathbf{X}(t)$ of production of activity s at location i at time t;
- the population distribution over regions at time t, $\mathbf{b}(t)$; and
- inter-zonal distances $d(i,j)$.

Technical coefficients and per capita consumption coefficients are readily available in most countries, even at the regional scale. The distance function parameter β_s may be estimated using some form of optimisation. In an empirical application in the Netherlands, which will briefly be discussed below, a simple line search algorithm was used for the distance parameter for each sector, using the Pearson correlation coefficient between sectoral growth $\dot{X}_s$ and $V_s = K_s - X_s$ as the criterion variable. The results are presented in Table 15.2.

All values of β are positive, which implies that interaction between sectors decreases with increasing distance between them (the function uses $-\beta$ as the coefficient value). The smallest coefficients are found for the recreational sector, transport and banking. The value of 0 would imply a completely flat demand field. This is plausible for transport, but less so for banking and certainly not correct for the recreational sector. The largest value, and a very small demand field, is found for

Table 15.2 *Estimated distance deterrence parameters* β_s *and resulting correlations between sectoral growth* $\dot{X}_s$ *and* $V_s = K_s - X_s$

Economic sector		Coefficient	Correlation *r*
1	Agriculture	0.25	0.26
2	Energy, mining	0.30	0.09
3	Industry	0.70	0.45
4	Construction	2.00	0.14
5	Wholesale	2.00	0.75
6	Retail	5.00	0.18
7	Recreation, hotels, restaurants	0.00	0.02
8	Transport communications	0.00	0.81
9	Banking, insurance, business services	0.00	0.32
10	Other services	5.00	–0.07
11	Public sector	0.15	0.07

retailing and other (domestic and health) services, which is again quite plausible. Industry has an intermediate value of 0.75. The resulting correlations between sectoral growth and the difference between carrying capacity and the actual level of production are in general positive and significant, but not very high. These results are in line with the results obtained by Feser and Sweeney (2000). Although using a different approach, they found empirical evidence that economic clustering, as indicated by the technical coefficients of the input–output table, is associated with spatial clustering as well.

The model of carrying capacity was applied at the regional level in the Netherlands (see van Wissen, 2000 for details). Equation (15.11) is a deterministic difference equation defined at the meso level of a regional multi-sector economy. The spatial level in the empirical application was the municipal level ($I = 685$), and 11 economic sectors were distinguished. However, the model was given a micro interpretation. The growth rate of sector s at location i at time t may be viewed as an underlying latent variable that determines the growth potential of individual firms of sector s in location i. Firms in this application are equal to business establishments. The data were taken from a register of business establishments in the Netherlands, called LISA. LISA is a longitudinal administrative register that includes all addresses in the Netherlands where paid work is being carried out. Although the agricultural sector and self-employment are not completely represented, and the province of North Holland is not covered, this register is used as the most important source for spatial information about business establishments in the Netherlands (see Kemper *et al.*, 1996). Here we used the data from the years 1990 and 1991. Individual firms are the agents of economic growth through new firm formation, firm closures, relocations and firm growth. In this application economic growth was operationalised in terms of birth and death probabilities of firms, as well as firm growth for incumbent firms. Within this demographic framework, birth and death probability functions, as well as firm growth functions, were estimated in which the variable $V_s(i,t) = K_s(i,t) - X_s(i,t)$ was used as an explanatory variable. The coefficient should be positive for firm birth and firm growth and negative for firm death. The results of this application, as

presented by van Wissen (2000), were moderately favourable for the model. For firm birth and growth the expectations were indeed confirmed, with positive and significant coefficients. However, for firm death the coefficient was negative, as it should be, but insignificant.

15.8 Conclusions

In this chapter we introduced the notion of spatial carrying capacity, based on a model of sectoral and spatial interactions between submarkets of the economy. The resulting model can be viewed as a dynamic spatial model of growth in a multi-sector economy. The characteristics of this model were illustrated in a simulation context using a deterministic difference equation. The speed of adjustment of the process, the spatial deterrence function and the inter-sectoral interactions turn out to be crucial variables in shaping the spatial equilibrium of the economic system. Moreover, the existence of equilibrium is not guaranteed. The simulations showed that a very dynamic economy, with high speed of adjustment, may result in oscillatory behaviour of the level of economic production. A very strong distance effect has the same oscillating effect. Moreover, with high distance friction, economic activities tend to concentrate in just a few regions, leaving other regions largely empty. The simulations also showed that a change in technology, resulting in a reduction of the technical coefficients and thus in reduced inter-sectoral interactions, changed the equilibrium distribution without entering instability.

The concept of carrying capacity can be applied empirically. The required amount of information is limited, and usually readily available. Sector-specific distance parameters have to be estimated. In an empirical application in the Netherlands the estimated distance parameters were to a large extent, although not completely, according to theoretical expectations. Moreover, there are first signs that the concept of carrying capacity as developed here may be useful in explaining and predicting regional sectoral growth.

In conclusion, the concept of carrying capacity as defined in this study deserves more attention, both theoretically and empirically. From a theoretical point of view the model has many interesting properties and through the relation with the input–output table the link with macro-economic variables is established easily. The model is one way of making the concept of agglomeration economies operational, by explicitly taking into account inter-industry linkages as well as their spatial representation. The model may be used at the meso level of sectoral and spatial submarkets. The usefulness of the approach at this level is not studied in depth yet, but from the theoretical, simulation and empirical results reported in this chapter, further explorations in that direction look promising.

Planning a Network of Sites for the Delivery of a New Public Service in England and Wales

Mike Coombes and Simon Raybould

Abstract

The Family Law Act (1996) aimed to introduce across England and Wales a new service of Information Meetings (IMs) for people considering divorce. Attendance would be compulsory, which meant that the service would have to be provided in places that left few people objecting to attending one. The research reported here identified a suitable pattern of sites at which IMs could be held. Several methods of analysis were needed: a regression model estimates the spatial distribution of potential IM attenders; survey data analysis measures people's willingness to travel to attend IMs; multi-criteria analysis establishes the list of sites which meet the necessary criteria; and location-allocation modelling identifies which of these sites would minimise the travelling which would be required of attenders. The chapter summarises this mapping and modelling research programme, and highlights the key elements of sensitivity in the results. One important part of the process is to identify which are the issues to be resolved by the researchers and which are the decisions that remain with the client government department.

16.1 Introduction

When the Family Law Act was passed in 1996 some of its most innovative aspects were put 'on hold' until a programme of research studies had provided the basis for deciding how to implement these innovations (Walker, 2001). In particular, Part 2 of the Act made provisions for Information Meetings (IMs) that would be compulsory

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

for married people intending to initiate divorce proceedings. The compulsory nature of the IMs implies that they would have to be delivered in such a way that few people would be likely to object to attending one. The research programme involved evaluating a range of alternative *pilot* IMs – for example, varying the length, style and content of the meeting – in different regions. This chapter summarises one distinct research strand, identifying a set of potential IM sites whose locations would make it unlikely that many people would object to attending IMs specifically because they could not readily reach any of the IM sites.

The research described below aimed to provide the information needed by the Lord Chancellor's Department (termed 'the Department' here) in order to decide the number – and location – of sites at which IMs would need to be provided. It should be noted at the outset that the term 'site' here denotes an approximate location (e.g., the Victoria area of Westminster): the research did *not* aim to choose specific premises as venues for IMs. In practice, the Department's policy decision would centre on judgements as to the likely impact on married people if, for example, the government felt it was no more obliged to provide all areas with a local IM site than it is to provide a university in every locality. By providing IMs at relatively few sites the implementation costs should be minimised, but at the risk of increasing the number of objections by people who found the sites hard to reach. The research challenge is thus to identify how many sites would be needed – and where these should be – so that few people would have to travel far to reach one.

There are many existing public services which are provided through networks of local sites: examples range from the various kinds of court provided by the Department to other local public services provided by central government (e.g., Job Centres). These networks have typically evolved over many years, gradually adjusting to alterations in the services provided and also to changes in the pattern of demand such as the development of new towns. Each of these networks evolved differently to meet its own service's needs, so none of them provides an ideal blueprint for the selection of IM sites. Although the networks of sites used by other public services evolved over long periods, sophisticated methods of analysis have increasingly become available to help maximise the sites' accessibility to their users. For example, Thomas *et al.* (1991) illustrated the value of a location-allocation model in helping to inform decisions on which of the North West region's courts to close while minimising any increase in the distances people have to travel to reach their nearest court. The basic elements of a location-allocation modelling strategy are:

- mapping the spatial distribution of demand for the service;
- measuring people's reluctance to travel to access the service;
- identifying candidate sites for providing the service; and
- selecting the optimal sites from these candidates.

It is the final step which uses the location-allocation model itself and here it becomes most clear how the results' optimality depends on certain assumptions, including those which are embedded in the three previous steps.

This chapter reports location-allocation modelling to tackle the highly unusual proposal to 'roll out' a full national network of sites rapidly for a new public service:

this is clearly more a case of a 'big bang' than the process of evolution which is characteristic of the public sector. The rapid development of a new network is rather more familiar in the private sector than in public services, although even the vigorously growing commercial services such as multiplex cinemas have in fact been 'rolled out' over several years. It is notable that location-allocation modelling has been extensively adopted for site selection in the private sector (Ghosh and Harche, 1993). In the private sector, the key requirement is usually that the sites are close enough to large concentrations of people so as to maximise the likely profitability of the network. By contrast, the public service emphasises more the minimising of differences in service provision across the country. The general framework of location-allocation modelling provides for choices to be made between such different objectives, so that each analysis can be 'customised' to meet the specific objectives of that particular application.

The analyses in this chapter build up the information that is needed for a location-allocation model relevant to identifying sites for IMs. By way of clarification, it should be stated at the outset that all the analyses – the three preparatory stages and then the location-allocation modelling itself – rely upon a geographic information system (GIS) which can provide a high level of resolution through recognising up to 10 000 separate areas across England and Wales (these areas are the local government wards existing at the time of the 1991 Census). Fotheringham *et al.* (1995) showed that the size and shape of the zones used in a location-allocation model can influence the results of the analysis, but here the level of detail provided by nearly 10 000 zones means that there is very little loss of accuracy in a national-level model when the analysis treats each ward's population as if it were all located at the ward's population-weighted centroid. Straight-line distances between the respective centroids are similarly assumed to provide robust estimates of the distances between wards. All models simplify some of the complexity and peculiarities of the real world, the important task is to portray accurately enough the major factors that will shape the evaluation of the alternative scenarios to be explored (Densham and Goodchild, 1990).

The first preparatory analysis is outlined in Section 16.2 and is termed *demand distribution* because it attempts to estimate, for each local area of the country, the number of people who may attend IMs. It is necessary to make broad estimates of the 'population at risk' of attending IMs because the Department has not suggested restricting attendance to an identifiable category of people, such as those people who have petitioned for divorce. A key problem to be faced is that there is insufficient information available on the current whereabouts of relevant population groups (e.g., couples who have been married between five and 10 years). The information that *is* available is modelled to provide plausible estimates at the highly localised scale; this level of detail is necessary for the location-allocation modelling to identify a set of sites that will be as near to as many people as possible. The second preparatory step – described in Section 16.3 – analyses data from the pilot IMs on the extent to which people are deterred from attending IMs if they have to travel further. The results of this *distance deterrence* analysis provide an essential input to the location-allocation model. If people are very strongly deterred, then the model is designed to focus on reducing the minority of very long journeys in more remote areas; if

distance deterrence is not so severe, then the emphasis will be more on making smaller reductions to the journeys of very many more people through the provision of additional sites in heavily populated areas. Section 16.4 of the chapter describes the third preparatory set of analyses that provide a set of suitable *candidate sites* for the location-allocation model. For example, the mountainous centre of the Lake District is unlikely to be a suitable site to serve the population of Cumbria even though it is equidistant from all the county's main population centres (which lie in an arc around the periphery of the Lake District from Kendal through Barrow and Workington to Carlisle). The type of site favoured by people who attended IMs during the pilot phase of implementation provides the basis for identifying the criteria that sites need to satisfy. These candidate sites will then be input to the location-allocation model so that only suitable sites could be included in an eventual network. Section 16.5 describes the location-allocation modelling itself, then Section 16.6 provides a brief evaluation of the results. The chapter ends with some conclusions about this particular research, as an example of modelling in a dynamic policy context.

16.2 Estimating the Demand Distribution

The first step in the modelling research is to produce a set of local area predictions of the numbers of people likely to attend IMs in any year. An annual national total was estimated by the Department separately, and the local area predictions are used to 'share out' this total national demand between the local areas. For the modelling here to choose the best IM sites, this national total value is not actually relevant: the other inputs to the model ensure that central London would be the 'first choice' site regardless of whether the national annual demand was a hundred or a million people.

The best starting point for a model to estimate the likely local distribution of IM attenders is the number of divorces registered at each of the county courts across the country, so the modelling used the 180 county courts for which the number of divorces in the mid-1990s was known (between 165 000 and 170 000 a year in England). This dataset provided only a count of divorces at each court: there is no available dataset with postcoded addresses of divorce petitioners, so assumptions are needed about where people who divorce at any specific court actually live. The first step of this process was to define court catchment areas in terms of 1991 wards, for which areas it would then be possible to compile Population Census data as the basis for the model's independent variables. The catchment area definitions sought to reflect the guidance that the Department publishes, in which around 25 000 'places' are listed and allocated to individual courts. Substantial efforts were needed to allocate each ward to a court area, because there is no linkage between the 25 000 'places' listed in the directory and either wards or any other set of standard statistical or administrative areas. A further necessary step was to group together some county courts, because divorce petitions are not heard in every court. Information on other patterns of movement, notably commuting, was used for this grouping: for example, the Caerphilly county court area was grouped with Cardiff because this city is the predominant destination of out-commuters from Caerphilly and the adjacent

Table 16.1 *Sample of divorce petitioners at North East courts*

	Female (%)	Male (%)	All (%)
Petitioned in 'local' court	77.6	72.5	76.2
Petitioned in 'adjacent' court	17.3	12.3	15.9
Petitioned elsewhere in region	2.3	11.6	4.9
Petitioner from outside region	2.8	3.6	3.1
N	*353*	*138*	*491*

villages. The output from this step is an estimated catchment area of each divorce court.

Although there is no national dataset about where the people who divorce at each court in fact live, anecdotal evidence suggested that people do *not* always use their local court. The addresses of a sample of people who petitioned at courts in some of the North East pilot areas was postcoded as part of the research. Table 16.1 presents the evidence from this dataset as a test of the appropriateness of the catchment areas that have been estimated here. Over three-quarters of petitions were from people who did indeed live within the estimated catchment areas. The proportion was slightly less for male petitioners, but they are notably in the minority in practice (McCarthy and Simpson, 1991, established that men were more likely to move away from the marital home during the divorce process). Of those who petitioned at North East courts but did *not* live within that court's estimated catchment area, most lived just across that estimated catchment area boundary in one of the adjacent areas. A substantial degree of 'boundary hopping' is in fact inevitable with courts so closely spaced as are, for example, Newcastle and Gateshead (bearing in mind that both North and South Shields also have divorce courts). In many parts of the Tyneside conurbation neighbouring people have petitioned at different courts, so adjustments to the estimated catchment area boundaries could barely, if at all, reduce 'boundary hopping' in such areas.

This interpretation is borne out by the results in the other areas where a court sample was collected. Those areas that cover a similar urban/rural mix to the North had a very similar proportion of court sample members petitioning at their 'local' court. More heavily urbanised areas such as Greater Manchester and, most especially, London had noticeably higher proportions of petitioners 'boundary hopping' due to the very close spacing of courts there. All the same, the only practical assumption here is that the numbers of people moving around the country to petition for divorce roughly cancel each other out, so that the number registered at each court should be a fairly close approximation to the number of petitioners who live in that court area and – for the purposes of this research – also should provide a close approximation to the number of potential IM attenders.

Using these 180 court catchment areas, a regression model was developed which used the courts' number of divorces as the dependent variable, and their catchment areas' population size and characteristics as the independent variables. This model could then be used to 'shift scales' down to the ward by predicting the number of divorces likely to arise from each ward's population size and characteristics. These ward-level predicted values will then be turned into 'shares' of the national total of predicted values, which in turn will provide the basis for locally 'sharing out' the total number of people expected to attend IMs nationally.

The dependent variable is *the number of divorces per thousand married men*: the variables were generally defined in terms of male characteristics because some of the potentially important factors (such as unemployment) are not so well measured for women. There is not a huge literature on the factors that may be important in shaping the rate of divorce in this country, although Clarke and Berrington (1999) recently provided a valuable summary. Research on the subject has also been hindered by the limited official statistics available, because divorce registration procedures date back many years and do not, for example, record either party's date of birth and this hampers some longitudinal analyses of divorce (cf. Kiernan and Mueller, 1999).

The age of married people – and the duration of their marriage – are identified in the literature as major influences on the likelihood of divorce. The modelling experimented with a number of detailed age groups variables, with the final model eventually selecting a variable relating to the 16–44 age group. Ethnic minority populations were represented by four variables which measured the proportion of men aged 20–54 who were (a) Afro-Caribbean or (b) Pakistani/Bangladeshi or (c) Indian/Chinese or (d) Irish (see Berrington, 1996 and Beishon *et al*., 1996, for the background research). As well as a variable on the proportion of men in low-skilled occupations, two alternative measures of male unemployment were made available to the model as options to represent the issue of poverty and/or insecure employment, which is known to be linked to divorce (Böheim and Ermisch, 2001). Three other employment-related variables were explored, all representing factors that the literature suggests to be positively associated with increased rates of divorce (e.g., Gibson, 1996):

- the proportion of employed men who have security-related occupations;
- the proportion of married women who either are self-employed or have full-time jobs; and
- the proportion of all households that included two earners but no children.

A variable on the proportion of younger men in the area who are married was among the variables to represent demographic factors that could represent contextual influences on the local level of divorce. The two final variables assessed were both more familiar features of area-based modelling. A housing tenure variable measured the proportion of households that are owner-occupying (this has been argued to be negatively associated with the probability of divorce). The other variable tested was a measure of the level of urbanisation in each area (Coombes and Raybould, 2001).

One important feature of area-based modelling such as this is that two variables which have similar distributions across the areas analysed can 'cancel each other out' in their effect on the dependent variable. As a result, modelling the difference between areas' populations can yield rather different results to modelling the behaviour of the individuals who make up those populations. A particularly clear example of this 'cancelling out' involves the ethnicity variables. It is known that Afro-Caribbeans have higher divorce rates than white people, whilst the Pakistani and Bangladeshi groups have low rates. At the scale of analysis undertaken here, the same areas – in practice, the more rural areas – tend to have populations that include very few people from either of these broad minority ethnic groups. As a result of this similarity of the geographical patterns of the Afro-Caribbean and the Pakistani/Bangladeshi variables, they tend to 'cancel each other out' in the court area analyses and so neither emerges as significant in the model.

After considerable experimentation on technical aspects of the modelling, and also on the precise detail of the independent variables, the robust model to emerge included significant variables, all taking the expected signs, on the age and class/occupation of local populations *plus* a factor lowering the rate according to the proportion of the younger men in the area who are currently married. The latter variable suggests a contextual effect that produces greater resistance to divorce in areas where the proportion of young men who are married is higher than the national average. To check the sensitivity of the modelling, the analyses were run on each of two separate years' data, as well as the two in combination. The results were encouragingly consistent in the selection of variables as significant, and in the calibration of those variables. There is also no clear pattern to the residuals from the model which would call for additional variables to be included. Yet in practice the model's predictions do not widely diverge from an alternative set of results based purely on the number of married people living in each area. Although it is rather disappointing that the efforts devoted to developing this model have not provided a dramatic improvement in the accuracy of predictions vis-à-vis those which could have been obtained by assuming a simple per capita divorce rate, it might also be seen as reassuring that the estimates here do not substantially depart from 'bedrock' demographic data. As a result, this model has been used here to predict the ward-level distribution of the numbers expected to attend IMs nationally: this then provides the demand measure for the location-allocation model.

16.3 Estimating the Level of Distance Deterrence

The next step is to model the degree to which people are reluctant to travel to reach an IM site. This reluctance can be estimated here by considering the behaviour of people in the pilot areas. For each person registering their interest in attending an IM during the pilot phase, their *nearest* IM site was identified by calculating straight-line distances between their home postcode and the locations of all IM sites which provided at least one IM after the date on which the person registered.

Table 16.2 examines both these distances to nearest sites, and the actual distances travelled to pilot IM sites. The first row presents the distribution of distances, for the

Table 16.2 *Distance from meeting sites*

	Distance band (km)					
	0–1	1–2	2–5	5–10	10–20	over 20
% people who attended IMs:						
distance to IM site attended	2.7	7.8	29.0	26.8	20.9	12.8
distance to nearest IM site	4.5	10.0	35.4	30.7	16.0	3.4
% non-attenders:						
distance to nearest IM site	4.7	10.9	36.1	29.7	15.9	2.8

people who *did* attend IMs, between the IM site which they attended and their home address. The next row shows the distances between the same people's home locations and their nearest meeting site. The difference between the values in the two rows is rather modest, suggesting that the vast majority of people attended their nearest meeting site (although nearly 10% did in fact travel over 20 km when there was a nearer meeting site). The third row shows the distance to the nearest site for those *non-attenders* whose home location is known. Comparing the second and third rows suggests that the distance to the nearest meeting is not necessarily the major influence on people's likelihood of attending: if non-attendance had been very substantially fuelled by remoteness of meeting sites, then a noticeably higher proportion of non-attenders would have been found to live in areas which are a longer distance away from the nearest IM site.

Table 16.2 can also be seen to provide an overview of the kinds of distances which people are prepared to travel to attend IMs. More than one in eight of the people attending pilot IMs travelled more than 20 km from their homes, and over a third attended sites at least 10 km away. People who had attended pilot IMs were interviewed, and given other opportunities to feed-back their views, but very few references were made to the remoteness of IMs posing a substantial difficulty. As a result, it might be hesitantly concluded here that for *most* people a journey of up to 20 km is unlikely to pose a major problem.

There was, perhaps surprisingly, little difference between the median distance travelled by women and men (6.3 and 6.6 km respectively). The median distance travelled by car users (7.3 km) was around 50% longer than that for the users of each of the other methods of travel except train, hinting at the higher levels of mobility which are commonplace among more affluent people. This issue is explored here by using the Townsend Index of deprivation (Townsend *et al.*, 1988), which measures average levels of deprivation (positive scores), or affluence (negative scores), for each ward in the country. People who registered an interest in attending one of the pilot IMs provided their home postcode for the research so the Index value of their home area can be identified. Table 16.3 draws upon these calculations for all people attending pilot IMs, grouping them according to their home area Townsend Index values. The first row shows a notable pattern, in which people living in the most deprived neighbourhoods are found much more often to live near to IM sites. This result will be

Table 16.3 *Home neighbourhood and likelihood of attending IMs*

	Townsend Index values					
	Up to –4	–4 to –2	–2 to 0	0 to +2	+2 to +4	Over +4
Distance from nearest pilot IM (km)	14.1	10.4	11.1	12.0	10.4	4.2
Probability that attended	0.85	0.83	0.82	0.81	0.77	0.69
(% of all who registered)	(12.4)	(28.7)	(23.5)	(15.3)	(10.0)	(10.0)

mainly due to many deprived areas being in inner cities, which are thereby near to the pilot IM sites whose locations were mostly in town or city centres.

The relationship between the level of deprivation of people's home neighbourhood and the likelihood of them attending IMs can be examined directly with the evidence about people who had made themselves known to pilot projects. Table 16.3 shows that the majority of people known to the research are from non-deprived areas: the three left-hand columns, which cover people from non-deprived areas, include around 65% of all people in the pilot research dataset. The second row then reveals, for each type of area, the proportion of the people who expressed an interest in attending who did indeed attend a meeting. There is a consistent, if unspectacular, tendency for the more affluent groups to be more likely to attend a meeting whilst those from the most deprived areas are the least likely to have attended.

The extent to which people's reluctance to travel to attend IMs increased with their distance from the nearest site provided the basis for the distance deterrence model here. The first step was to categorise people who expressed an interest in attending a pilot IM according to the distance they lived from an IM (viz. the first category includes all who lived under 1 km from their nearest site, the second category includes those at least 1 km from a site but less than 2 km away, and so forth). For each category, an appropriate 'typical' distance was assumed (e.g., for the first category this was 0.3 km, and for the second 1.3 km). Not everyone who registered an interest did eventually attend an IM and, in practice, people who lived further from an IM site proved to be less likely to attend. The distance deterrence model uses the proportion of people, in each distance category, who did *not* attend an IM as the dependent variable in a non-linear regression against 'typical' distances (using SPSSx). The beta value from the regression is then taken as the distance deterrence coefficient in the location-allocation modelling.

Ever since the early gravity models, the default distance deterrence value has been 2 and, in practice, empirical evidence has quite often found that the model which best fits the data on people's resistance to travelling has the distance squared. Rather higher distance deterrence is found for very 'everyday' activities, whereas the 'one off' nature of IM attendance suggests people may be more willing to travel further. On this basis, a distance deterrence exponent value nearer to 1 might be expected here. In fact, the modelling found the exponent's value to be slightly below 1 when the whole research sample population was analysed.

The distance deterrence analyses were also run on sub-groups of the data: the research sample had been partitioned according to Townsend Index scores, so as to identify separately those who live in deprived/average/affluent areas. These sub-groups' exponent values show the variation which would have been expected, with the deprived group's value found to be 1.2 whilst the affluent group's was 0.9 (and the average group's is 1.0). Given that the policy concern is that the IM sites should be accessible to *all* groups, it seems appropriate to use the more deprived group's deterrence value in the location-allocation model. In other words, the IM sites were then selected on criteria which, in effect, assumed that everyone attending IMs has the higher resistance to travelling which was found among those living in more deprived areas. This approach also protects the analysis somewhat from the probability that many of the people included in the research data do not appear to be so deterred from travelling longer distance simply because they are 'volunteers' who come from more affluent backgrounds. Even so, the relatively low level of the deterrence values which have been found here were broadly to have been expected, given that IMs are concerned with such major issues in people's lives.

A footnote to these analyses is that the distances calculated here have all, in effect, assumed that people have travelled from home to IMs. Table 16.2 had shown that a notable minority of people did *not* attend the IM site nearest to their home, which suggests that the travelling to IMs may often be undertaken as part of a multi-purpose journey. In particular, people may quite often travel from work rather from home (e.g., in their lunch-break). As a result, people's decisions about 'how far is too far' may quite often be based on calculations which are rather different from the distance-from-home measures which have been estimated here.

16.4 Identifying Candidate Sites

One of the key concerns in identifying suitable IM sites is the more restricted level of mobility of some members of the population. A site in the countryside equidistant between three nearby towns might seem to be a geographically 'fair' solution, but would this be appropriate? In particular, would such a site be suitable for people without access to a car? In the absence of comprehensive public transport service information, the search for suitable IM sites *could* be restricted to places within a certain distance of a major road, but the assumption that all such roads have a reasonable level of public transport services would not be a particularly safe one. By contrast, it *is* likely that the 'high street' of a town and city centre, or a major sub-urban centre, will feature quite high levels of public transport services from its catchment area. This approach to site selection was reinforced by the findings from the pilots, in which people stressed their preference for IM sites located in busy areas to which people go for a variety of purposes.

Considerable data analysis was required to implement this strategy because there is no 'off the shelf' list of appropriately defined town centres. Following substantial experimentation, the criteria for a candidate site were set as the requirement for the location to have at least two of the following characteristics:

- it has a Benefits Agency office;
- it has a market (open or covered); and
- it is a substantial focus for commuting flows.

These characteristics were chosen partly because they were likely to be associated with places frequented by less affluent people and so be more likely to identify centres which have better public transport provision.

The list of Benefit Offices used here does not include 'neighbourhood' Benefits Agency offices, which would have provided a much longer list but would not have been suitable for indicating 'high street' locations. Market towns were identified as locations holding a retail market – on days other than Sundays or Bank Holidays – more often that once a month. No source provides an up-to-date comprehensive list, so the method adopted here was to include any town recorded as holding a market in one or more of four different sources (ranging from a general-purpose gazetteer of towns to the developing Internet site of the National Market Traders' Federation). This inclusive approach minimised the risk of 'missing' a town – which thereby might not be identified as a candidate site – purely due to incomplete data.

The identification of commuting foci was automated. The first step was to analyse the data on flows between wards in the 1991 Census commuting dataset. Of over two million such flows, the program distinguished those of at least 10 (note: these are in fact flows which involve over 100 people, due to the sample frame of this dataset). The next step was to identify wards whose centroids are so close together they can be considered to be parts of the same location. Wards whose centroids are less than 1.5 km apart are in effect, linked together. (This device side-steps the tendency in some towns for a major employer to be located a short distance away – and thus possibly in a different ward – from the High Street where the Benefit Office and/or market is likely to be located.) Wards whose centroids were no more than this distance apart were then grouped together for the purpose of counting the number of large flows to them. The criterion adopted was that a (grouping of) ward(s) had to have at least three large commuting flows to be considered a substantial commuting focus here. Figure 16.1 illustrates the results of the analysis in the North East region. It can be seen that this multi-criteria approach tends to find the 'high street' centres of most small to medium size towns. The locations qualifying with just one of the three criteria are mostly suburban parts of the larger towns (e.g., Newcastle). Over 2000 potential sites nationally possess at least one of these three characteristics, of which 647 had at least two and so make up the list of candidate sites. Together these 647 provide a very comprehensive coverage of the country, with only a few rather remote upland areas more than 25 km from all of them.

16.5 Location-Allocation Modelling

All the research detailed so far in the chapter has been necessary preparation for the location-allocation modelling. As the core of the challenge which was faced, it needs to be described here in a little detail. The location-allocation modelling used the

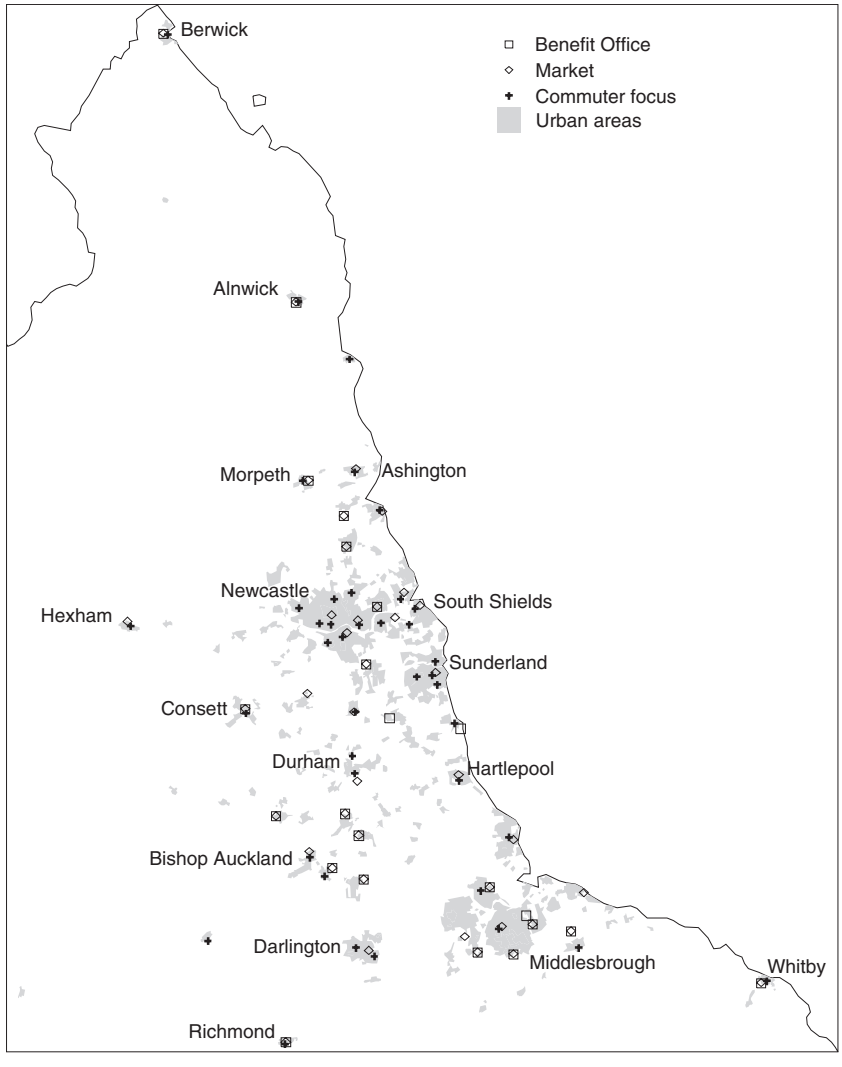

Figure 16.1 *Candidate sites in North East England*

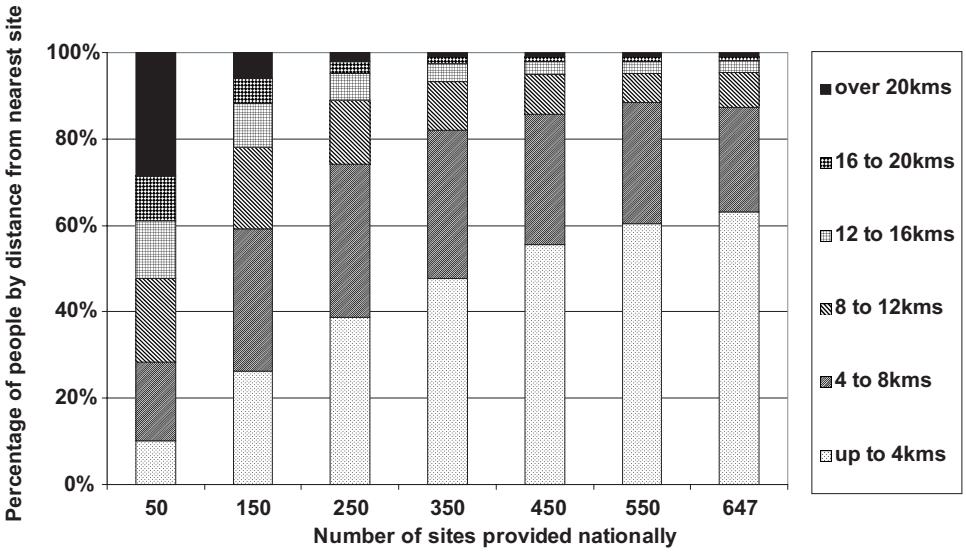

Figure 16.2 *Distance to nearest site, depending on the number of sites*

ARCPLOT module within the ARC/info package. The 647 candidate sites were input, along with the demand distribution model's estimate of demand from each ward, plus the distance deterrence coefficient. The analyses used *mindistpower* as the *locatecriteria*: this means that the analyses sought to choose sites which minimise the total distance travelled, but with these distances weighted by the distance deterrence coefficient. The optimisation procedure needed to be as fast as possible, given the very large number of wards and sites involved, so the default heuristic GRIA was applied. The allocation results were exported to Excel for post-processing and presentation. An additional point of information is that the Department did not set a minimum workload – a number of people to use each site over a year – although this could be expected to reduce costs (Densham and Rushton, 1996). For the record, it appears that this analysis (with nearly 10 000 separate demand locations and nearly 650 candidate sites) is one of the largest ever applications of location-allocation modelling.

The strategy for the modelling was to carry out many different analyses, each reflecting a different scenario from a wide range of options. As has been stressed from the outset, the key policy decision here is 'how many sites should IMs be provided at?' Figure 16.2 summarises the results from the analyses, in terms of the distances people would have to travel, depending on the Department's choice over the number of IM sites. It can be seen that increasing the number of sites much above 250 makes surprisingly little difference to the proportion of people attending who have to travel rather long distances. As an extreme extension to these analyses, it was found that over 2500 sites would have been needed for less than 5% of people to have to travel over 8 km (5 miles). The decision was made by the Department to explore in detail the 250 site option, which provides 95% of potential attenders with a site no more

than 16 km (10 miles) from their home. One notable advantage of this decision for the modelling was that it then became unnecessary to build in site capacity constraints (cf. Murray and Gerrard, 1997), because this number of sites meant that even the busiest one was estimated to have fewer people attending it over the course of a year than had been separately estimated to be a maximum practical workload for one site.

There were no data available, on local patterns of journeys made for comparable reasons, on which to base the predictions of where people would go to attend IMs (cf. Hodgson, 1990). The basic modelling was rooted in the assumption that people would attend IMs after making a journey from home. As noted earlier, a substantial minority of the research sample of people appeared to have travelled to the IMs from work, while others combined the trip with a visit to shops or other facilities. This confirmed the wisdom of only allowing 'high street' locations as plausible sites; it also meant that the distribution of jobs, rather than resident population, provided a better 'starting point' for calculating the distances travelled by some people.

In the absence of a reliable estimate of the proportion of people travelling to IMs 'as if from work' (rather than from home), five scenarios were run with different break-downs of the total attending (viz. 100% 'as if from work' rather than from home; 75% 'as if from work' and 25% from home and so forth). It was notable that it was in the conurbations where the results were most sensitive to the choice of scenarios, with additional city centre locations more likely to be selected when the proportion assumed to be travelling from home was lower. Even so, the overall level of sensitivity to this parameter setting was quite low: town and city centres are usually the optimal locations for IMs *whether or not* people are travelling mostly from the suburbs, so the locations of the selected sites tend not to change greatly between the different scenarios. It was also found that slightly fewer people have to travel longer distances for options in which a proportion of the people are travelling 'as if from work' due to the fact that, on this basis, more of them are assumed to start their journeys in or near town and city centres.

Figure 16.3 shows the location of sites, chosen by any of the five scenarios – with differing proportions assumed to travel 'as if from work' – in the North East region. Sites shown by a diamond in a square were selected by all the five scenarios; those shown as just a square were selected by three or four, while sites represented by diamonds were selected by only one or two scenarios. The remaining candidate sites, shown simply by crosses, were not selected by any of these five analyses. As already indicated, the areas with the most instability tend to be in and around the larger cities. Even there, the effect was often simply to shift the chosen site a mile or two, helped by the fact that quite a large number of the 647 candidate sites are located just a short distance away from each other in the major cities. Looking at the national picture, it was unsurprising that the London area showed the highest level of instability, although again very many of the changes there simply shift the selected site a relatively short distance. Given these location-allocation modelling runs – each finding the optimal 250 sites based on one of five different scenarios in terms of the proportion of people travelling 'as if from work' – the final step was to identify the sites selected by at least three out of the five runs. Figure 16.4 shows the 249 sites selected in this way, and draws attention to the rather few parts of the country, most

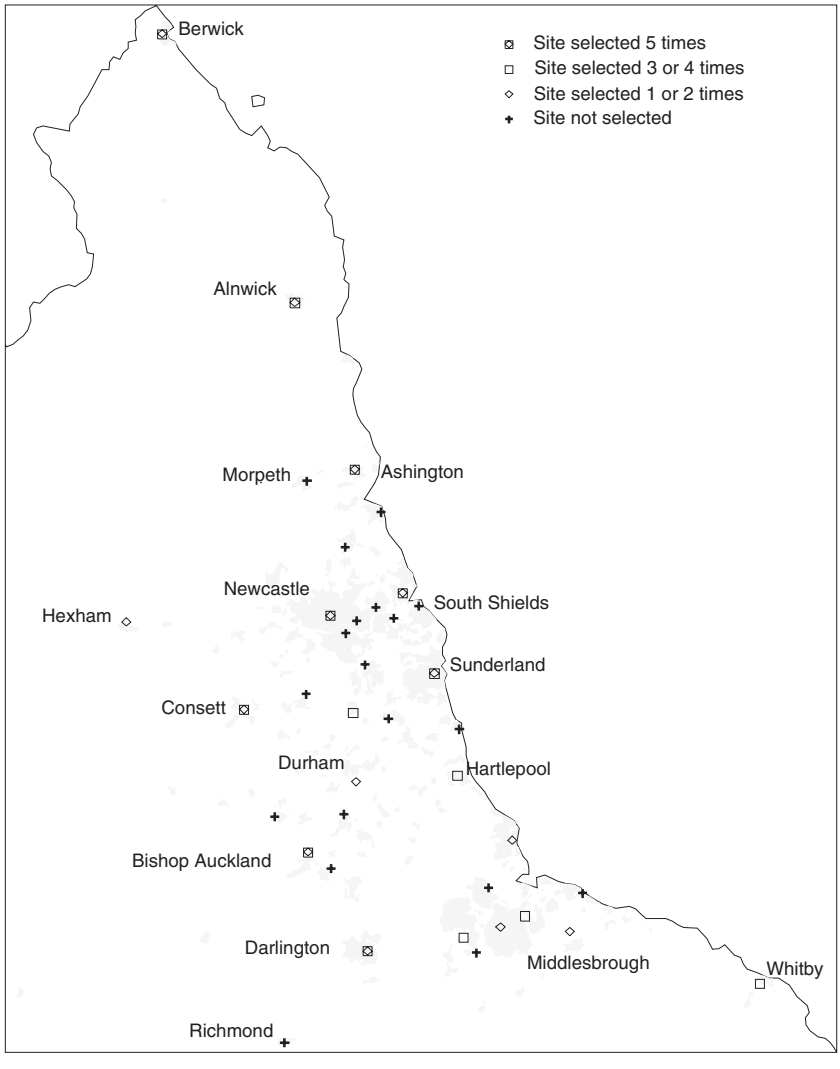

Figure 16.3 *Site selection in North East England*

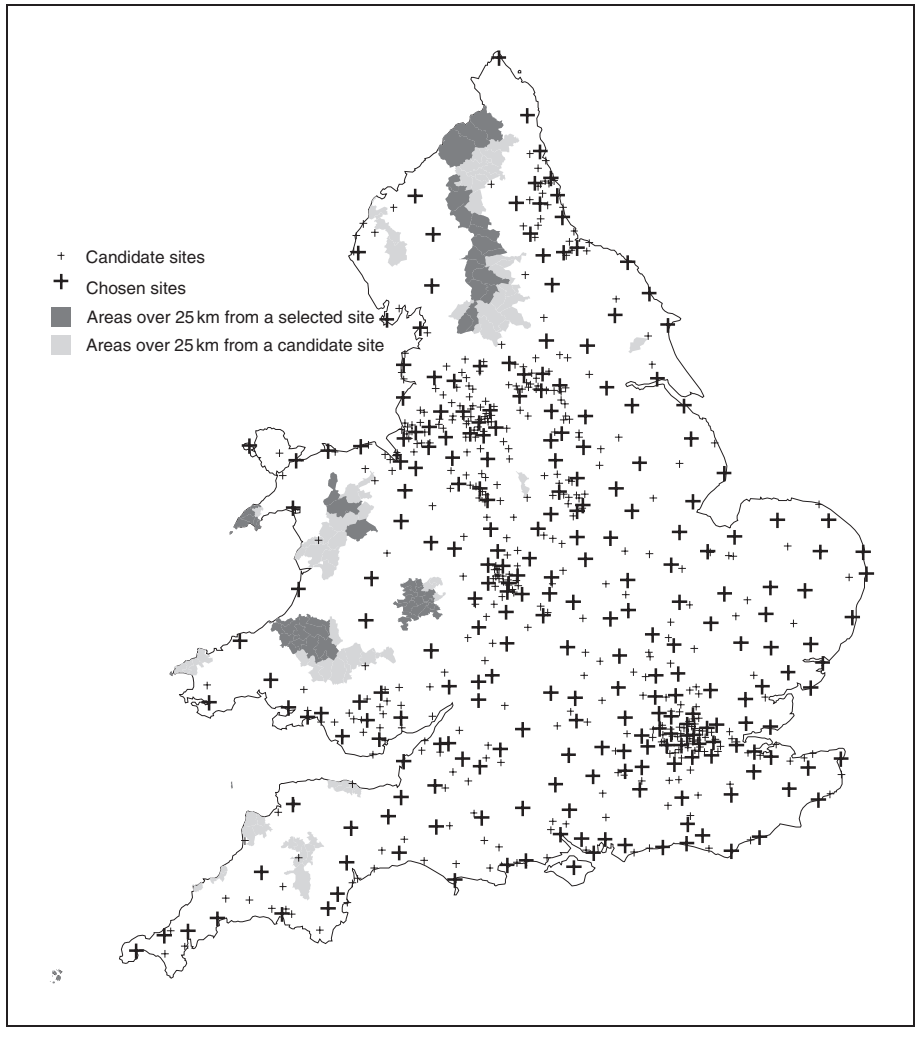

Figure 16.4 *Candidate and selected sites*

of which are in fact only thinly populated, where people would face journeys of over 25 km to their nearest IM site.

16.6 Evaluation of Selected Sites

One way of assessing the results from the modelling is to compare the 249 sites' accessibility with that of the network of Divorce Courts and, in addition, the Benefit

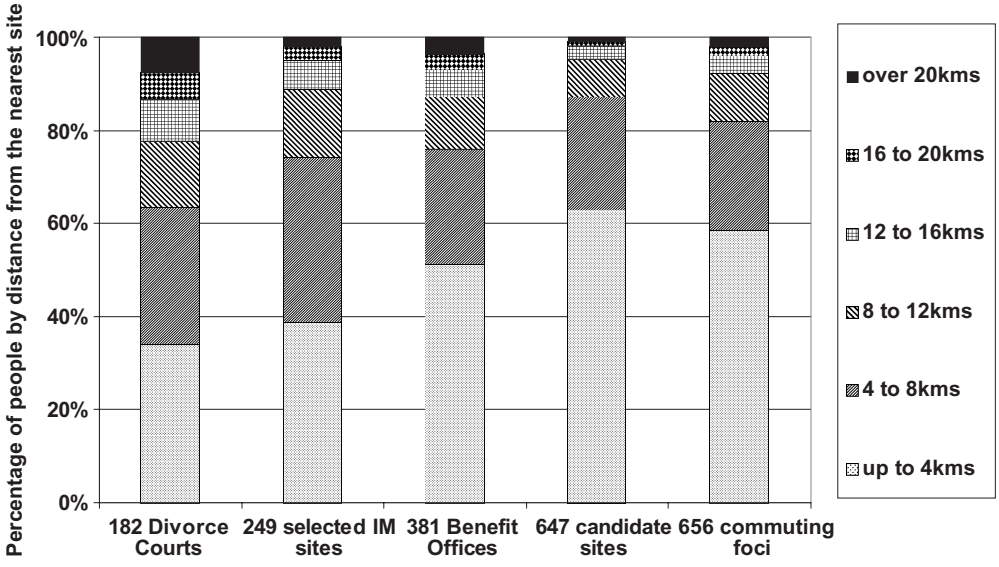

Figure 16.5 *Distance to nearest of the 249 sites, and to the sites of comparator networks*

Offices and commuting foci which were part of the analysis to identify candidate IM sites. Figure 16.5 shows that only the two sets of well over 600 sites substantially surpass the 249 selected IM sites in the proportion of people who would have less than 4 km to travel. In fact the location-allocation model has identified a network of sites which does seem to have minimised the number of people having to travel very long distances. These comparisons give a substantial degree of reassurance that the 249 sites identified here make up *at least* as 'fit for purpose' a network as do these long-established sets of sites whose levels of accessibility seems to attract little public criticism.

16.7 Conclusions

Evaluation suggests that the site identification method which has been developed proved able to identify an appropriate network of sites. This is not necessarily to argue that the set of 249 sites is definitely the best possible network of sites for IM provision: the aim was the more modest one of answering questions which are popularly phrased 'what if . . . ?'. More formally put, the results from the analyses are based on a specific set of hypotheses, assumptions and policy preferences. The modelling has been explicitly designed to allow different scenarios to be explored and, as a result, to assess the sensitivity of the results to changing from one option to another. Figure 16.2 provided the clearest illustration of this sensitivity testing, but many other permutations have been explored to build up the central case results which have been described here. The analytical challenge, which has been met, was to test scenarios with numbers of sites numbered in the hundreds – and nearly 10 000

'demand points' – when location-allocation models are more often applied to a single city or urban region (e.g., Yeh and Man, 1996).

For reasons unrelated to the modelling, the government has subsequently decided not to proceed with a national implementation of IMs. The new proposal is for a set of Family Advice and Information Networks: new research has begun to evaluate this alternative way of providing information to divorcing couples. The decision to change policy – and so not to implement the provision of IMs as outlined here – was based on concerns over just what couples need at times of possible family breakdown. The decision did not turn on any of the geographical issues discussed in this chapter. In its own terms, this research successfully met its objectives. Perhaps the single most important lesson to be drawn was that the results are viewed with more confidence, especially by policy-makers who are unfamiliar with these geographical issues and techniques, if a range of scenarios are presented. Handling uncertainty 'upfront' in this way was found helpful especially, of course, if the results did not vary too radically between the different scenarios. The research also proved, in practice, that uncertainty over policy shifts cannot be handled in a similar way.

Acknowledgements

We are grateful to the Lord Chancellor's Department who funded the research underlying this chapter, as part of a major research programme directed by Professor Jan Walker at Newcastle University's Centre for Family Studies (NCFS) (*see *Information Meetings and associated provisions within the Family Law Act 1996: Final Evaluation Report*, http://www.lcd.gov.uk/family/fla/fullrep.htm). We also fully acknowledge the inputs of numerous colleagues in the research programme, both within NCFS and elsewhere, whose contributions helped to ensure that the methodological developments briefly reported here were as appropriate as possible in meeting the overall objectives of the research programme. We also thank Dr Paul Densham (UCL) for his comments on the modelling work carried out.

All the GIS-based analyses conducted here depended on the use of ARC/Info software from ESRI(UK) who very kindly agreed to its use not only for the authors' academic research but also for this contract-funded research.

New Methods for Assessing Service Provision in Rural England

Martin Frost and John Shepherd

Abstract

This chapter describes work undertaken on behalf of the Countryside Agency to use detailed information on the location of services and households to provide evidence that underpins policy development in two interrelated areas within England. The first is based on household access to services and facilities in rural areas while the second examines the role of small and medium-sized towns in acting as local centres of service provision. Commonly used geographical information system (GIS) procedures including the identification of nearest services and the use of point in polygon allocations are employed to measure levels of access to services and to generate service profiles of the towns. The results show that measuring access to services produces a generally more favourable view of rural service provision than the 'presence and absence' ratios traditionally used by the Agency. The profiles of small and medium-sized towns show high levels of variability suggesting a rather chaotic form for the concept of 'market towns' that in recent years has been a strong component of public policy.

17.1 Introduction

Although rural service provision has been a longstanding policy issue in England (for an early statement see, for example, Moseley, 1979), there has been an acceleration of interest in the 'state of the countryside' in recent years as the declining fortunes of farming, combined with the loss of many local shops and services in rural areas, has reinforced a recognition by the Government that problems of poverty and exclusion are found in both rural and urban areas of the country. The Government's view

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke
Copyright © 2004 John Wiley & Sons, Ltd. ISBN: 0-470-84409-4

is captured in the introduction to the Rural White Paper, published in the Autumn of 2000 by the Department of Environment, Transport and the Regions, as follows: 'The challenge for rural communities is clear. Basic services in rural areas are overstretched. Farming has been hit hard by change. Development pressures are considerable. The environment has suffered' (DETR, 2000, p. 9).

The Rural White Paper (subsequently referred to as the RWP) goes on to set out a range of initiatives and targets relating to service provision, housing, transport, farming and the quality of the environment. In an era of 'evidence-led' policy development it is, perhaps, a little surprising that the level of empirical underpinning of many of these initiatives was, and still is, rather limited. In this chapter, we describe how the use of geo-referenced information analysed through GIS procedures has been used in research undertaken for the Countryside Agency to develop a more effective range of evidence in two key areas of Government initiatives: levels of access to rural services, and the role of market towns as centres of local service provision and economic development in rural areas.

In both areas of development, the work has been based on using information on the presence of individual service outlets in which the location of the outlets is either defined directly by a six-figure national grid reference (in the case of some commercial retail data such as that supplied by CACI) or has an address containing a unit postcode to which a grid reference can be attached. A range of data has been accumulated from both commercial sources and public agencies that locate many of the services identified by the Countryside Agency as of key importance in influencing the quality of life in rural areas of England.

The prime concern of the Agency, however, has been to progress from the identification of 'presence and absence' of services in two directions. The first is to assess, at the level of individual households, the geographical proximity that households have to their local services. The second is to use the range of services present within England's market towns to assess their 'vibrancy' in providing services and facilities to households living in surrounding areas.

In both developments, a combination of standard GIS procedures has been used to achieve these objectives. The analysis of household access to local services rests on the ability to identify an accurate geographical position for small groups of households using the postcode of their addresses and being able to locate (for each targeted service) the distance separating them from their nearest outlet. In the case of market towns, the emphasis is on being able to locate services within the built-up areas of towns that generally do not conform to recognised administrative boundaries (such as wards or local authority boundaries). This requires a point in polygon approach that has been supplemented in some of the analyses with the addition of buffer areas around the physical limits of each town that allow for recent expansion.

The chapter is divided into two parts. In the first part, we review the traditional ways of capturing information about the location of rural services as a basis for describing how this has been improved by adopting GIS approaches linked to digitally encoded national sources of information. In the second part, a discussion of the concept of market towns is followed by a demonstration of the profiling of these towns that is based on the capacity to locate key services within their boundaries.

17.2 Access to Services in Rural Areas: Identifying the Problems

The RWP generated no less than 15 headline indicators by which the state of rural areas within the UK was to be assessed. One of these was headed 'Geographical availability of services' and committed the Countryside Agency to maintain regular monitoring of the proportions of rural households living at specified distances from key services. The current list of key services monitored by the Agency includes banks and building societies, cash points, supermarkets, petrol stations, primary schools, secondary schools, doctor's surgeries, job centres, libraries and post offices. Although the notion of households' access to services may appear to be a simple one, producing measurements on a national scale that might be suitable to support the monitoring specified by the government has, traditionally, been far from easy. The problem has three components. The first is knowing where services are located, the second is knowing where households are, and the third is estimating the distances separating the two.

17.2.1 The Location of Services – The Rural Survey Approach

The traditional source of information on the location of services in rural areas has been the periodic surveys of rural services conducted by the Rural Development Commission (RDC). These were conducted in 1991, 1994 and 1997, and relied on parish clerks to complete questionnaires detailing the nature and extent of service provision within their parishes. The questionnaires were ambitious. They requested details on shops, pubs, post offices, banks, educational facilities, health facilities, medical facilities and recreational facilities, together with aspects of housing, local transport and welfare provision.

The basic data collection unit for all surveys was the civil parish which, in addition to its role in the reporting of other official data (notably from the Census of Population), constitutes an important focus of local democratic politics and policy action. The surveys covered only 'rural' parishes that were defined as those with a resident population of less than 10 000. The surveys recorded counts of the number of service outlets and facilities that lay within each parish. The results for the 1991, 1994 and 1997 surveys were published solely as paper documents (Rural Development Commission, 1992, 1995, 1998) with tabulations of the proportions of parishes containing a particular service or facility or a particular number of service outlets. Although this approach utilised the only comprehensive network of potential data collectors in rural areas, the parish clerks, its use in determining the location of rural services for the purpose of assessing levels of access was weakened by two key problems:

- *geographical coverage*: not all parish clerks filled in the forms or filled in the forms completely. Although considerable effort was put in by Rural Consultative Councils to achieve high response rates, in some counties response rates could be as low as 65%, even when an overall response rate close to 80% was achieved by the 1997 survey; and

- *urban/rural interaction*: limiting the surveys to parishes containing fewer than 10 000 residents ignored the fact that many rural areas are close to towns or cities (which do not, in any case, contain defined parishes) and have access to the services and facilities contained in the urban areas.

Either one of these shortcomings means that it is not possible to use these records as a way of identifying consistently how far rural households have to travel to access their nearest service or facility. For many households the nearest facilities might lie in a neighbouring town or in a neighbouring parish which did not respond to the surveys.

17.2.2 The Problem of Locating Households

Using parishes – or indeed any administrative areas – as the sole basis for analysing information on services in rural areas also accentuates the problem of identifying the location of households accurately enough to permit sensible analysis of their distance from local services and facilities. Counts of residents and households within parishes are only generated by the decennial Censuses of Population. Even then, the value of these counts is diminished by the size and irregular shapes of many parishes. There is great variation in parish sizes (about 30 current parishes are of fewer than 100 hectares while 15 are larger than 10 000 hectares) and, for many parishes, their elongated form makes it problematic to distinguish a meaningful centroid.

17.2.3 Assessment of Access from Survey Evidence

The combination of parish survey-based evidence on the location of services in rural areas, combined with the use of parish populations to assess the distribution of households, has severely limited the degree to which previous rural surveys have been used to measure levels of access to services. This is clear in the terminology used in the report on the 1997 Rural Services Survey (RDC, 1998) in which the term 'provision' of services is used consistently instead of any measure of 'access'. All tables within the report show the numbers of service outlets cross-tabulated against the population size of the parishes in which they fall, with many of the key headlines within the report summarising the proportions of parishes that do *not* contain a particular service or facility. A good example to illustrate some of the difficulties that may arise from this is to consider post offices as a key rural service. In 1997, 43% of responding parishes in the rural services survey did not contain a post office (RDC, 1998). By 2000, this figure had risen to 46%, reflecting the progressive closure of small rural post offices (Countryside Agency, 2001). Yet, using the GIS procedures outlined in the next section of this chapter, it was estimated that nearly 94% of households living in rural areas had a post office within 2 km of their homes.

The key variable in explaining the difference between these two sets of figures – one based on provision, the other based on access – is the uneven distribution of population across parishes. In the 1991 Census of Population, about 13% of all

parishes had 100 or fewer residents, rising to 27% of parishes if the threshold is increased to 200 residents. In 2000, 88% of parishes with fewer than 100 residents did not contain a post office with an equivalent figure of 78% for those with between 100 and 200 residents. A concentration on provision alone is clearly weighted by the significant number of parishes that were defined many centuries ago but now contain few residents and correspondingly few services.

17.3 Using GIS Procedures to Measure Access to Rural Services

The development in recent years of a greater availability of digitally encoded lists of services and households that permit accurate geo-referencing, together with the software to link the two together, has transformed our ability to measure access to services at detailed spatial scales throughout the country. This can be seen in the contents of the Rural Services Survey of 2000, the first to integrate a parish-based survey with GIS-based calculations of household access to services. The key services used in these calculations are shown in Table 17.1.

All of these lists are supplied with the unit postcode of the service outlet. Where necessary, the Postcode Address File (PAF) was used to attach national grid references to each record (all CACI-sourced records are already geo-referenced). Additional data cleaning, using the Royal Mail's Address Manager to locate individual addresses where postcode details were inaccurate, was necessary to maximise the number of successfully matched postcodes. Address Manager software allows users to enter portions of an address and identifies an accurate matching unit postcode where an initial postcode has been wrongly recorded within the original digital lists.

Table 17.1 *Sources of digital lists of service locations within the Rural Services Survey, 2000*

Service	Data source	% successfully grid referenced (after cleaning)
Primary schools	DfES (Register of Educational Establishments)	100
Secondary schools	DfES (Register of Educational Establishments)	100
Post offices	Postcode Address File	98.8
Benefit offices	Benefits Agency	99.7
Job centres	Employment Service	99.5
Doctors' surgeries	Binley's Register of General Practitioners	99.5
ATMs (cash machines)	LINK Network plc	90.0
Banks and building societies	CACI Ltd	Already referenced
Hospitals	Yellow Pages and Dept. of Health	100
Petrol stations	CACI Ltd	Already referenced
Supermarkets	CACI Ltd	Already referenced

Source: RSS2000 Technical Report.

From Table 17.1, it can be seen that the rate of success in attaching grid references was generally high. Only ATMs posed any significant problems at this stage of the analysis.

Once grid-referenced, software was constructed to identify, for each unit postcode in England, the location of its nearest outlet for each service. This was assessed on the basis of the straight-line distance connecting the centroid of the postcode (using Royal Mail's Address Manager with 1 m centroid accuracy) to the grid reference of the service outlet. Whilst there are some limitations with this methodology over road lengths, straight-line calculations were used as the most practicable way of computing distances for about 1.3 million residential postcodes within England. After each unit postcode had been assigned a distance to its nearest service outlets, two avenues of development were used in the Rural Services Survey of 2000. In the first, the pattern of access was presented visually through plotting individual postcodes as points to generate maps at national and regional scales showing areas of relatively high or low access. An example showing the shortest distance to a hospital for all non-commercial postcodes in England is contained in Plate 7 (taken from Countryside Agency, 2001). Each dot on the map (there are about 1.2 million dots) represents a unit postcode with its colour indicating distance to the nearest hospital.

The real purpose of the map is to permit visualisation of those areas that are relatively remote from hospital services, picked out in dark blue in this example. Key areas in this category include North Cornwall and West Devon, the Welsh borders together with Lincolnshire and East Yorkshire. In addition, the sparsely settled highland areas stand out as blank, focusing attention towards those areas that are both relatively remote *and* relatively intensively settled.

In the second avenue of development, the fact that the number of households within each unit postcode can be estimated from its counts of residential delivery points was used to estimate, for standard administrative units (wards through to counties, regions and England as a whole), the proportions of households within each area having specified levels of access to key services.

An example of one of the products of using this approach is shown in Table 17.2. Developing the example of access to post offices used earlier in the chapter, this shows the breakdown by Government Office Regions of the proportions of rural households living within specified distances from their nearest post office.

The households used in this calculation are all those living within wards defined as 'rural' by the Countryside Agency. The results further confirm the arguments made earlier in the chapter that considering provision of facilities at a parish scale does not provide a meaningful view of the degree to which the great majority of households within rural areas live quite close to their nearest post office.

In these examples, using GIS linked to the increasing availability of machine-readable lists of services that can be, or already are, geo-referenced, combined with an ability to locate unit postcodes and their constituent households, has greatly improved our ability to address the three key issues of estimating access to services outlined earlier. It has provided a direct and generally cost-effective route to determining where services are located, where households are located and of estimating the distances separating the two. It has achieved this with comprehensive national

Table 17.2 *Proportions of rural households living within a specified distance from their nearest post office*

Government Office Region	0–2 km (%)	2–4 km (%)	>4 km (%)
East	92.3	7.0	0.7
East Midlands	93.8	5.7	0.5
North East	93.2	5.6	1.1
North West	95.0	4.4	0.6
South East and London	93.4	6.3	0.3
South West	93.9	5.8	0.4
West Midlands	91.9	7.7	0.4
Yorkshire & Humber	94.4	5.0	0.6
England	93.5	6.0	0.5

Source: Rural Services in 2000 (Countryside Agency, 2001).

coverage eliminating the problems of non-response to surveys and the problems of limited geographical coverage omitting services contained in the larger urban areas. The approach outlined here parallels that used in the construction of the access to services domain within the Indices of Multiple Deprivation (IDM) 2000, defined over a smaller range of services, further confirming the degree to which GIS methods are becoming central to the construction of monitoring of an increasing number of key Government policies and performance targets.

17.4 The Role of Market Towns

17.4.1 What are Market Towns?

The debate over access to services in rural areas has developed a further dimension over the last two years with the recognition that the bases for efficient and sustainable provision of a wider range of services in the countryside are likely to be found among the small and medium-sized towns. Compared with the need for provision of certain basic services within, or accessible to, villages and hamlets, market towns are perceived as having a wider economic and social role in rural areas, that is 'as a focus for growth in areas which need regeneration, and more generally as service centres and hubs for surrounding hinterland, exploiting their potential as attractive places to live, work and spend leisure time' (DETR, 2000, p. 73).

However, whilst the general perception of a market town may be deeply ingrained in the English psyche – viz. a free-standing, small to medium-sized place with a market square, a reasonable provision of professional, business and retail services serving a rural catchment area and, probably, a tourism function based upon the presence of historic buildings – in reality, the so-called 'market towns' are now a far more varied set of elements in the settlement system. In recent years, the profound changes that have taken place in the rural economy and its demographic and social

structure have been partly driven by and partly mirrored in the functional evolution of 'rural' towns (Newby, 1985; Champion, 1989; Hodge and Monk, 1987; Marsden *et al.*, 1993). Moreover, the direction and pace of that evolution has been different in different parts of the country, depending on such contextual circumstances as levels of regional prosperity, location relative to larger urban places, access to motorways and other major roads and national planning policies (Shepherd and Congdon, 1990; Errington, 1997).

The RWP itself acknowledges the inherent variety suggesting that market towns are 'small rural and coastal towns, many of which serve a rural hinterland whether or not they have ever had traditional rural markets. Some may have grown up around a canal or railway junction or as a coastal resort while continuing to be an important commercial and leisure focus for a rural hinterland' (DETR, 2000, para 7.2.1). However, the first statement of a formal definition is given, with no further rationale, in the comment that 'there are over 1,000 towns in England with populations between 20,000 and 2,000' (ibid.). In particular, there is no hint here of a relationship between population size and the functional 'endowment' serving to help define market towns for policy purposes.

17.4.2 Problems of Estimating Indicators of Market Town Prosperity

Capturing the diversity of market towns in empirical terms is neither easy nor always totally convincing but, in attempting to do so for policy development and monitoring purposes, GIS have an indispensable role to play. In general terms, GIS have two main contributions to make in relation to the study of smaller urban places:

- they facilitate the integration of point and boundary data that make it possible to identify service levels available within and around market towns; and
- they permit the estimation of market town characteristics based upon the linkage of data captured at different geographic scales and for different types of data collection unit.

It is these contributions that we focus on here. A third area of analytical contribution, that of distance analysis, which is important in characterising the location (distance) of market towns relative to larger towns and cities to which they may look for jobs and major services/leisure opportunities and smaller places which they themselves supply with 'lower order' goods and services, is not covered.

In practical terms, and in the context of data specifically for England and Wales, the key problems of conducting empirical analyses of small and medium-sized urban places qua 'market towns' are as follows:

- the key dataset on urban places in England defines such places in terms of contiguous urban land uses (producing 'Urban Areas') and not, as in the case of the USA, for example, in terms of urban functions or the provision of jobs or services to the surrounding area (ONS/GRO, 1997; Office of Management and Budget, 1998);

- the boundaries of Urban Areas, which were last defined in 1991 are, at the time of writing, significantly out of date whilst, in some parts of the country in particular, it was known from other sources that there had been extensive residential development on the outskirts and within the catchment area of market towns (Bibby and Shepherd, 1997);
- those datasets which were available to characterise market towns (principally, though not exclusively, the Census of Population), are reported in spatial units (wards, districts, etc.) that, in terms of geographic scale, are better suited to analytical work on larger urban places rather than small ones and this difficulty is considerably magnified for those places in the lowest range of the market town 'hierarchy', i.e., in the region of 2000 residents;
- problems of the way market towns are defined as urban places and of the 'fit' of data reporting units to this definition make it very difficult, on the basis of quantitative data alone, to distinguish between 'true' local service centres and places with a significant or overwhelming dormitory function; and
- finally, no readily available information exists upon which to estimate the catchment areas linked to each town, a task which is important not only for 'free-standing' places, but to distinguishing or estimate overlapping market town catchments in areas with complex urban settlement patterns (ERM, 2000).

What follows relates entirely to the study of English (and possibly Welsh) market towns. In Scotland, different datasets are available which render certain aspects of studies of rural towns more straightforward.

17.4.3 Market Town Size and Regional Distribution

Although the 20 000 to 2000 population range for the definition of a market town is implicitly accepted as an indicator rather than a strict definition, its existence has nevertheless entered into the vocabulary of policy on market towns and has resulted in the list of places for consideration in strategic analyses of market towns within this range. The RWP gives a template for service availability in the East Midlands which defines 'Larger Market Towns' as having populations between 10 000 and 25 000 and 'Smaller Market Towns' as those with populations between 2000 and 10 000 (DETR, 2000, Table 7.1). However, the Countryside Agency's market town headline indicator of economic health focuses on Urban Areas in the 20 000 to 2000 range. This endemic flexibility in definition and the lack of certainty as to the character of market towns due to data problems, both imply the need for equally flexible (and powerful) approaches to policy analysis of which GIS is one such tool. Analytical flexibility is inherent, for example, in the need for awareness of:

- towns larger than 20 000 population which clearly form 'market town' functions in relation to their catchment area but which, because of their larger size, may be inappropriate for market town policy initiatives;

- places that are around the 2000 population level which, because of lack of services or the nature (lack of) settlement in their periphery, may not have an important catchment area function; and
- places that were (perhaps some way) below the 2000 population level at the time of definition but which nevertheless do serve a local catchment area.

There are two main ways in which small market towns may be omitted from current analyses: places which have grown significantly since the base population data (from the 1991 Census) were derived and places which were not originally defined for technical reasons related to the geographical 'capture' of population data within urban area boundaries. Bishop's Castle in Shropshire is a good example of the latter, a small, even classic market town, which fails to meet the population criterion because a 100 m buffer around the urban area fails to capture a sufficient number of census enumeration districts (ONS/GRO, 1997, p. 3).

As noted above, the identification of a place as a market town depends upon a boundary dataset for urban areas that relies upon a strict land-use definition of urban places. Using these data, there are 1210 market towns defined strictly on the '2000 to 20 000' principle within England. They range from Stow-on-the-Wold (with a 1991 population of 1999) to Thetford, in Norfolk, with a population of 20 058. This range excludes some towns which clearly serve a rural hinterland but which are only moderately larger, e.g., Newton Abbott (23 801), Chippenham (25 961), Sevenoaks (24 489) and Bishop's Stortford (28 403). On the other hand, it includes places which have either an extremely restricted 'catchment area' function (e.g., Westhoughton, population of 23 307, essentially a part of Greater Manchester) or are an appendage of a larger place (e.g., Bessacar, population of 19 907, now predominantly a suburb of Doncaster).[1] For the purpose of most analyses reported here, we have included essentially free-standing urban places in the population range 2000 to 30 000. Note, however, that this now incorporates some evident non-market towns such as Addington, an 'out-county' estate just outside Greater London, but just excludes Bury St Edmunds in Suffolk, a very clear candidate for true market town status.

The distribution by population size of market towns in this range is shown in Table 17.3. Over half the candidate market towns have fewer than 5000 residents and four-fifths (80%) have less than 10 000 population. In view of the dominance of market towns in the lower end of this distribution, there is a strong case, at the policy level, for closer scrutiny of the impact of size on market town type, service provision and catchment area range. At the level of empirical analysis, it further emphasises the need for awareness of the technicalities of definition (especially those, as noted above, in the linkage of census and other areas to urban land use boundaries) and especially any peculiar local instances of the fit of such areas to boundaries. Here, painstaking perusal of GIS mappings becomes *de rigueur*.

The absolute and proportional distributions of the size of market towns by region are shown in Tables 17.4 and 17.5. There are significant differences between regions in the proportional table, which indicates different regional settlement patterns based

[1] Bessacar (and no doubt others like it) is included on a technical point relating to the way discontinuous parts of larger urban areas are defined.

Table 17.3 *The distribution of market towns in England by population size*

Population size	Number	%
Over 20 000	64	5.0
15 000–20 000	80	6.3
10 000–15 000	111	8.7
5 000–10 000	309	24.3
2000–5000	710	55.7
Total	1274	100.0

Total	710	309	111	80	64	1274

Table 17.5 *The proportion of market towns by population size and region, 1991*

Region	2–5000 (%)	5–10 000 (%)	10–15 000 (%)	15–20 000 (%)	>20 000 (%)	Total (%)
East of England	62.2	20.3	7.7	5.4	4.5	100.0
East Midlands	59.0	26.1	6.8	5.6	2.5	100.0
North East	50.0	28.0	8.5	6.1	7.3	100.0
North West	40.8	34.0	10.7	3.9	10.7	100.0
South East	58.3	19.4	7.1	9.1	6.0	100.0
South West	52.0	26.2	10.9	5.9	5.0	100.0
West Midlands	58.8	22.7	7.2	5.2	6.2	100.0
Yorks & Humbs	54.8	25.8	11.6	6.5	1.3	100.0
Total	55.7	24.3	8.7	6.3	5.0	100.0

upon different economic circumstances. Such differences have significant implications for market town policy (especially in relation to regeneration and equity issues), the interpretation of indicators and the evaluation of individual market town initiatives. Tables 17.4 and 17.5 indicate a generally even distribution of market towns by population size across regions, with the exception of the North West which is under-represented in the category of towns of 2–5000 and over-represented by towns with

more than 20 000 population. However, this may have as much to do with the underlying definition of a town using land use criteria as with functional attributes and town–catchment area interactions.

The analyses that follow are the first stages in an attempt to identify some order in this group of settlements as a step towards identifying effective indicators of their condition and of identifying towns which are of particular importance to a rural hinterland. It is essentially experimental work that is trying to close the gap between policy and understanding.

17.5 Using GIS to Estimate Service Provision in Market Towns

The fact that the Urban Area boundaries and associated populations defining market towns were 10 years out of date at the time of the analyses was a cause for some concern. As previous studies had shown, small and medium-sized towns were the fastest growing places between 1971 and 1981 and the forces that had generated that growth were unlikely to have abated by much, if at all, in the subsequent decade (Champion, 1989; Shepherd and Congdon, 1990). The problem in gaining some idea of the rate of change among this particular set of towns lay in the scale difference between the areas for reporting inter-censal population estimates (i.e., wards with populations assigned from pro-rating local authority district estimates), and the smaller market towns which formed the majority of the overall size distribution of these places. One simple way to obtain population change information would have been to assign wards to market town urban areas on the basis of a boundary intersection/coincidence rule, for example, incorporating those wards which had any part of their boundary shared with or crossing that of an urban area. In practice, however, intersecting ward boundaries are not only a very poor fit to Urban Areas, but can also lead to complex overlapping of ward boundaries in locations where there are geographic clusters of the smallest market towns, thus making it difficult to allocate population growth to particular places.

An illustration of some of these difficulties can be seen in Figure 17.1. This shows both urban areas and ward boundaries centred on the Braintree urban area in Essex that in 1991 had a resident population of just over 30 000 people. Even at this scale, right at the top of the market town range, Census wards divide the town unevenly and often contain significant areas outside the built up area. In addition, the detailed rules by which the 1991 Urban Area boundaries were fixed often lead to rather ragged boundaries, particularly where urban sprawl has taken place. This can be clearly seen in the ward to the north of the centre of Braintree where a straggle of urban development protrudes into what would otherwise be an undeveloped ward. On the west side of the map another case can be seen where a smaller urban centre is divided into two more or less equal parts by the boundaries of two large rural wards.

Our initial approach, therefore, was to focus on the immediate environs of market towns by defining a consistent 500 metre buffer for all towns in the dataset and to use this to capture residential delivery points (RDPs) from Royal Mail's Address Manager database. This procedure had been used in the development of the Rural

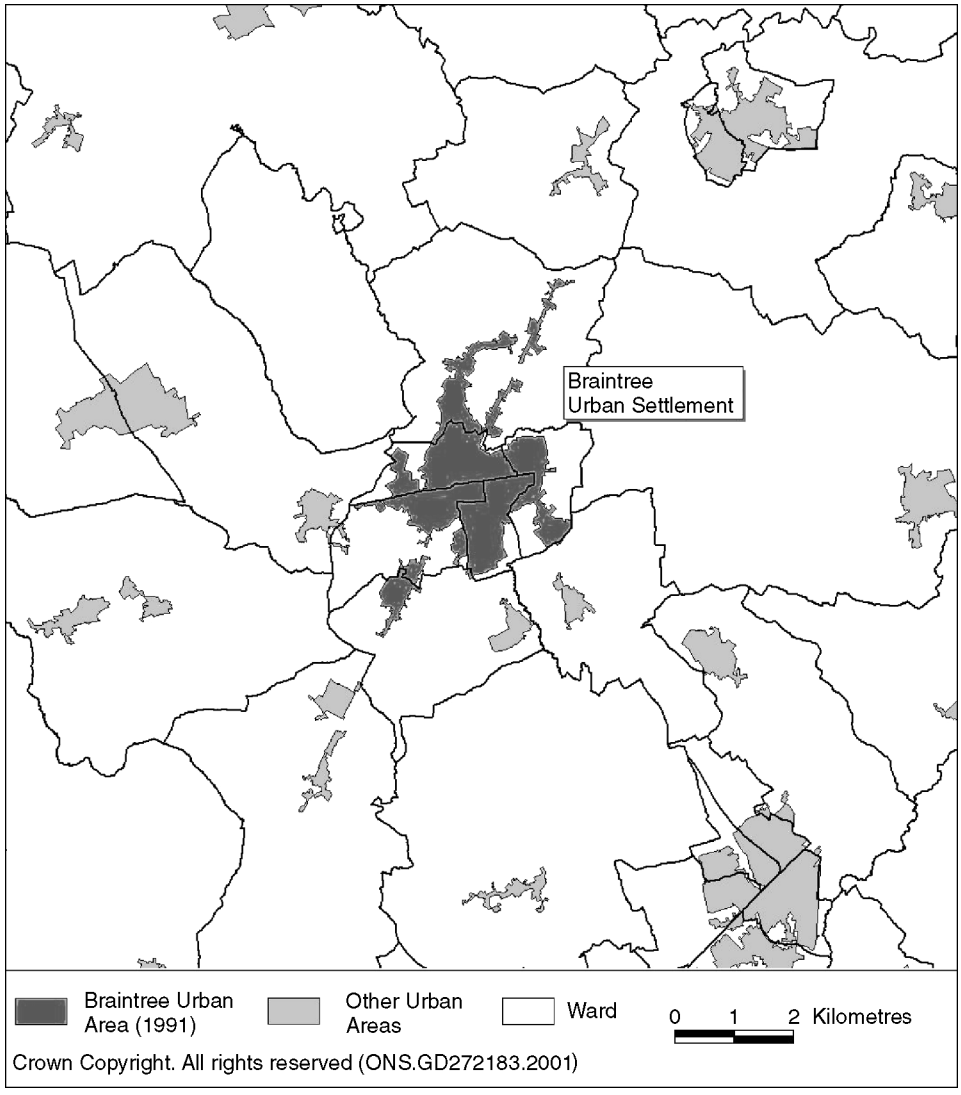

Figure 17.1 *A large market town and 1998 ward boundaries. From Countryside Agency. © Crown Copyright*

Settlement Gazetteer (RDC/HC, 1998) and in earlier studies using postcoded information to track population change (Raper *et al.*, 1992, pp. 220–33). In this case, however, there was no attempt to transform RDPs into population on the basis of regional or local differences in household size since, again, information on the latter, being derived from the 1991 Census was also likely to be inaccurate. In addition, there was no attempt, though it could be done, of differentiating between total household

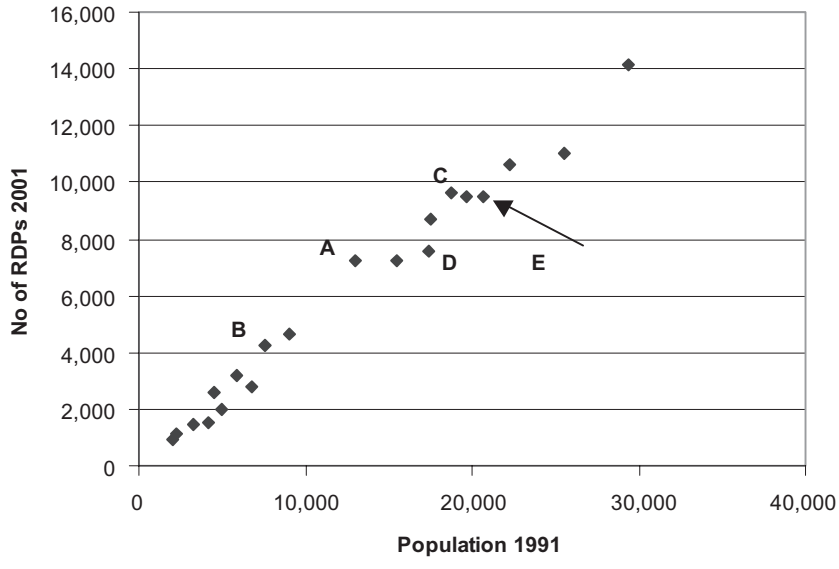

Figure 17.2 *Selected market towns; population 1991 (Urban Area) and number of Residential Delivery Points 2001 (Urban Area plus buffer)*

change (i.e., RDPs within Urban Area + buffer) and purely urban edge change (i.e., RDPs within the buffer).

Figure 17.2 shows a close relationship between population in 1991 and the number of RDPs in 2001. Of potentially more interest here, however, are the apparent departures from a 'straight-line' relationship reflecting, in some part at least, differences between market towns in levels of household growth in the period 1991–2001. These departures emphasise the importance of the economic structures of market towns and their regional contexts in accounting for population change. Stronger than expected growth can be seen in some of the small and medium towns in the south (e.g., East Dereham (A), Norfolk; Sherborne (B), Dorset; Spalding (C), Lincs) while those falling short of expectations are predominantly northern towns with a strong industrial or mining base (e.g., Spennymoor (D), Durham; Workington (E), Cumbria).

The first test rests on the well-established concept of urban hierarchy. We would expect certain medium to high level key services to be located in some of the larger towns in this group. The services selected from those where digital lists were available were banks (and building societies), secondary schools, supermarkets, large DIY outlets, Benefit Offices and Job Centres. To allow for fringe growth around the DETR urban boundaries an additional 500 metre buffer was added to each settlement.

These results demonstrate the considerable size ranges over which these services are found (Table 17.6). Only Benefit Offices and principal DIY outlets seem to have any power as threshold indicators of key centres and even for these it is limited. Most services are found throughout the size hierarchy, although with a tendency to be more completely and intensively present in the larger settlements.

Table 17.6 *Presence and absence of selected services*

	Largest town without service	Smallest town with service
Bank	15514	2000
Secondary school	18336	2012
Supermarket	15514	2052
DIY chain	19907	4591
Benefit Office	19907	6466
Job Centre	19907	2245

Sources: DfEE, CACI, Countryside Agency.

Given this range of occurrence, the initial approach to identifying the more important local service centres was based on overall relationships between population size and the number of service outlets found in each town rather than pursuing the concept of population thresholds. For a selection of important local services (secondary schools, banks and building societies, and supermarkets), the number of services present in each town was predicted using simple regression equations based on population size. The results were as follows:

$$Y_{bi} = -0.32^{**} + 0.00042^{**}P_i + e_{bi} \ (R^2 = 0.58) \text{ for banks} \tag{17.1}$$

$$Y_{si} = 0.02 + 0.00018^{**}P_i + e_{si} \ (R^2 = 0.59) \text{ for supermarkets} \tag{17.2}$$

$$Y_{di} = 0.45^{**} + 0.00013^{**}P_i + e_{di} \ (R^2 = 0.41) \text{ for doctors' surgeries} \tag{17.3}$$

where Y = count of services present, P = resident population in 1991, i = 1:1272 market towns and ** represents $p < 0.01$.

The residuals from these equations were then summed across all three services to derive an indicator of consistent over- or under-endowment of services. This is then divided by the population of each town to assess the intensity of these deviations.

$$I_i = \sum e_{ti} / P_I \tag{17.4}$$

where I = the intensity indicator and t = 1,3 service categories.

The purpose of this approach is to identify towns where there are significantly more services than would be expected from their local populations, suggesting a broader service centre specialisation. Table 17.7 shows the 12 towns with the strongest signs of positive specialisation in service provision.

Most of these towns appear as reasonably free-standing local service centres. The exception is Hemingford Grey which is part of a cluster of Urban Areas around Huntingdon/St Ives. Overall these suggest that there might be some path here to identifying the elusive market towns. This view is reinforced by considering the 12 towns with the lowest scores (Table 17.8). Many of these towns are either close to, or part of, larger urban or suburban settlements while some like Hatfield and New

Table 17.7 *Towns with strong service centre functions*

Town	Over-representation score
Stamford	2.30
Uttoxeter	2.41
Evesham	2.54
Tiverton	2.73
March	2.75
Tewkesbury	2.76
St Austell	3.16
Beverley	3.41
Diss	3.99
Wetherby	3.99
Hemingford Grey	4.03
Windermere	4.25

Table 17.8 *Towns with weak service centre functions*

Town	Under-representation score	Comments
New Addington	–3.84	near Croydon
Maghull	–3.74	outskirts of Liverpool
Hatfield (Yorks)	–3.55	close to Doncaster
Westhoughton	–3.08	close to Wigan
Golborne	–2.88	close to St Helens
Borehamwood	–2.75	fringes of London
Hoylake	–2.56	close to Birkenhead
Winsford	–2.49	more difficult to explain
Nailsea	–2.35	close to Bristol
New Rossington	–2.28	close to Doncaster
Trowbridge	–2.17	fairly close to Bath
Aylesford	–1.94	close to Maidstone

Rossington were developed partly as colliery settlements in addition to being close to a regional service centre.

Finally, we use this approach to examine the 'service level endowment' scores for a selection of classic free-standing small and medium-sized market towns. These are shown in Table 17.9.

It will be noticed that few of these scores are particularly strong but all are positive. Of the 1275 market towns defined in simple population terms, 735 show negative scores on this indicator, so to achieve 10 positive scores from the selection of towns is an interesting result. It confirms a little further that this approach has potential value in sifting the mixed group of towns that are now the focus of considerable policy effort.

Table 17.9 *Scores for free-standing towns*

Town	Town scores
Ely	0.07
Framlingham	0.08
Harleston	0.48
Bicester	0.24
Malton	1.51
Market Drayton	0.65
Bourne	0.21
Horncastle	0.56
Market Rasen	0.40
Thirsk	1.24

17.6 Conclusions

This chapter has demonstrated that relatively simple analytical approaches involving standard GIS procedures such as nearest neighbour measures and point in polygon allocations can, in combination with digital lists of services and households, be used to underpin the development and implementation of rural policies in England. At the moment, this work is in its early stages of development and will continue to be developed in coming years to provide a firmer base from which to specify and operate plans for greater rural support. At this stage, possibly the most interesting conclusions are not contained in the work itself but relate more to its timing.

In spite of public agencies widely proclaiming the virtues of evidence-led policy development, the political momentum of measuring access to services and, particularly, the use of the market town label preceded any systematic and thoughtful investigation of the concepts underlying the terms. All of the evidence points to the fact that little initial thought was given to how these terms might be effectively operationalised to produce measurements that would provide policy development with meaningful support.

In this setting, the application of GIS methods has provided a flexible way of responding to an empirical need generated by the speed of policy announcements and development of political agendas outstripping the capacity of public agencies to explore and comprehend relevant conceptual frameworks. We would argue that there is a risk in this flexibility. The power of modern software, linked to the increasing availability of digitally encoded information, can easily come to be seen as offering a quick fix to any empirical need thrown up in the policy development process. On the evidence of current practice, not all of these needs will be amenable to sensible analysis. The chaotic conception of market towns comes very close to this in bundling together towns with dissimilar functions, characters and histories into a common grouping linked only by their population size. If only some geographical analyses for exploring the nature of the current settlement and service-based urban hierarchy had

been undertaken before, rather than after the term was coined, things might have been different – and better!

Forecasting River Stage with Artificial Neural Networks

Pauline Kneale and Linda See

Abstract

Forecasting models are required to determine continuous river stage for drought and water resource management, and for real-time forecasting of extreme flood events. The models use telemetred data from raingauges and river stage gauges located at key points in the catchment. Stage forecasts are traditionally made using physical models, but these large-scale systems have not proved to be accurate enough to provide timely flood warnings. Artificial neural networks (ANNs) provide an alternative modelling technology for building flood forecasting models. Artificial neural network software has been developed and installed for operational use by the Environment Agency in Northumbria, UK. This chapter describes its use in practice and compares the results using two feedforward neural network algorithms. Results from three experiments on three different sizes of catchment are compared. Overall the results suggest that ANNs are useful for operational purposes and represent an improvement over ARMA and regression modelling schemes.

18.1 Introduction

There is a continuing risk of flooding in the UK from rivers and from the sea. Some five million people live in two million properties that are situated in flood risk areas in England and Wales. Although there are over 36 000 kilometres of flood defences, the risk of flooding is too low in some areas for further physical defences to be considered cost effective. Therefore, timely flood warnings are required to give businesses and residents the opportunity to protect themselves and their properties. This

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

requires real-time forecasting models to be in place which are capable of providing accurate river stage forecasts. Stage is the depth of flow above the river bed which is then used to calculate flow rates and volumes. The UK Environment Agency is responsible for providing flood warning services on main river channels, and they, in conjunction with DEFRA and local and regional authorities, are responsible for giving advice to planners.

Forecasting river stage has proved problematic. There are many examples of the continuing development of statistical and deterministic models but accuracy and reliability remain issues in a forecasting area where the events of primary interest, i.e., extreme floods, are infrequent and non-linear (Cameron *et al.*, 2000; Horritt and Bates, 2001; Mellor *et al.*, 2000; Stewart *et al.*, 1999). Artificial neural networks (ANNs) provide a potentially useful alternative to traditional flood forecasting approaches with rapid development times relative to large-scale physical models. ANNs are biologically inspired computational models that map a set of inputs, in this case rainfall and river stage data, to a set of outputs, such as river stage at downstream stations. The network achieves this task by learning the patterns in an historical dataset through a training or calibration process. Once trained the neural network can be utilised in a predictive capacity with unseen, independent input data and tested for accuracy using independent validation data. The results should be reliable provided the training dataset is representative of all the relationships being modelled, which is always an issue with flood forecasting. The largest flood event may be the next one and occur tomorrow.

There are many opportunities for neural network use in hydrology, and its application is becoming increasingly widespread (Dawson and Wilby, 2001). River stage forecasting is just one hydrological situation where ANNs are being adopted, as exemplified by Abrahart *et al.* (2001), Campolo *et al.* (1999), Chang and Hwang (1999), Dawson and Wilby (1998), Golob *et al.* (1998), Openshaw *et al.* (1998) and See and Openshaw (1999, 2000). In an early study, Hsu *et al.* (1995) showed that the non-linear ANN model provided a better representation of the rainfall–runoff relationship of the medium size Leaf River basin near Collins, Mississippi than the linear ARMAX (AutoRegression Moving Average with eXogenous inputs) time-series approach or the conceptual SAC-SMA (Sacramento Soil Moisture Accounting) model. They acknowledged one key difference in modelling philosophy; ANNs do not provide models that have physically realistic components and parameters and so are no substitute for conceptual watershed modelling. But they point out that ANNs provide a viable and effective alternative to the ARMAX time-series approach for developing input–output simulation and forecasting models in situations that do not require modelling of the internal structure of the watershed. In forecasting river stage there is no absolute requirement for physically realistic variables or mirroring of the catchment structure. Thus, ANNs are particularly useful as forecasting tools in situations where the relationships between the key variables are non-linear or cannot be adequately described by dynamic equations, or where the data are limited and more complex process models cannot be adequately calibrated.

Elsewhere in hydrology ANNs have been used to forecast water quality: phosphorus levels in 927 catchments across the USA (Omernik, 1997), river pH (Moatar *et al.*, 1999), Cryptosporidium and Giardia concentrations (Neelakantan *et al.*, 2001) and PAHs in water samples (Cancilla and Fang, 1996). Other examples include the

prediction of fish numbers and habitat preferences in rivers (Lek and Baran, 1997; Mastrorillo *et al.*, 1997; Gozlan *et al.*, 1999) and algal numbers by Maier *et al.* (1998), Recknagel *et al*. (1997) and Whitehead *et al.* (1997).

While the range of hydrological applications using ANNs is encouraging, there is a pressing need to trial models cited in the literature, many of which are implementations in experimental or historical mode, to operational real-time settings. This work represents one of the first attempts at making this technology transfer. This chapter describes the development and application of operational neural network flood forecasting software, which was undertaken in collaboration with the Northumbria office of the UK Environment Agency (EA). Neural network theory and a description of the software tools are provided. Three case studies illustrating the application of the software highlight the ability of the networks to forecast events from limited records and beyond the range of the training data. Models were built using data from a seven-month winter period and tested using data from three further periods of continuous river stage data. The results were also compared with more conventional statistical models, multiple linear regression and autoregressive moving average models (ARMA).

18.2 Client Requirements

River stage forecasting, whether for engineering design or flood warning purposes, is one element in a wider hydrological modelling framework (Figure 18.1). A forecasting model sits between the data sources and a decision-making process. Although hydrological modelling has been developing since the 1920s, and numerical modelling has brought major advances since the 1960s, the accuracy of results is not yet satisfactory. Flood forecasting systems in current use are generally based on either distributed modelling ideas or on mass transport equations, which essentially move blocks of water down the river (HEC-RAS, 2001; ISIS, 2001; MIKE 11, 2001; NOAH 1D, 2001; RFFS, 2001; SSIIM, 1997; van Kalken *et al.*, 2001). The complexity of natural systems and the number of processes that continuously interact to influence river levels make traditional modelling based on mirroring natural processes with process-based equations very difficult. Where processes can be modelled numerically, there are constraints imposed by the spatial availability of data and the cost of collecting this data in real time.

Any modelling system is a considerable financial issue for an agency or company. Investment is required in the numerical model, the acquisition of historic and real-time input data and trained analysts to interpret the results. For real-time forecasting this involves a team of analysts available 24 hours a day, to interpret results and implement flood-warning procedures. Once a forecasting system is established within an organisation, moving to alternative systems will only happen if there are seen to be clear advantages, preferably in both financial and forecast accuracy. The cost of moving to a new system and the different modelling approach of ANNs are barriers to the acceptance of the technology.

At present the EA uses a number of conventional hydrological models. In a report, Marshall (1996) stated that 'the development/calibration of the models has, with few exceptions, not yet reached the stage where warnings can be reliably based on the

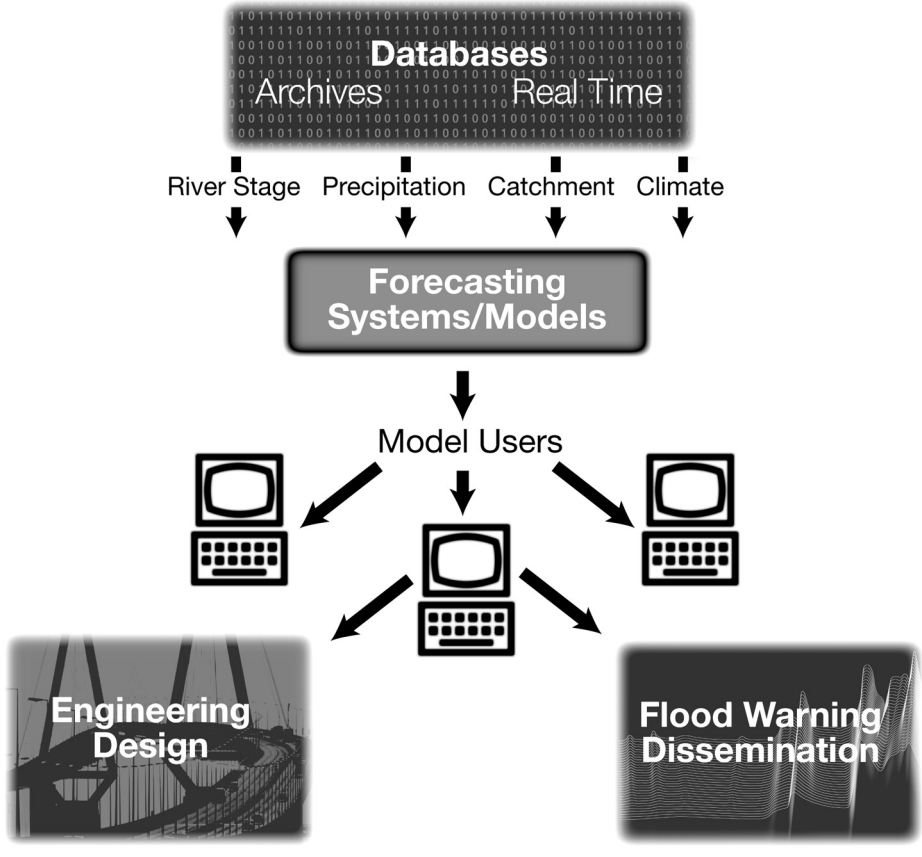

Figure 18.1 *Generalised framework for hydrological forecasting*

forecasts produced. The systems provide considerable help to duty officers by collecting, processing and displaying telemetry and radar data on a region-wide basis, but their operational performance as forecasting systems cannot yet be measured' (p. 7). Although none of the models in the regional offices were considered fit for operational purposes they are still in use at present. This leaves a gap in the market for alternative technologies that have the potential to provide affordable, accurate forecasting that is operationally straightforward. The neural network software developed for the EA represents an initial attempt to fill this market gap.

18.3 Methodology and Software Tools

18.3.1 Artificial Neural Networks

The basics of ANNs are discussed in detail by many authors (see e.g., Bishop, 1995; Gurney, 1997; Haykin, 1998); only a brief description is therefore provided here.

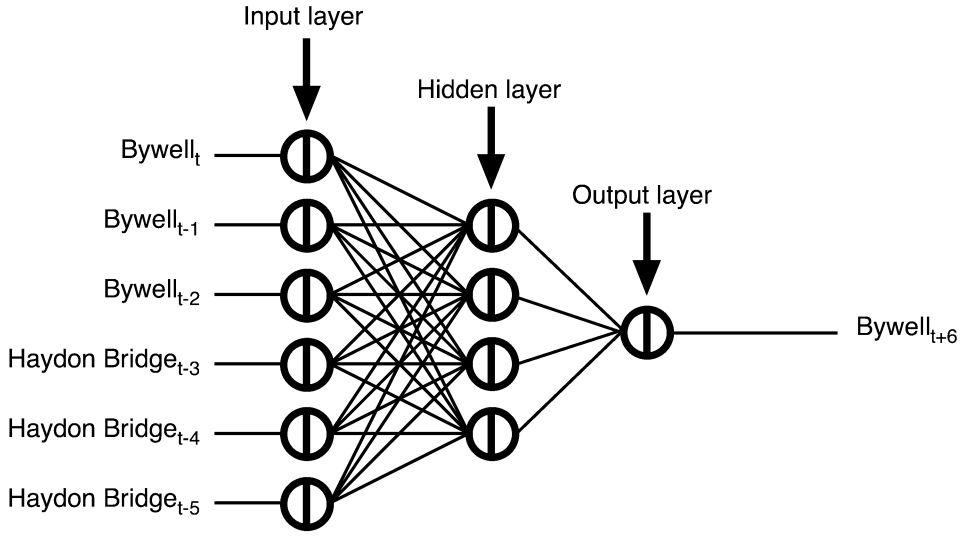

Figure 18.2 *Basic structure of a neural network*

ANNs perform a mapping of inputs to outputs via a series of simple processing nodes or neurons. The ability to map a function is derived via the configuration of these neurons into a set of weighted, interconnected layers as shown diagrammatically in Figure 18.2, where the neurons in the first and last layers have a one-to-one correspondence to the input and output values, respectively. Bywell and Haydon Bridge are two of the stage gauging stations on the River Tyne. Bywell is the lowest gauge on the non-tidal river where a forecast is required, and Haydon Bridge is upstream on the tributary River South Tyne (Figure 18.3). In this neural network mapping, the inputs are river stage at the two stations at the current time t, and t_{-1}, an hour before, and t_{-2}, two hours before. The inputs can be any combination of variables that are thought to be important for predicting the output for a specific case, in this case river levels at the forecast and upstream stations and rainfall would be appropriate. Thus, ANNs are capable of incorporating a large number of variables in a flexible manner. The input layer is connected to the hidden layer, which is further connected to the output layer where the forecast is produced. It is the programme-defined weights that are updated in the network learning phase (Beale and Jackson, 1990).

The task of any neuron, k, is to integrate the n inputs, x_i, from an external source or from other neurons within the network as follows:

$$S_k = \sum_{i=1}^{n} w_{ik} x_i \tag{18.1}$$

where w_{ik} are the weights between neurons i and k, and S_k is the sum of the weighted inputs. The neuron then further processes this sum via an activation function, such as the sigmoid:

$$f(x) = \frac{1}{1 + e^{-S_k}} \tag{18.2}$$

To learn the relationships in the data the network is trained by iteratively adjusting the network weights in such a way that the network converges to an acceptable solution. Developed by Rumelhart and McClelland (1986), backpropagation is the first reliable algorithm for achieving this task and its development represented a major historical breakthrough in neural network research.

Backpropagation is a variation of the gradient descent optimisation algorithm. It is also known as the generalised delta rule for weight updating and is given by the following equation:

$$\Delta w = -\eta g \tag{18.3}$$

where η is a learning rate parameter greater than zero. The gradient, g, is calculated in two passes through the network. In the forward pass, the network output for pattern p is calculated. The error between the calculated output, x_k, and the desired value, z_k, is defined as:

$$E_p = \sum_k (x_k - z_k)^2 \tag{18.4}$$

In the backward pass, the partial error associated with the pattern is backpropagated through the network to update the weights. Weight updating can take place after each pattern or after each training cycle in which all the patterns are presented to the network. The network is trained until a stopping criterion has been satisfied such as an increase in error in the validation data set. When this situation occurs, further training will result in an overtrained network and an inability to generalise to independent data. The backpropagation training algorithm can be slow to converge so a momentum term can be added to the weight update equation to speed up the training process (Bishop, 1995).

A second, faster training algorithm incorporated into the forecasting software is Quickprop, developed by Fahlman (1988). In contrast to backpropagation, Quickprop is a second-order method because it uses information provided by the second derivative of the error surface to take larger steps down the gradient of the error function. The method assumes that the shape of the error surface is parabolic and it tries to move from the current position to the minimum of the parabola at each step. Quickprop computes the derivatives in the direction of each weight; firstly, the gradient is computed with regular backpropagation and then a direct step to the error minimum is attempted. The weights are updated as follows:

$$\Delta w(t) = \frac{g(t)}{g(t-1) - g(t)} \Delta w(t-1) \tag{18.5}$$

where $g(t)$ is the partial derivative of the error function at the current time step and $g(t - 1)$ is the last partial derivative.

Despite significant computational and methodological advances, there are fundamental problems involved in the selection of an optimal neural network architecture. As Abrahart *et al.* (1999) show, the choice of algorithm is a subject of lively debate. To simplify the choice of algorithms, only backpropagation and Quickprop are currently incorporated into the flood forecasting software developed for the EA, as outlined in the next section. The networks are also provided with default settings so that the users can apply the software with minimal knowledge of ANNs. In the future, additional algorithms will be built into the software.

18.3.2 Description of the Neural Network Software

The PC-based neural network model was developed for operational flood forecasting purposes by the University of Leeds and implemented by the Northumbria Environment Agency's flood defence and water resources department in December 1999 (Kneale and See, 1999; Kneale *et al.*, 2000a and b).

The software was designed so that the EA operators can develop and maintain their neural network models independently. It is written in Visual BASIC v.6 as a standalone program. The program can either use historical or real-time rainfall and stage data to forecast stage, and was programmed so that the EA staff could use it with data for any of the main rivers in the Northumbria region. The interface is designed to be user friendly. It contains a series of interactive lists that guide the operator through each stage of the forecasting procedure. There are three main components: an interface for specifying the data, a neural network component and a graphing feature.

The Data Component

The data interface provides a diagrammatic river network which permits the user to specify the forecasting station, the forecasting time horizon, station inputs to the network and the location of data files. A list of steps is provided on the right-hand side of the screen to guide the user through the process. Once the input data and files are specified, the user can build a training data set for the network. The following functions are available within the data component:

- *Data pre-processing*: There are two processes: (a) creation of hourly averages from the 15-minute stage data available from the historic records as used here, but some users might choose (b) first-order differencing of the data series prior to building the training data set in order to render it stationary.
- *Station selection and forecasting horizon*: The forecasting station is selected along with the forecasting horizon, ranging from 1 to 24 hours.
- *Build the training data set*: This function builds the training dataset from each of the station inputs specified by the user.
- *Travel time specification*: This allows the user to change the average travel times between stations.

The Neural Network Component

The neural network component allows the user to set up a neural network, choose an algorithm and specify training parameters. The trained network can be saved to a file or loaded and used to make forecasts. The functions available within the neural network component include the ability to:

- *Configure the network*: Specify the number of inputs and hidden nodes. Set training parameters if defaults are not desired. Choose one of two available network training algorithms: backpropagation or Quickprop.
- *Specify data set*: Indicate the name of the training or testing data set.
- *Select mode*: Real-time operational forecasting or training on historic data.
- *Train the network*: Train the network for the number of iterations specified by the user.
- *View the network performance*: Examine the training or testing statistics.
- *Save/load a network*: Save the trained net or load an existing one.
- *Forecast stage*: Use a trained network to forecast the stage at the user specified station.

As mentioned previously, the software has two neural network algorithms: standard backpropagation (Beale and Jackson, 1990) and Quickprop (Fahlman, 1988). In practice a researcher exploring the use of neural nets will look at alternative algorithms and choose the one which is most efficient for each investigation. Including two algorithms gives users the opportunity to experiment with different solutions and explore relative performance accuracy.

The Graphing Component

The graphing component provides the user with an interface to graph any input data set or to view network forecasts on a historical or real-time basis. The results required for hydrologists are a graph of the actual and forecast stage in metres on a common time frame. In some hydrological modelling the forecasting procedure checks the actual stage against the forecast value and then calculates the next step ahead based on the updated, real stage. In ANN modelling there is no step ahead updating, the forecast is continuous.

18.3.3 Use of the Software

There are two main ways to use the software. In the first mode, a single model is created with a set forecasting horizon. For example, networks can be built to predict river stage from 1 hour ahead up to 24 hours ahead. Predictions are always made from t_0 to produce a single forecast x hours ahead, where x is the forecasting horizon chosen by the user. To produce a continuous set of forecasts at three-hour intervals, for example, the user would need to build eight networks with increasing forecasting horizons. The second use is the more conventional forecasting model in which

a single network is created with a short forecasting horizon, such as 1 hour, and stage and rainfall information are used to produce continuous forecasts over the next 24 hours.

It is important to recognise that a neural network must be developed for each specified forecasting station, so errors are not propagated downstream as occurs in a flow routing model. The programmes do not use any of the forecasted information as inputs to create additional forecasts. All the graphs in this chapter are validation forecasts created using independent data, and there is no step updating and correction as one would expect in a conventional hydrological forecasting model. In real-time operation the model can be run to make a new forecast every 15 minutes or whenever further real-time stage or rainfall data become available. The neural network forecasting model runs in seconds and can be retrained with new data in minutes. The retraining time is governed entirely by the time taken to access the real-time input data. It has the potential to be a very useful operational forecasting tool.

18.4 Case Studies

18.4.1 Background

The Tyne catchment in Northumberland, north east England, UK, has two main channels: the North and South Tyne. The River Nent and the East and West River Allens are important, ungauged lateral inflows (Figure 18.3). The underlying geology of the catchment largely consists of Carboniferous limestone and Millstone Grit. The Pennine upper reaches respond very quickly to rainfall inputs, the time between rainfall and rising river stage can be minutes. There is an approximate lag time of 4 hours between the raingauge at Alston and the river gauging station at Haydon Bridge. Flood alerts are often issued to the flood-risk areas along the river. Bywell is the lowest non-tidal gauging station on the River Tyne.

In these examples forecasts of stage are made for flood events at Alston, Haydon Bridge and at Bywell. Two types of forecasting are undertaken: event-based and continuous. Event-based forecasting involves extracting flood events from the historical record and using these small datasets to develop neural network models. Continuous forecasting uses a dataset over a continuous time period such as the winter period. Alston and Bywell are used to assess the value of ANNs for event-based forecasting using different forecasting conditions. Alston is a good example of a flashy headwater catchment where runoff starts at almost the same time as it rains. Bywell is a lowland station downstream from the North and South Tyne confluence. It is critical in providing flood warnings for Newcastle upon Tyne. In the experiment using Bywell, stage is forecast using only data from stations on the River South Tyne. Haydon Bridge is used for long-term forecasting based on continuous input data rather than individual events from the training record.

For the event forecasts the digital river stage archives (1985–2000) were searched to find the highest stage events at the input stations and Bywell. For the Alston experiments the input data were stage at Alston and rainfall at the Alston raingauge. For the Bywell forecasts, data from Haydon Bridge, Featherstone, Alston and the

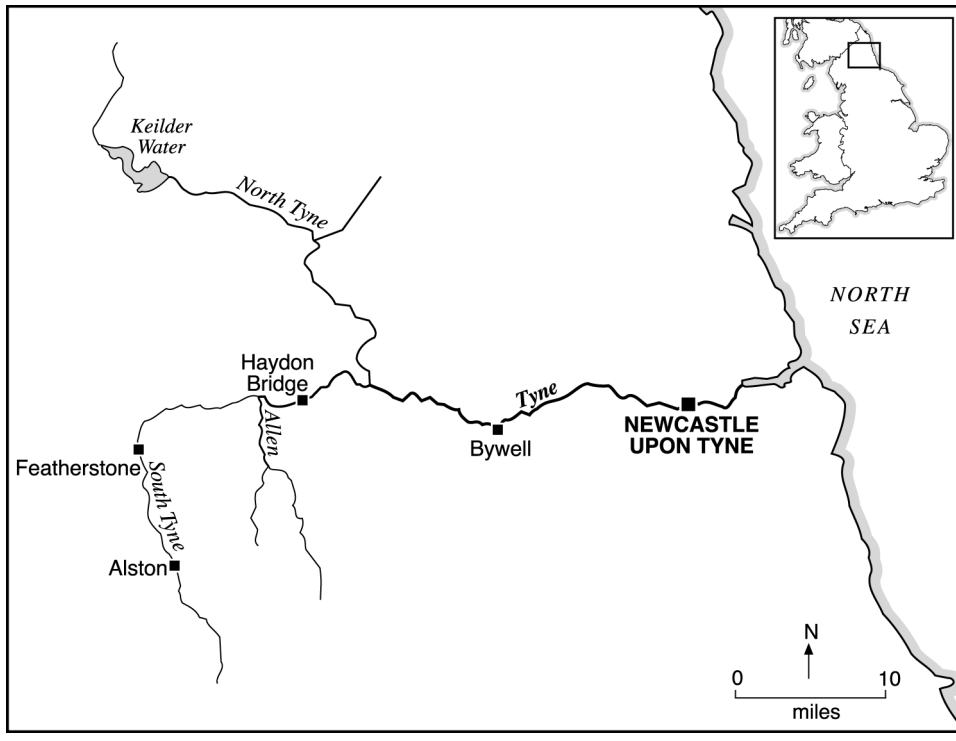

Figure 18.3 *Map of the catchment*

raingauge at Alston were used. In each case the 11 largest events were ranked. The odd-numbered events were used as the training series and the even-numbered events used for independent model validation. Networks were generated using both the backpropagation and Quickprop methods and for various lead times and training epochs (number of training iterations). The limited size of the event training data sets was deliberate to see how well the forecasts were made with small datasets.

For the long-term continuous forecasts at Haydon Bridge, the input data were stage at Haydon Bridge, Featherstone, Alston and the raingauge at Alston. Again backpropagation and Quickprop routines were compared.

Evaluation of the accuracy of forecasts by hydrologists is problematic. There is no single statistic that is uniquely helpful, primarily because the data of interest is frequently the rare high flow events in the record. For real-time on-line forecasting eyeballing the forecast stage is crucial, but where longer records are available statistical methods, root mean square error (RMSE) and the Nash and Sutcliffe (1970) index are standard hydrological procedures (Cameron *et al.*, 2002; Legates and McCabe, 1999). In addition to these measures we look at the accuracy of forecasts with respect to the real warning times which operators use on this river to notify the public of a flood event.

18.4.2 Event Forecasting for Alston

Alston is the headwater gauging station on the River South Tyne. It is a Pennine, upland moorland and rural catchment, with very flashy runoff patterns. The hydrographs (graphical representation of changing stage on a river) rise and fall within hours as water runs rapidly from the hillside to the river. In this type of catchment flood warning times are very short so any increase in warning capability is an advantage. For the EA flood warning team, the accuracy in forecasting the peak is not as significant as having a good forecast of the rising limb which triggers flood warning actions downstream.

A series of experiments have been undertaken using the approach outlined above, i.e., the flood events were extracted and ranked, the networks were trained on the odd-numbered events and validated on the even-numbered events, using both backpropagation and Quickprop algorithms to produce forecasts for 1 and 2 hours ahead. Two further variations were introduced. In the first case, models were developed to forecast stage at Alston using the stage data alone. In the second case, both the stage data and the rainfall records from a continuously recording, 'tipping bucket' gauge nearby, were input to the model.

The results showed that adding information from the raingauge significantly improved the forecast timing in this flashy catchment. Where a forecast is made using the gauging station data alone, the network cannot forecast a rise in stage until it observes a rise in stage, so the forecast of rise is delayed by at least the time step used in the calculations. The earlier inputs from the raingauge kick-start the forecast rise in river level. Examples of validation forecasts on the largest event in the record (Figure 18.4a) and a more typical event (Figure 18.4b) illustrate the forecasting ability of the networks. In these examples, the data resolution is 1 hour but these forecasts could be improved by using 15-minute stage and rainfall input data.

Similar results were also obtained in a parallel study for Kilgram, a comparable flashy Pennine station on the River Ure in the headwaters of the Yorkshire Ouse system. At both Alston and Kilgram, the Quickprop algorithm performs slightly better than backpropagation. While the peak is not always hit precisely, the warning levels on the rising limb were either hit on time or hit slightly ahead of time. This is an advantage because the sooner a warning can be given the longer local people have to respond. In future work, including rainfall data from real-time radar images could improve the quality of flood forecasts.

These results suggest that ANNs can be useful in flashy headwater areas with short response times and if further raingauge data are available, possibly from adjacent catchments, that could also improve the forecast. They also indicate that where data are limited, as in this example where only seven flood events were used in the training series, a neural network can provide a useful forecast.

18.4.3 Event Forecasting for Bywell

Two contrasting approaches were taken in this case study. Firstly, as in the Alston experiment, the highest 11 stage events for which there are data at the four input

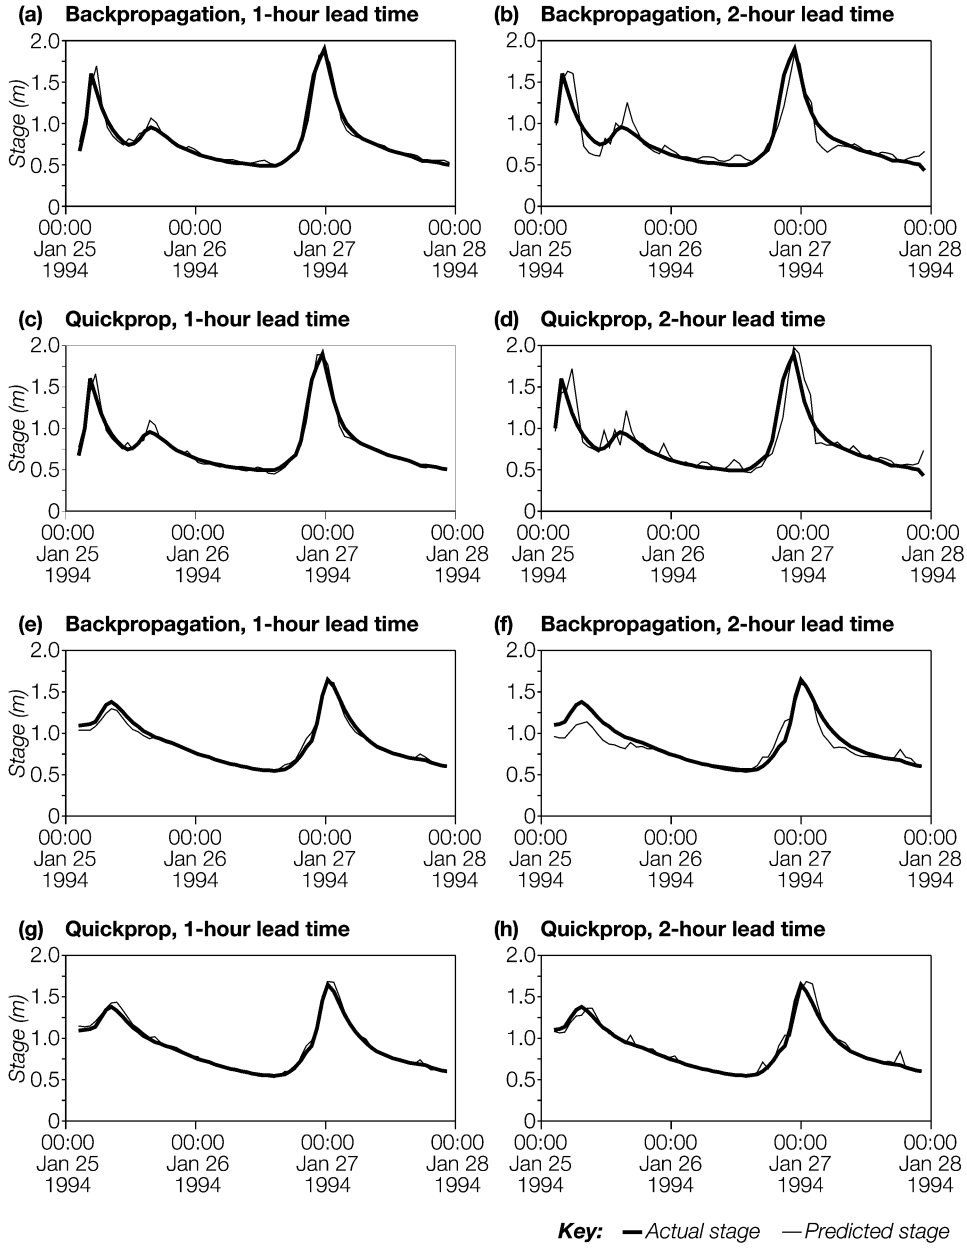

Figure 18.4 *Validation forecasts for events 1 (a–d) and 2 (e–h) at the Alston stage gauge, using stage at Alston and the raingauge data from Alston as inputs, and trained for 3000 epochs using the odd events*

stations and Bywell were ranked. The odd-numbered events were used as the training series and the even-numbered events were used for independent model validation using both the backpropagation and Quickprop methods for 1 and 2 hour lead times. The first flood warning alarm stage at Bywell is 3.5 m.

The peak forecast for the largest event in the record is acceptably modelled in both shape and timing (Figure 18.5a and b). The 3.5 m warning stage is forecast more accurately by the backpropagation algorithm for both 1 and 2 hours ahead. The lowest event on record (Figure 18.5b) is, by contrast, overpredicted at the peak and the warning times are forecast up to a couple of hours early. This may be in part due to the slower travel times of lower flood peaks down to Bywell and that this was the lowest event in the validation record. However, this peak height would not cause a flooding problem in the catchment.

This experiment was then extended to develop models for a longer lead time, i.e., 6 hours. However, the results proved less than satisfactory. The peaks and total runoff were underestimated and the forecast time of rise was delayed by 2 hours. While the hydrograph shape was correct, this model is operationally less useful, although under extreme circumstances it may be better than nothing. The fast response time of the catchment, where travel from Alston to Bywell is of the order of 6 hours, means that looking from 6 hours out there has not been enough significant rainfall and rise in stage to indicate that a significant storm runoff could be expected. The Quickprop algorithm performed better than backpropagation here. Under normal forecasting circumstances the network would be created using stations on both main rivers and from the reservoir at Kielder. If forecasts of this type are to be valuable then experiments that look at the radar rainfall in adjacent catchments should be integrated with the neural network data to provide longer lead time warnings.

In the second approach the event data were used to see how the neural network models would handle flood event data outside the training envelope. The critical question here is can neural nets cope when asked to model stage patterns that are higher or lower than the data used to develop the model? In this experiment the challenge is greater in that the model is given no guidance from stage levels at Bywell itself, or from the whole of the North Tyne system. The three highest flood events were excluded from the training series. The neural network was generated on events ranked 4–11 and used to forecast stage at Bywell for the three unseen events. Results for the third largest and largest unseen events are shown in Figure 18.6a and b. The training data has peaks ranging from 3.05 to 4.57 metres. The validation forecasts are for events peaking at 4.75–5.88 metres.

Encouragingly, Figure 18.6a shows a good forecast of both peak and timing for an event with stage 18 cm higher than seen in the training set. For the highest event on record with a peak of 5.88 metres, and without knowledge of the North Tyne inputs which contribute 40–50% of the stage, the forecast is very respectable for the rising limb but not surprisingly in three of the four forecasts underestimates the peak (Figure 18.6b). The results suggest that the network can cope with forecasting rising limb responses for extreme stage events. The accuracy of the peak and the modelling of alarm levels would seem to be appropriate for routine forecasters' purposes.

In modelling terms, it was to be expected that given a limited number of flood events and a situation where the validation data are outside the range of the

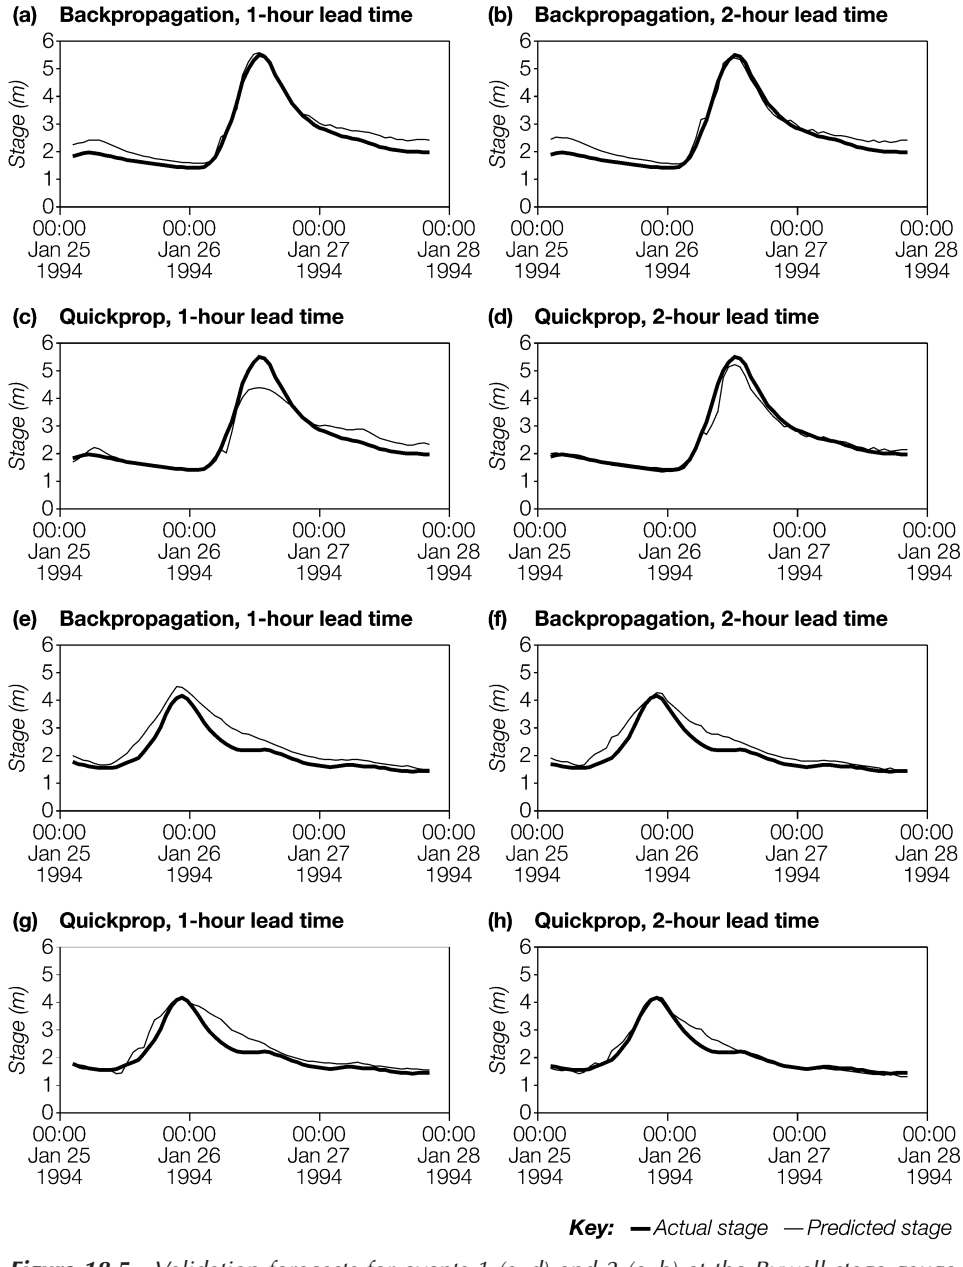

Figure 18.5 *Validation forecasts for events 1 (a–d) and 2 (e–h) at the Bywell stage gauge, using stage at Alston, Featherstone and Haydon Bridge and the raingauge data from Alston as inputs, and trained for 3000 epochs using the odd events*

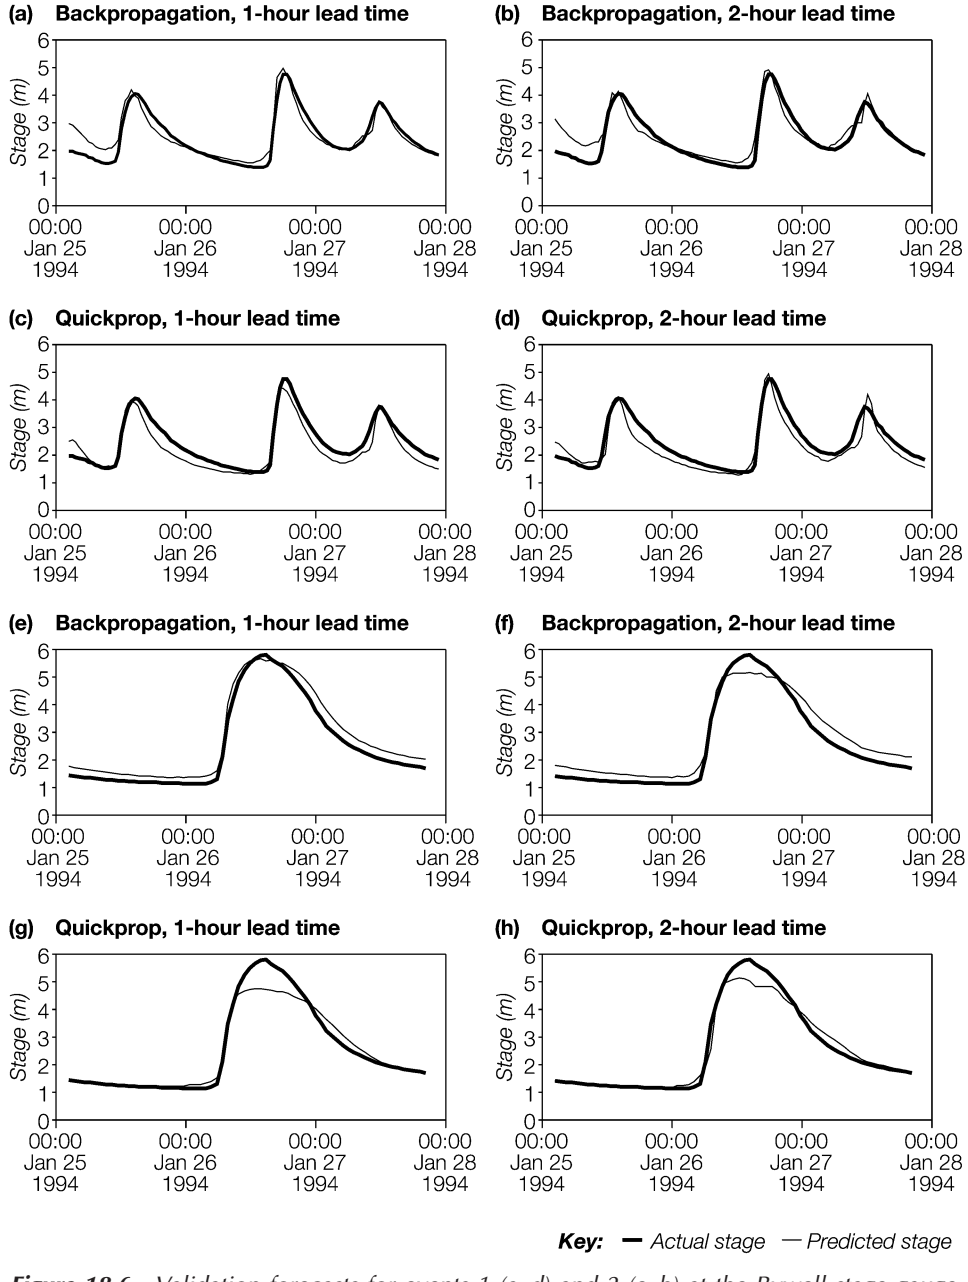

Figure 18.6 *Validation forecasts for events 1 (a–d) and 2 (e–h) at the Bywell stage gauge, using stage at Alston, Featherstone and Haydon Bridge and the raingauge data from Alston as inputs, and trained for 3000 epochs with the events ranked 4–11*

training data set that the model would underpredict very high events (Figure 18.6b) and overpredict a low event (Figure 18.5b). Ideally models would be developed with longer training sets, but where new gauging stations are installed and records are short, these results indicate that neural network models are useful even with limited data.

18.4.4 Continuous Forecasting for Haydon Bridge

In this set of experiments, models were developed to forecast river levels at Haydon Bridge. The inputs used were stage at Haydon Bridge and Featherstone, and stage and rainfall at Alston. The ANNs were trained for 3000 epochs using both the back-propagation and Quickprop algorithms, various experiments having shown that there was minimal improvement in the networks' ability to forecast at larger numbers of epochs. The networks were trained on data from October to April of 1996–97 and validated using data for October to April of 1994–95, 1995–96 and 1997–98. Table 18.1 shows the summary evaluation statistics for all four years for the two ANNs. The networks are compared with results from models developed using multiple linear regression and ARMA (AutoRegressive Moving Average) techniques.

The Nash–Sutcliffe and R^2 statistics are encouragingly high for the neural network models. The multiple linear regression and ARMA models do slightly less well. RMSE values, indicating the absolute error in stage between the actual and forecast levels, are of the order of centimetres for all models. Quickprop produces the best model followed by backpropagation, multiple linear regression and then the ARMA model.

Table 18.1 *Evaluation measures for long-term calibration of neural networks, multiple linear regression and ARMA models*

Note: *Forecast did not reach the operational stage at all.

Table 18.1 summarises the results for the entire seven-month winter series, but in event forecasting the accuracy with which the networks predict the operational alarm stage of 2.0 m on the rising limb of the hydrograph is also very important; Table 18.2 details the results from 17 independent, validation events. The Quickprop neural network proved to be the most accurate of the four models in terms of predicting the timing of the alarm levels. The ARMA model consistently predicted the operational stage 2 to 3 hours late.

These results show that the multiple linear regression model did not reach the alarm levels on eight of the 17 events and was generally 2 hours late at other times.

If there were no significant inputs between the gauging stations then one might expect a linear relationship between stage at Featherstone and Haydon Bridge, and a linear routing model or regression equation should work well. However, the River Allens join the Tyne between Featherstone and Haydon Bridge, as does the River Nent just downstream of Alston adding significantly to the discharge. The ability of ANNs to handle non-linearities, for example from ungauged tributaries, is its strength over alternative linear approaches.

In addition to improved accuracy, a clear advantage of the neural network software is that model development times are rapid, even over a long continuous time series. In these experiments the training runs took approximately 12 minutes for 3000 epochs, and validation of the models with the three years of winter data was virtually instantaneous. Multiple linear regression equations were also very fast to develop but their use appears to be limited. The ARMA models, on the other hand, required a great deal of experimentation and the results were not very satisfactory.

18.5 Conclusions

The incidence of river flooding is increasing and forecasts of global warming indicate that this trend is likely to continue. Building new flood defences to contain higher flows, defending vulnerable sites and domestic and commercial insurance claims all have serious financial implications. Accurate forecasting systems are required for real-time day-to-day emergency forecasting and for the planning and design of new defences. ANNs are flexible mathematical structures capable of identifying complex non-linear relationships between input and output data sets. Their use in hydrological forecasting is still very new but it has been shown here that they can provide a viable alternative approach to statistical models.

This software has been in use since December 1999. Operators report that it is easy to use and straightforward to manage in both training and real-time operations. The experiments described here are designed to test the system response given difficult hydrological conditions with the emphasis on testing to see whether the alarm levels on the rising limb of the hydrograph can be satisfactorily forecast. The results would give the operators time to generate warnings at the first alarm stages.

Efficient use of a neural network model requires a model trainer who builds appropriate networks and selects the best algorithm. To find the lowest error solution may take many runs, but training runs are quick to do, typically less than 10 minutes per run. Given this high operational speed, a series of experiments can be defined to ensure that alternative algorithms and stage regime models are fully investigated. Forecasters can therefore make a mature selection of networks for operational use on the basis of wide experience. Real-time forecasts with established networks are effectively instantaneous once the data are downloaded. Forecasters must therefore take the time to investigate the effects of model architecture to ensure the validity of the results. However, having established a suite of models for operational use, these may be used in the flood room by additional operators after a short period of training (one day at most). Moreover, the experience with the software to date indicates

that it is a viable technology that should be considered as an additional tool for hydrological forecasting.

The software was developed in response to a growing demand for user-friendly access to ANNs but integrated within a single, user-customised software environment. These approaches are already used commercially in areas such as database mining and financial market prediction, but this software represents the first commercially available, operational hydrological forecasting tool that allows for the development of river stage forecasting models. In addition to incorporating other neural network algorithms, it is envisaged that the software will eventually be linked to a GIS in order that forecasters can visualise the flood wave as it travels down the catchment, both from a plan and a 3-D perspective. The spatial element will also allow forecasters to calculate flood inundation. The potential for constructing spatial decision support systems that incorporate the expert knowledge that is currently embedded in human forecasters remains an exciting area for future development.

Undertaking Applied GIS and Spatial Analysis Research in an Academic Context

Robin Flowerdew and John Stillwell

Abstract

This is the final chapter in a book that has aimed to demonstrate the utility of applying quantitative methods to solve real-world problems in human geography. The collection clearly exemplifies the wide range of applications and flags up the potential for future endeavour. Yet doing applied research within the confines of an academic environment is neither easy nor straightforward. This chapter concludes the book by describing the setting and some of the applied quantitative work done at the North West Regional Research Laboratory and at the Yorkshire and Humberside Regional Research Observatory during the 1990s. Some of the constraints under which the organisations operate are discussed, along with more detailed examples of four applied projects. Finally, some comments are made on the future scope for commercial applications of geography and their implications for the discipline.

19.1 Introduction

The chapters contained in this volume have reported on a spectrum of applications of GIS, spatial analysis and geographical modelling for a variety of clients in a range of different contexts. Whilst certain contributions refer to projects undertaken by individuals working as consultants for companies in the private sector (such as PricewaterhouseCoopers, David Simmonds Consultancy) the majority of the applications have been undertaken by researchers employed by organisations created

Applied GIS and Spatial Analysis. Edited by J. Stillwell and G. Clarke

within their universities specifically to provide an environment in which applied research can flourish (such as CURDS, Nexpri, SERRL), or by academics working from within their respective university departments. These university-based studies reflect the extent to which 'applied geography' has emerged within the discipline of geography and how quantitative and computer-based approaches have been at the forefront of this development over the last 20 years in particular.

In the sections of this chapter that follow, we concentrate on three aspects of applied research. Firstly, we review the rationale and structure of two different institutional models for applied research established in neighbouring regions in the north of England, the North West Regional Research Laboratory (NWRRL) and the Yorkshire and Humberside Regional Research Observatory (ReRO). Secondly, the types of projects undertaken by each of these organisations are reviewed and selected GIS or spatial analysis-based applications are detailed for exemplification. Finally, based on our personal experiences of working for the NWRRL and ReRO respectively, we identify some of the major benefits arising from applied research but set these positive factors against a number of constraints or difficulties that have been associated with the conduct of this type of research.

19.2 New Regional Research Institutions for Applied GIS and Spatial Analysis

19.2.1 Introduction

Government funding for the social sciences, including human geography, comes via the Economic and Social Research Council (ESRC), renamed from the Social Sciences Research Council because of Government scepticism in the 1980s about their findings (which were often at variance with the underpinnings of Government policy). Then (and now) the ESRC received a tiny proportion of the total science budget, and had to argue its case to maintain this share. It saw its best chances of obtaining funding through emphasising that some parts of the social sciences were relevant to business and industry, and that social sciences too could adopt the technological 'laboratory' style of the physical sciences. GIS came along at just the right time and met the criteria. Arguably at least GIS was part of human geography and hence social science; requiring 'equipment' and 'laboratory facilities' (just like 'proper science'); seemingly objective and free from questions of values and interpretations; and with the potential to be relevant to a wide range of clients and 'customers'.

At the same time, the ESRC also attempted to exert more influence on the future of the social sciences, increasing the extent to which it decided what areas to put funding into, as opposed to merely being responsive to the ideas of practising social scientists. This was done through creating research initiatives or programmes, whose general topics were announced in advance with a request for proposals, several of which were to be funded. In addition to those proposals that were funded, this strategy had the effect of encouraging other research groups to think about the issues and

in some cases to appoint relevant staff. Unsuccessful ESRC research programme proposals have often been funded through other ESRC research money or by other funding agencies, so the research programme approach can be regarded as levering more research in the specified area than is actually funded.

19.2.2 The Regional Research Laboratories

It was in 1987, prior to the publication of the Chorley Report on the development of a national GIS policy, that the ESRC began the trial phase of its Regional Research Laboratory (RRL) initiative, moving in 1988 to the main phase. Eight RRLs were created in the main phase:

- the South East RRL (based at Birkbeck College London and the London School of Economics);
- the Midlands RRL (based at the Universities of Leicester and Loughborough);
- the North East RRL (based at the University of Newcastle upon Tyne);
- the North West RRL (based at Lancaster University);
- the Urban and Regional Policy Evaluation RRL (based at the Universities of Liverpool and Manchester);
- the Wales and South West RRL (based at the University of Wales Institute of Science and Technology and the South West Regional Computing Centre at the University of Bath);
- the Scottish RRL (based at the University of Edinburgh); and
- the Northern Ireland RRL (based at the University of Ulster).

In addition, the RRL initiative provided support for a Co-ordinator (Ian Masser, at the University of Sheffield) and a Technical Advisor (Mike Blakemore, at the University of Durham). The individual RRLs were constituted by a team of academics with permanent contracts with their universities, supplemented by appointed research staff. In five cases, the RRL was run by geographers, who also played a major role in a sixth, and people whose disciplinary affiliation was to geography, although sited in a planning department, dominated another. Over time, the composition of these RRLs has changed, as a result of moves of key people from one site to another and changes in degrees of involvement. Another trend was for the multi-site RRLs to split, so that the roles of the LSE, Loughborough and Bath diminished, and the Urban and Regional Policy Evaluation RRL split into two separate operations at Liverpool and Manchester. Other groups doing GIS research have also been granted 'RRL status', so groups from Glamorgan, Glasgow and York, among others, are part of RRL.net, the organisation that exists to coordinate the former RRLs in their post-ESRC situation.

The intention of the RRL Initiative was to provide resources for the groups receiving funding to allow them to become 'well-founded' laboratories for GIS work

(Masser, 1988). Money was provided for equipment and for staff, but the RRLs were always expected to become self-supporting through working on a commercial basis with clients in government and industry. At the end of the main RRL funding in 1991, the RRLs remained in existence but have followed different paths, some effectively disappearing while others have grown in size through a mixture of strategies.

There were always some ambiguities and contradictions in the roles that they were expected to play, reflected in part in the name. Part of the original idea was that each RRL would be particularly responsible for collecting and providing access to datasets about its own region, and for liaison with potential clients in that region. This function worked reasonably well in the RRLs with responsibility for Scotland, Wales and Northern Ireland, where there were government and commercial offices with devolved responsibilities with which they could work. The English RRLs, however, tended to work with datasets and organisations at the national level, and although they may have built up closer relationships with local government or other organisations in their own regions, their roles quickly became demarcated in terms of subject specialisation rather than region.

The term 'Research' also relates to an ambiguity in the role of the RRLs. The requirement to become self-supporting appeared to demand a concentration on commercial and consultancy work. However, the potential 'users' of the research, especially those from the private sector, were very concerned that the RRLs might become subsidised competitors for their own companies. Hence there was also a requirement on the RRLs to conduct basic research in GIS, which might lead to innovations that could be developed commercially by private sector organisations. Many or most of the RRLs applied successfully for GIS-related funding for what were clearly research projects, and indeed ESRC funded several projects in this general area, including a collaborative research programme with the Natural Environment Research Council (NERC).

It is clear that the RRL designation 'laboratory' was part of the ESRC's attempt to provide the social sciences with a more scientific image. Although RRL staff seldom wore white coats and handled test tubes, the RRLs did usually possess large rooms where several people worked together at a range of computers. For many in human geography this may have been a change from the model of the single scholar working in isolation in his or her own office with occasional trips to the library or archive. In the next section we outline the ReRO model which provided an alternative approach to bringing together academics from differing institutions to work together on applied projects.

19.2.3 The Yorkshire and Humberside Regional Research Observatory

No RRL status was awarded to a university in Yorkshire and Humberside. This was surprising given the large group of applied geographers at the University of Leeds and the international status of the modelling work carried out there under the leadership of Alan Wilson. In fact a consultancy business named GMAP had already been set up within the University and had begun to flourish, using spatial

interaction modelling to advise companies on locational decisions and building intelligent GIS (Clarke *et al*., 1995; Birkin *et al*., 1996). However, in 1990, separate from its commercial consulting activities under the GMAP banner, the Yorkshire and Humberside Regional Research Observatory (ReRO) was created to provide clients in the region with access to a region-wide data and analysis service.

Initially, ReRO was a joint venture between the School of Geography at the University of Leeds and the Centre for Urban Development and Environmental Management (CUDEM) at Leeds Polytechnic (later Leeds Metropolitan University). The aim was to create a network of research centres, or 'Associate Research Units' (ARUs) as they became known, each offering a range of skills and expertise in data collection and processing, problem-solving, strategy formulation and policy analysis. Such a network was regarded as being advantageous in that research teams might be assembled at relatively short notice from different ARUs with the skills and local knowledge required to respond to any particular request for research from the public or private sector. Two further units, the Policy Research Unit at Leeds Polytechnic, and GMAP Ltd, became part of the network at the outset and research units from other universities in the region joined the network subsequently, including the School of Geography and Earth Sciences at the University of Hull, the School of Social and Professional Studies at the University of Lincolnshire and Humberside, the Regional Office, University of Sheffield, the Policy Research Centre (PRC) and the Centre for Regional Economic and Social Research (CRESR) at Sheffield Hallam University, the Institute for Transport Studies at the University of Leeds as well as groups of researchers at the Universities of Bradford, Huddersfield and York. Thus, through its network of ARUs, the Observatory was able to bring together not only subject specialists with skills in data processing, spatial analysis and policy evaluation, for example, but also academics and researchers with a wealth of knowledge and understanding of their own local geographical areas, thus creating a rich base of experience and expertise and a unique resource with which to address the range of strategic, developmental and research issues related to Yorkshire and Humberside.

The general structure of ReRO (Figure 19.1) indicates that the ARUs represented the formal members and, through a Committee of Members, constituted the strategic development body for the Observatory through its annual meeting. ARUs paid an annual subscription for the benefits of being part of the research network. The executive function of the Observatory was managed through the Board of Directors consisting of five senior academics from the ARUs. The day-to-day management and operation was handled through the ReRO Office housed in the School of Geography. In the early 1990s, the Director was supported by a secretary, a research associate, a graphics design technician and a data manager, all of whom were appointed on a part-time basis.

Research Council funding was never secured by ReRO, whose staff, running and development costs were financed entirely from subscriptions from the member ARUs, overhead earnings (20%) from research contracts and consultancy work, sales of ReRO publications and a limited amount of sponsorship from companies such as Coopers & Lybrand Deloitte, Barclays Bank, Halifax Building Society and Northern Foods.

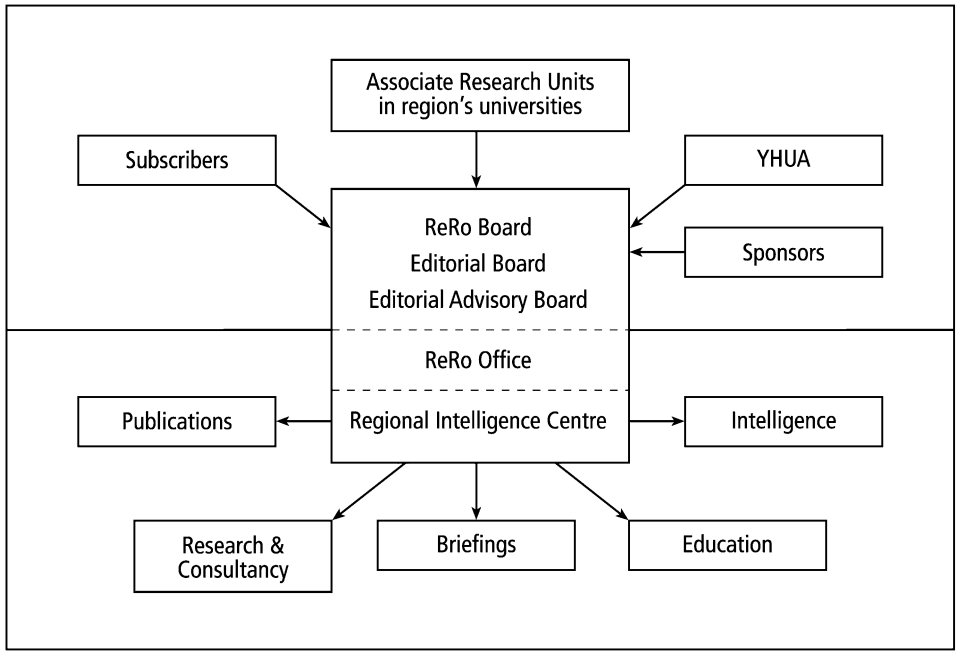

Figure 19.1 *The structure of the Yorkshire and Humberside ReRO*

19.3 Applied Research Activities

In the following two sub-sections, we discuss the range of research activities by the North West RRL and the Yorkshire and Humberside ReRO and present two more detailed examples of projects undertaken at each of the two centres.

19.3.1 Projects at the North West RRL

One very important category of research activity at the North West RRL has been the larger and longer term projects funded by research councils, some of which have been theoretical in nature. They are particularly valuable because they have tended to run for quite a long time, promoting financial stability and job security for the staff employed as researchers. They have usually brought in a substantial amount of money and should have led to opportunities for publication in the academic literature (though the need to chase the next project has sometimes meant that fewer papers reach publication than should be the case). Work in this area has been initiated by RRL staff and allows the RRL to build alliances with others around the university (or outside). The NWRRL has worked on projects involving spatial statistical models, areal interpolation and the modifiable areal unit problem. There have also been research council funded projects that have been more specific, such as evacuation modelling in the context of emergency planning.

In the more applied context, work has been done with Eurostat on GIS software for EU applications, with the European Environmental Agency on environmental databases, with the Home Office on developing GIS software for the Safer Cities Programme, and with the Department of Environment, Transport and the Regions (DETR) on pollution modelling using the critical loads approach. Much of the RRL's work, however, is made up of much smaller and shorter term projects, often based on the employment of relatively straightforward GIS capabilities for practical purposes. Such projects may only bring in a few hundred or thousand pounds, but are relatively simple to accomplish. A common type of project involves the mapping of data of various types, usually involving the conversion of unit postcodes to grid references. Sometimes the work involves aggregation of the data to areal units and production of choropleth maps. Another type of small project is the construction of a spatial database, for example the Lancaster Urban Archaeology Database which involved creating and linking georeferenced records for archaeological finds in the city of Lancaster. Sometimes the work is basically data analysis, not necessarily involving GIS skills. The RRL has also been asked to assist in the design of spatial sampling, involving the collection of data on household waste and the analysis of rural poverty among older people. Another frequent task has been to solve routing problems, for example through examining the extra travel distances or times if a particular facility is closed down or another one is opened. This type of analysis has been important in the study of health care and leisure facilities as well as commercial service delivery systems. A particularly important set of tasks has been the study of visibility, especially in relation to the location of wind farms, where the RRL has developed close links with a number of companies, providing technical expertise for planning enquiries as well as relevant information for siting issues.

Two examples of applied research provide an indication of some of the advantages and disadvantages of being an RRL in particular contexts. The first is an ESRC-funded project on using GIS to measure remoteness in the context of issues related to funding for public services, and the second is a large public financed project on the problems for North West England of changing demographic trends.

Remoteness of Services

This project was primarily academic rather than commercial, though its genesis was very much applied. The original beginning of interest in this area was a set of consultancy projects with local authorities relating to the Standard Spending Assessment (SSA) system. The latter was designed to provide a fair basis for central government to disburse funds to local government with the objective of providing standard levels of service across England. The formulae used were open to question on several grounds (Flowerdew *et al.*, 1994). In particular, several rural authorities felt that the SSA calculations did not adequately reflect the additional costs they incurred because of the time taken to deliver services to clients. The project was based on the idea that GIS provided a methodology for calculation of the actual distances that service deliverers would have to travel to reach the entire population. If assumptions were made about how service delivery centres were located, estimates of the costs in service delivery could be derived. Calculations of this type could be done for

all local authorities, on the basis of several sets of assumptions about the locations of service delivery points. These estimated costs could then be compared with existing allocations. The ESRC agreed to support the project, which employed one research assistant half time for a year.

In the event, the project suffered somewhat from being carried out alongside several other commercially funded projects. It was difficult for the researcher concerned to spend 50% time on this project when there were other shorter term projects requiring significant input to a tighter deadline. More pre-processing of data was required than anticipated before the calculations could be started, and the latter proved to be more time-consuming than expected. Although the availability of experienced staff may have been an advantage of being conducted within an RRL, the necessity of carrying out the work at the same time as other commercial projects proved to be a problem. A further problem arose in writing up the results of the project, which conflicted with the necessity for all staff members to proceed with tendering for new projects to maintain the RRL's income flow, and to carry out those projects for which tenders had been successful. This was exacerbated by the Research Council's policy of paying overheads at rates much lower than commercial ones. Such projects are still worth doing for an RRL, however, because they are worthwhile for the group's academic profile, even if they do not bring in much additional money.

Ageing Population

Another project undertaken by the RRL involved studying the implications of changing population structures for North West England. This project was sponsored by a consortium of regional-level bodies, including the North West Regional Assembly, the North West Development Agency, the Government Office for the North West, the National Health Service Executive North West and Age Concern. The main aims of the project were to produce population projections by age at the district level for the North West and to investigate the consequences of these projections for a range of economic, social, health and planning issues.

Population projections are available from the Office of National Statistics for the population as a whole until 2025. However, for the purposes of this project it was important to project conditions at the local level for a longer period, and also to project the populations at the local level for population subgroups, including ethnic groups and the disabled population. These projections raised a number of interesting academic issues as well as being highly relevant to policy questions. A crucial issue in the reliability of projections turned out to be the effect of students, whose migration behaviour, before and after moving away from home for higher education, is particularly difficult to estimate given available data (Simpson, 1995). It seems likely that the use of census data may underestimate student population in university cities and the use of National Health Service registration data may overestimate it. As a result, the methodology used in this context produced wildly disparate projections for places with large student populations.

Producing local-area projections by ethnic group and disability status also raised methodological issues. Arbitrary decisions had to be made to produce these

projections and the unavailability of all the desired data meant that simplifications and unrealistic assumptions were necessary. For example, it was difficult to make projections for places that had a very small population in one ethnic group but had experienced migration of ethnic group members in or out. If migration for the ethnic group was assumed to be proportional to the population of that ethnic group, this could result in a very rapid and totally unrealistic rise (or a rapid disappearance) in the numbers of that group. Accordingly, we assumed that the numbers of migrants rather than their proportion would remain constant. Whereas government has, quite understandably, refused so far to make projections by ethnic group, we felt constrained to produce the best projection we could, even though we knew it was unrealistic in several respects.

In any exercise of this nature, it is vital to draw a distinction between projection and forecast. The nature of a projection is that it is based on the continuation, in some sense, of current trends. This is quite unlikely in many situations and, in some cases, it is more than likely that an undesirable projection will generate some sort of policy response to prevent it actually coming true. Of course there are many other factors, predictable or otherwise, which will mean that the assumption of conditions remaining constant will not be accurate.

19.3.2 Applied Research through Partnership

In summary, ReRO developed a portfolio of activities that can be grouped broadly under five headings:

- research and consultancy: through the assembly of multi-institutional and multi-disciplinary teams;
- intelligence: through the interpretation and analysis of data rather than mere cataloguing of current data sources;
- education and training: through a European initiative to provide a pan-European course in training of regional managers;
- publication: through a regular journal, *The Regional Review*, and a periodic bulletin; and
- networking: both amongst its member ARUs but also with relevant bodies in the region and beyond.

The majority of these services are provided through collaboration between one or more of the ARUs and examples of research contracts are listed in Table 19.1. In most cases, the applied work was focused at the regional scale and was carried out at a time when the regional tier of agencies and administrative institutions was embryonic. Work has been commissioned by central government departments, national agencies, regional agencies, local government bodies, charitable organisations and private sector companies.

The view at ReRO was that urban and regional planning and policy-making had substantial needs for information and intelligence. Good regional data capture, maintenance and analysis were considered imperative as the basis upon which to

Table 19.1 *Examples of ReRO research contracts*

Title of research project	Funding body

Research into School Performance	Government Office for Yorkshire and the Humber
Developing a Strategic Framework for Yorkshire and Humberside: Review of Existing Policies and Strategies	The Regional Assembly for Yorkshire and Humberside

understand problems and to evaluate feasible solutions. Yet it was evident that few guidelines were available as to which particular demographic, economic, environmental or social variables should be used to measure regional performance. This vacuum has been highlighted by the debates on measuring 'sustainability' that preoccupied various organisations in the 1990s. ReRO always placed a high premium both on the collection of data and on 'adding value' to that data. On the one hand, this involved maximising the availability of computer technology to manipulate, analyse and display data. On the other hand, it also meant using expert local knowledge to provide reliable interpretation of the cross-sectional and time series datasets that have been assembled. As with the North West RRL, several of the smaller projects undertaken by ReRO involved collecting or assembling data, geocoding postcode-based records and mapping spatial distributions of phenomena such as inward investment establishments, poorly performing schools or organisations receiving funding from the Prince's Trust. Further details of two projects are provided to exemplify the nature of the applied GIS-based and spatial analytical work.

Adjustment of Population Projections

In the early 1990s, the data available from the 1991 Census provided local authorities with the opportunity to evaluate the accuracy of the 1989-based sub-national population and household projections for 1991 produced by the Office of Population Censuses and Surveys (OPCS, 1991) and the Department of the Environment (DoE, 1991) respectively. ReRO was commissioned to carry out this assessment for the region by the Yorkshire and Humberside Regional Planning Conference (representing the interests of all the local authorities in the region) and the Regional Office of the DoE. In

addition, the ReRO research team, comprising staff from the Universities of Leeds and Sheffield Hallam, were asked to utilise the findings in the formulation of a range of alternative population and household projections which could subsequently be used to inform the assignment of land for the future development of housing, part of the process of formulating Regional Planning Guidance (RPG).

It was found that, overall, the 1989-based projections for the region as a whole underestimated the mid-1991 estimates by 0.5% of its 4.9 million inhabitants but that differences between projections and estimates varied appreciably by local authority and by age group. In North Yorkshire, for example, overprojection of the total population was due to significant overprojection of those living in the county of young working age, offsetting an underprojection of those aged over 40. In Humberside, on the other hand, the population projections were lower than the population estimates for mid-1991 in almost all age groups, providing a substantial underprediction of the population of the sub-region as a whole. One of the key factors in explaining the differences was net migration. A methodology was developed to update the existing 'official' population and household projections for local authorities rather than constructing a new projection model (ReRO, 1993). The procedure for adjusting the population projections involved applying revised population base factors and adjusting the net migration assumptions on the basis of three scenarios about the range of possible futures. A modelling methodology was then used to convert the population projections into a revised set of household forecasts and involved subtracting the institutional populations from the projections, applying marital status factors (the proportions of a given population group that are either single, married or widowed/divorced) to the male and female projected populations by age group, and finally applying headship rates (the proportion of members of a population group defined by age, sex and marital status that are heads of households) to the relevant age–sex–marital status group projections. The details of the methodology and results of the project have been reported in Gore and Stillwell (1994).

The experience of undertaking the project was both rewarding and frustrating for the researchers involved. A huge database was created, a large amount of new demographic information about the region was uncovered, and an innovative solution was derived to a difficult problem. However, it became very clear to the research team at an early stage in the project that what was required to do a proper job was a full multi-regional population projection model linked to a regional model for household projections which would generate outputs that could be converted into projections for a variety of different uses. Frustration arose from the inability, due to time and cost constraints of the project, to deliver a fully fledged regional model that would become an immensely useful tool to support this type of analysis in the future. Further experience of undertaking applied quantitative research in population geography for local and regional authorities has been reported in Stillwell and Rees (2001).

Educational Performance

In the mid-1990s, ReRO was contracted by the Government Office for Yorkshire and the Humber to undertake a study of the educational performance of primary and secondary schools throughout the region. Recent studies by Gordon (1996) and

Clarke and Langley (1996) had shown the extent of spatial variation in school performance and preliminary work at the Local Education Authority (LEA) level had indicated huge variations in performance in Yorkshire and Humberside at Key Stages 2 (age 11) and 4 (age 16). At one end of the spectrum, the average numbers of pupils achieving level 4 in English, Mathematics and Science at primary schools in North Yorkshire were 66.4%, 66.5% and 73.5% respectively whereas equivalent figures for Kingston upon Hull, at the other end of the performance league table, were 55.8%, 54.5% and 63.1%. Similarly, the average percentage of pupils attaining five or more A* to C GCSE grades was 52.7% in North Yorkshire and only 24.1% in Kingston upon Hull (Stillwell and Langley, 1999). This geographical disparity is explained by a number of factors collectively summarised as levels of social disadvantage. These factors include children's personal characteristics, family structures, socioeconomic features, educational levels and ethnicity.

The focus of the project was to examine the geographical variations in achievement in more detail by looking at the performance of individual schools. This involved filtering out special schools, non-state schools and schools for which sets of examination results were incomplete and then geocoding the schools remaining in the database according to their unit postcodes. The locations of the schools were mapped against a set of ward boundaries and the best and worst performing schools were overlaid on a ward-based choropleth map of deprivation as measured by the Department of Environment's Index of Local Conditions, a measure based on seven deprivation indicators from the 1991 Census (unemployment, children in low earning households, overcrowded housing, housing lacking basic amenities, households with no car, children in unsuitable accommodation and educational participation at age 17). The spatial coincidence between schools performing badly and higher levels of deprivation was particularly significant. However, one of the key difficulties in linking examination performance and social deprivation is the use of ward-based socioeconomic characteristics as measures of school catchment area, when it is well known that social conditions vary within wards and that the size of school catchment areas differs widely from location to location. Consequently, one of the most important recommendations of the project was to use GIS buffering techniques to identify enumeration districts within a defined radius of each school and to compute new socioeconomic indicators based on the areas located within the buffer (see Stillwell and Langley 1999, for details). Gender-specific data was also made available to the researchers to look at the extent to which girls across the region were performing better than boys. Remarkable variation exists in the gender-gap, even at LEA level, where the East Riding was ranked 18th out of all 129 LEAs with 12.5% difference between the proportion of girls and boys getting five or more grades at A* to C, and North East Lincolnshire was ranked 124th, where the difference was only 3.9% (Bright, 1998). The project found no spatial relationship between the size of the gap and level of examination performance.

19.4 Cultural Differences, Constraints and Opportunities

The overviews of selected projects presented in the previous section exemplify some of the work undertaken within two different research institutions specifically

established to conduct applied research. In this section, some generalisations regarding the relative nature and priorities of applied work in contrast to academic work are offered and some of the benefits and problems associated with applied research are considered. Here we focus primarily on the role of the RRL although many of the points made relate to applied research in an academic context more generally.

19.4.1 Differences Between the Applied and Academic Research Cultures

There can be little doubt that operating within the framework of an RRL had a major impact on the nature of the work done and on the balance between theoretical and applied work. This is partly because an RRL has a particular remit to work in the GIS field, but largely because of the financial arrangements under which it has had to operate since the conclusion of RRL funding. The key issue of course is that the RRL employs a number of staff funded to work on GIS projects in general rather than on any one specific project. The first priority in considering possible work is therefore to provide enough money to pay the staff, and if possible, to give them a reasonably long-term degree of security. One major difference between RRLs and commercial consultancy companies is that the director of the RRL will usually have job security through a continuing contract with a university. The negative aspect of this is that he or she will also have academic responsibilities, and must be prepared to fit consultancy work around teaching commitments, marking examinations, and other non-applied research.

The differences in time scales between academic and commercial research are well known. Academic projects have a long lead time and last for a considerable period, sometimes for several years. Commercial projects are likely to come up with little prior notice, insufficient time to prepare the tender (especially when it may involve staff in a number of different institutions), no lead time between winning the project and starting work, and usually a very tight time scale to final report. Academic time scales allow posts to be advertised so that a new employee can be brought in with appropriate skills. For commercial projects, it is essential to have staff available already with the right sorts of skills and with time available to work on the project intensively and immediately. Generally universities find it difficult to operate in this way, but in an RRL it is easier, provided that staff have the willingness and the ability to try their hand at a wide range of projects. Certainly, the more commercially orientated environment makes it very hard for any on-the-job training to be accomplished or for RRL funding to be used for supporting research students.

The academic environment still tends to be fairly casual about punctuality. In the commercial world, however, clients are more concerned that work be produced on time. In many circumstances, their business needs mean that a sub-optimal answer provided on time may be more useful than a better answer which does not arrive until two or three weeks after it was needed. Sometimes it may in fact be more important to say something than to say the right thing. Decisions have to be made to fixed deadlines, and sometimes a client may be worse off if no decision is made than a decision that is flawed. Whereas in the academic world, few people would want to argue for their point of view unless they had carefully considered the arguments and the available data; in the commercial world there is seldom time for reflection.

The *modus operandi* of applied research creates difficulties because work is often concentrated at certain times of the year and absent at other times. Also, because most commercial work is on a tight timetable, it is relatively hard to schedule it to iron out the peaks and troughs. This causes difficulties in that RRL staff may be overworked at one time and at a loose end at another. The latter should not be a problem, in that slack periods can be used for writing up work that has been done already (though this seems surprisingly difficult to do for commercial projects), or for seeking out new business. It may also be possible to bring in casual labour to help out at busy periods. Often a university is well equipped to do this because it contains well-trained students who may be prepared to work part time and short term on an interesting project. On the other hand, if RRL staff have different skills and interests, there may be times when one staff member is needed to work on several different projects at the same time while another has nothing to do, only for the situation to be reversed a few months later.

The establishment of the RRLs coincided with the development of Masters level courses in GIS, and these courses have been fruitful sources of researchers for the RRLs. This is particularly so where, as at Edinburgh and Leicester, successful MSc courses are taught in a department where an RRL is located. It has been relatively easy to persuade many of the best MSc students to stay on to work on RRL projects, or to become research students in the department. Even in other RRLs, such as the North West at Lancaster, finishing MSc students have been a good source of able and well-trained researchers, who have often been keen to acquire experience of the mixture of theoretical and applied research projects characteristic of RRL research. At Leeds, whilst GMAP recruited new graduates, masters' students and PhD students (particularly from geography) in considerable volume from year to year, the philosophy of ReRO was to assemble teams of established researchers from institutions within the region.

The best solution to recruitment and staffing problems is through establishing economies of scale. The more people there are, the easier it will be to accommodate changes in the workload, and to find somebody suitable to work on a short-term short-notice contract. Unfortunately, however, this requires a bigger overall turnover and one which is not sufficiently guaranteed to allow permanent appointments to be made. Over time, and with a consistent record of high-quality work, it becomes possible to build up the volume of work, but there is still going to be a workflow problem. Furthermore, writing tenders and submitting proposals is a difficult and time-consuming activity, which will normally fall to the leader of the RRL, whose task becomes increasingly difficult as the size of the operation increases.

The working environment for applied research has often in the past been at odds with a university's normal expectations of security for research staff. The researchers themselves need the promise of job security to commit themselves to working in an RRL, but university finance offices are reluctant to promise such security unless money is in hand or contracts have been won sufficient to pay the staff for whatever length of contract is specified. In a situation where income is irregular and projects may appear at very short notice, RRL directors may have to convince their institutions to take the risk that sufficient money will be brought in to pay for new appointments.

Another implication of the ambiguous position of an applied research community that sits between the academic and commercial worlds is that there may be a conflict between staff's research interests and the portfolio of funded projects. Sometimes the most interesting ideas may arise from unfunded or underfunded work; developing these ideas may only be possible by neglecting income-generating projects. Often, the most socially worthwhile projects are sponsored by organisations with very limited resources. Applied research staff may also feel an obligation to colleagues and students; a lot of time at the North West RRL, for example, has been spent in helping students with GIS problems, and in exploring possible GIS aspects of the research of colleagues with other interests. Although it is important to show colleagues in the same university how GIS and spatial analysis may help them with their research, there is sometimes a risk of setting up a free and unresourced GIS consulting service.

Academics are trained to make sure they provide proper acknowledgement of other people's ideas, and that any claims not substantiated within their papers must be referenced, so that other academics may verify their truth or trace their intellectual provenance. Nobody in commerce or government will have time to do this, and referencing sources is usually unimportant. It may even produce a negative impression, as it may be taken to emphasise the academic nature of the project, using the word 'academic' in its sense of 'not leading to a decision; unpractical' (Onions, 1972). The style of reporting on a project is also an important difference between academic and commercial requirements. Academics are used to hedging their conclusions with all manner of reservations and *caveat*s, always aware that what they are saying may depend on context and may be matters of probability, nuance or weight of evidence. Such mealy-mouthed conclusions are not popular in the outside world, where a plain and definite statement is required and a short executive summary of any major report is paramount since this is all that the key decision-maker is likely to read. The conclusions, and indeed the description of the project, must also be short, succinct and definite. When working on issues related to government policy, the 'taxi ride principle' applies; apparently there is little point in saying anything that is too long or complex for a civil servant to explain to a minister during the taxi journey from the Ministry to the House of Commons!

A further simplification is the tendency for decision-makers and the media to ascribe work not to the individuals who conducted it, nor to the RRL or ReRO, but to the university with which they are affiliated. Academics may be taken aback or overwhelmed with responsibility if their analyses and policy recommendations are ascribed not just to them, but to their universities. This is especially so if they are aware that many of their colleagues would not share their views about the issues involved.

From the academic's point of view, publication, especially publication in refereed academic journals, is an important part of career development. In fact this is much more important than dissemination of research that may be of practical relevance. Academics are notoriously bad at writing about the practical application of their work for the layperson to understand. This issue is particularly familiar to one of the authors after 12 years of editing a publication (*The Yorkshire and Humber Regional Review*) trying to inform policy-makers of regionally relevant research. Equally, applied projects may be difficult to write up for academic journals for a variety of

reasons. In terms of the points just discussed, the academic may need to reinsert the nuances and the qualifications that were taken out to meet the client's needs for clarity and definitiveness. There may also be problems relating to confidentiality concerns. A client may not want his or her company's problems or operating policies published to the world in an academic journal, and anonymising the client may be insufficient if describing the situation makes the identity obvious. If the academic analysis indicates problems with the client's activities, the client will not usually want these known. Equally, if the research has identified new and better ways of doing something, considerations of commercial confidentiality may mean that the new methods cannot be described explicitly lest competitors adopt them, destroying any commercial advantage that the clients may have gained.

There may also be problems from the academic side. Academic research is usually best regarded if its findings are general. Results specific to one place or one company are less likely to be regarded as important by journal editors and referees. If important details are withheld or anonymised for reasons of commercial confidentiality, the academic article is further weakened. The perspective may also need to be different. In most fields, academic work would be expected to present a neutral review of situations and problems, and an even-handed discussion of what can be done about them. In contrast, the commercial report will necessarily be based on the position of one specific actor, the client, and will be primarily concerned with what the clients can do for their own benefit rather than for the good of society as a whole.

19.4.2 Benefits and Constraints

Despite the differences and problems discussed above, most participants in the research efforts of the RRLs and ReRO would probably agree in seeing many benefits to involvement in commercial projects. First, the wide range of applications is highly stimulating and the requirement to produce solutions is very challenging. Certainly some commercial problems are repetitive and formulaic, but very frequently there are interesting differences which require variation of a standard approach, and in some cases require revisions of an existing method which may shed new light on the problem from an academic perspective. A very common situation occurs when a fairly standard situation is encountered but there are limitations in the data available to develop a solution, and interesting intellectual problems arise in trying to make the optimal use of whatever data can be found. Sometimes, new and very valuable datasets are unearthed which can be used in other research projects or contexts.

Second, some intellectual satisfaction can be gained from the problem-solving nature of much applied research. Admittedly the problems must be solved with limited time and sometimes limited data, and some academic researchers may find this frustrating because they recognise what might be possible with greater resources. However, there are compensations in the finite nature of the problems. A researcher can feel he or she has reached the best possible solution within the constraints available. In contrast, much academic research is inevitably open-ended; one always feels

slightly unsatisfied, in the knowledge that further research or further thought could produce a fuller or more sophisticated understanding of the point at issue.

For both the authors, quantitative geographers trained in the 1970s, applied research in GIS and spatial modelling has often involved a journey back in time, to some of the operational research and statistical models that were then at the cutting edge of geography. Though fashions have changed within the discipline and not many geographers get excited by location-allocation, spatial interaction models or multivariate classifications, they do have a commercial value. So do some of the skills that quantitative geographers have, less valued perhaps within academic geography than they were, but able to command a considerable price in the commercial marketplace, particularly if combined with some more advanced computer programming skills.

The use of the very term 'applied geography', or of 'applied GIS and spatial analysis' more specifically, begs some important questions. If geography is to be applied, what is it to be applied to? Who is to be doing the applying? Who will benefit from the application? If geography is to be applied for money, for the support of geographers working in higher education, then the answer must be that it will be applied for the benefit of those who have the resources to pay for it. This will usually be business or government, and it will usually be for their own benefit. It is rare for applied research to be performed in the interests of poor or excluded groups within society, simply because they are poor and excluded and hence unable to commission such work. The Joseph Rowntree Foundation is an exception to the general rule. Even within commercial organisations, it is the larger and more aggressive who are most likely to be clients. If geography is applied to help such companies with store location or market penetration, it will inevitably be at the expense of small businesses and corner shops with which we might otherwise tend to sympathise. In the RRL and ReRO context, however, ethical considerations of this type must be set against the ethical imperative to provide work and earn funds for the institution concerned.

It could also be argued that elements of applied geographical methods may themselves have questionable ethical effects. In constructing market areas or accessibility measures, for example, it is usual to adopt drive times as measures of accessibility. If facilities are located on this basis, their location pattern will no doubt make sense as far as car users are concerned, but there is a risk that those reliant on bus or rail travel, or other transport modes, will not be served adequately by the facilities. Further, for environmental reasons, we may not be happy to recommend a system that relies on even more universal usage of private cars with the well-known negative social and environmental externalities that they generate.

A further critique that applies to some aspects of applied geography in the commercial sector concerns invasions of privacy (Goss, 1995). Geodemographics and related marketing tools increasingly require large databases, including information about many individuals and local geographical areas. Some of this is collected in unobtrusive ways, such as recording address and purchasing information from store loyalty cards, or from participants in competitions and promotional activities. Apart from the invasion of privacy such activities can be regarded as constituting, there may be practical consequences, such as the refusal of credit, or the insistence on high insurance premiums, to somebody purely on the basis of where they live.

In terms of the concerns of contemporary geography, moreover, it can be argued that commercial applications lead to a focus on the tangible and perhaps on the economic. There may be little scope for studies in this area to engage with questions about values, interpretations and the taken-for-granted world. Arguably, a concern with the mappable and the unambiguously locatable tends to distract our attention from the ambiguous perceptions, interpretations and projects of those we are studying. The concern with the interests of clients, often largely their commercial interests, detracts from the full humanity of the people who are reduced to a geocode and a record of purchasing behaviour.

Other problems with a concentration on applied geography within an academic setting are institutional rather than ethical. Many of these have already been mentioned in the previous sub-section, such as the funding treadmill which requires a constant need to bring in more funding to keep the organisation going and to keep research staff in post. University administrations are not designed to promote commercial activities, however much current funding systems have forced them to try. Academic goals and commercial goals are not the same. Universities cannot ignore their finances and their need to bring in revenue, but to an important extent they still value truth and the search for knowledge. Commercial companies and government, quite rightly, have their own different goals and values, and an academic trying to combine both sets of goals must inevitably struggle to satisfy the latter without abandoning the former.

19.5 The Future for Applied Research

In conclusion, and despite the comments in the preceding section, our experience makes us generally optimistic about the future of applied geography and the use of the computer-based systems and methods that are now emerging for spatial analysis and forecasting. The geographical perspective, geographical data and geographical skills are highly relevant to many aspects of contemporary society. The activities of the RRLs, ReRO and companies like GMAP have done an enormous amount to make more people aware of how quantitative geography can be applied, and have helped some geographers understand better how to market their services and to meet the needs of outside clients. There is plenty of scope for applying geography.

Geographers may be in competition with other academics, especially economists, many of whom may be better integrated into the commercial and policy worlds. Certainly potential clients have a clear idea of how their organisations may benefit from applied economics, while geography still suffers from a ‘capes and bays’ or ‘geomorphology and climate’ image. Fiercer competition may come from consultancy firms employing the most recent generations of graduates or postgraduates. These firms have the economies of scale and the knowledge of client expectations to attract a lot of business. In contrast, academics may offer lower rates and more specialised knowledge, but often may be perceived as less likely to deliver on time, and more likely to produce work that is unhelpful to the client because it does not offer clear-cut solutions and recommendations. Our experience suggests that geographers in

commercial work in order to compete effectively must learn the importance of presentation, the importance of meeting deadlines, and the importance of presenting their work in a manner which the clients can most easily use.

Quantitative skills are necessary for much of what is done in the name of applied research. The quantitative revolution left geographers in the 1970s with degree courses that included statistical analysis and some practical work with maps and numerical data. Compared with many other social scientists, they could be effective in applying geography because they possessed practical and quantitative skills as well as the ability with write coherently about their results. In the current intellectual environment, some of these gains may be threatened. It is becoming easier to graduate in human geography without acquiring much quantitative expertise, and at the dissertation and postgraduate levels, there may now be more prestige in conducting a qualitative survey or a discourse analysis than doing quantitative analysis or modelling work. The discipline may lose out if we do not continue to teach and to apply quantitative skills. We must also be prepared to work to real-world rather than academic standards. The work must recognise the importance of punctuality rather than perfectionism. A willingness must be shown to commit to ideas and policies without having all the evidence.

We do not wish to argue that all geography should be applied, but there are huge opportunities for applying the work we do and it would be a great shame if we do not take further advantage of them, especially those that make use of GIS, analysis methods and modelling techniques. The examples contained in the earlier chapters of this book are testament to what has been achieved. Much more is possible in the future.

Acknowledgements

This chapter represents the fusion of ideas presented in earlier papers by Robin Flowerdew at the Annual Conference of the Royal Geographical Society with the Institute of British Geographers in Plymouth in January 2001 and by John Stillwell at a seminar on regional observatories at the University of Complutense in Madrid in November 2000.

Dedicated to my beloved wife, Roshi, and my children, Maria, Adam, and Harris

Preface

To fully appreciate the benefits of GIS applications consider the following hypothetical scenario. On March 10, 2004, following a heavy storm event, a sewer customer calls the Sewer Authority of the City of Cleanwater to report minor basement flooding without any property damage. An Authority operator immediately starts the GIS and enters the customer address. GIS zooms to the resident property and shows all the sewers and manholes in the area. The operator queries the inspection data for a sewer segment adjacent to the customer property and finds that a mini movie of the closed-circuit television (CCTV) inspection dated July 10, 1998, is available. The operator plays the movie and sees light root growth in the segment. A query of the maintenance history for that segment indicates that it has not been cleaned since April 5, 1997. This information indicates that the roots were never cleaned and have probably grown to "heavy" status. The operator highlights the sewer segment, launches the work order module, and completes a work order form for CCTV inspection and root removal, if necessary. The export button saves the work order form and a map of the property and adjacent sewers in a PDF file. The operator immediately sends the PDF file by e-mail to the Authority's sewer cleaning contractor. The entire session from the time the customer called the Authority office took about 30 min. The operator does not forget to call the customer to tell him that a work order has been issued to study the problem. This book presents the methods and examples required to develop applications such as this.

The days of the slide rule are long gone. Word processors are no longer considered cutting-edge technology. We are living in an information age that requires us to be more than visionaries who can sketch an efficient infrastructure plan. This tech-heavy society expects us to be excellent communicators who can keep all the stakeholders — the public, the regulators, or the clients — "informed." New information and decision support systems have been developed to help us to be good communicators. GIS is one such tool that helps us to communicate geographic or spatial information. The real strength of GIS is its ability to integrate information. GIS helps decision makers by pulling together crucial bits and pieces of information as a whole and showing them the "big picture." In the past 10 years, the number of GIS users has increased substantially. Many of us are using GIS applications on the Internet and on wireless devices without even knowing that we are using a GIS. Experts believe that in the near future, most water, wastewater, and stormwater system professionals will be using the GIS in the same way they are now using a word processor or spreadsheet. Except for the computer itself, no technology has so revolutionized the water industry. The time has come for all the professionals involved in the planning, design, construction, and operation of water, wastewater, and stormwater systems to enter one of the most promising and exciting technologies of the millennium in their profession — GIS applications.

According to some estimates, more than 80% of all the information used by water and sewer utilities is geographically referenced.

This book was inspired from a continuing education course that the author has been teaching since 1998 for the American Society of Civil Engineers (ASCE). Entitled ''GIS Applications in Water, Wastewater and Stormwater Systems,'' the seminar course has been attended by hundreds of water, wastewater, and stormwater professionals in major cities of the United States. Many models, software, examples, and case studies described in the book (especially those from Pennsylvania) are based on the GIS projects worked on or managed by the author himself.

This is my second GIS book for water, wastewater, and stormwater systems. The first book, *GIS Tools for Water, Wastewater, and Stormwater Systems*, published by American Society of Civil Engineers (ASCE) Press in 2002, was a huge success. The first printing was sold out, and the book achieved ASCE Press's best-seller status within months of publication. Whereas the first book focused on GIS basics and software and data tools to develop GIS applications, this second book focuses on the practical applications of those tools. Despite the similarity of the titles, both books cover different topics and can be read independent of each other.

STYLE OF THE BOOK

This book has been written using the recommendations of the Accreditation Board for Engineering and Technology (ABET) of the U.S. and the American Society of Civil Engineers' (ASCE) Excellence in Civil Engineering Education (ExCEEd) program. Both of these organizations recommend performance- (or outcome-) based learning in which the learning objectives of each lecture (or chapter) are clearly stated up front, and the learning is measured in terms of achieving these learning objectives. Each chapter of this book accordingly starts with learning objectives for that chapter and ends with a chapter summary and questions. Most technical books are written using the natural human teaching style called *deductive*, in which principles are presented before the applications. In this book, an attempt has been made to organize the material in the natural human learning style called *inductive*, in which examples are presented before the principles. For example, in most chapters, case studies are presented before the procedures are explained. The book has numerous maps and illustrations that should cater well to the learning styles of "visual learners" — GIS, after all is regarded as a visual language.

The primary learning objective of this book is to document GIS applications for water, wastewater, and stormwater systems. This book will show you how to use GIS to make tasks easier to do and increase productivity, and hence, save time and money in your business.

ORGANIZATION OF THE BOOK

There are 17 chapters in this book, organized as follows:

- Chapter 1, GIS Applications: Describes why GIS applications are important and how they are created

- Chapter 2, Needs Analysis: Explains how to avoid potential pitfalls of GIS implementation by starting with a needs analysis study

The next five chapters describe four GIS-related technologies that are very beneficial in developing GIS applications:

- Chapter 3, Remote Sensing Applications: Shows how to use satellite imagery in GIS applications
- Chapter 4, DEM Applications: Describes the methods of incorporating digital elevation model (DEM) data
- Chapter 5, GPS Applications: Discusses how to benefit from global positioning system (GPS) technology
- Chapter 6, Internet Applications: Explains the applications of Internet technology in serving GIS maps on the Internet
- Chapter 7, Mobile GIS: Provides information on using GIS in the field for inspection and maintenance work

The GIS applications that are of particular importance to water industry professionals are: Mapping, Monitoring, Modeling, and Maintenance. These four *M*s define some of the most important activities for efficient management of water, wastewater, and stormwater systems, and are referred to as the "4M applications" in this book. The next ten chapters focus on these four *M*s.

- Chapter 8, Mapping: Describes how to create the first *M* of the 4M applications
- Chapter 9, Mapping Applications: Describes examples of the first *M* of the 4M applications
- Chapter 10, Monitoring Applications: Describes the applications of the second *M* of the 4M applications
- Chapter 11, Modeling Applications: Describes the applications of the third *M* of the 4M applications
- Chapter 12, Water Models: Describes examples of the third *M* of the 4M applications for modeling water distribution systems
- Chapter 13, Sewer Models: Describes examples of the third *M* of the 4M applications for modeling sewage collection systems
- Chapter 14, AM/FM/GIS Applications: Describes automated mapping/facilities management/geographic information system (AM/FM/GIS) software tools for implementing the fourth *M* of the 4M applications
- Chapter 15, Maintenance Applications: Describes the applications of the fourth *M* of the 4M applications
- Chapter 16, Security Planning and Vulnerability Assessment: Discusses GIS applications for protecting water and wastewater systems against potential terrorist attacks
- Chapter 17, Applications Sampler: Presents a collection of recent case studies from around the world

Acknowledgments

Case studies presented in Chapter 17, Applications Sampler, were written specially for publication in this book by 18 GIS and water industry experts from 6 countries (Belgium, Bulgaria, Czech Republic, Denmark, Spain and the United States) in response to my call for case studies distributed to various Internet discussion forums. I thank these case study authors for their contributions to this book:

- Bart Reynaert, Rene Horemans, and Patrick Vercruyssen of Pidpa, Belgium
- Carl W. Chen and Curtis Loeb of Systech Engineering, Inc., San Ramon, California
- Dean Trammel, Tucson Water, Tucson, Arizona
- Ed Bradford, Roger Watson, Eric Mann, Jenny Konwinski of Metropolitan Sewerage District of Buncombe County, North Carolina
- Eric Fontenot of DHI, Inc., Hørsholm, Denmark
- Milan Suchanek and Tomas Metelka of Sofiyska Voda A.D., Sofia, Bulgaria
- Peter Ingeduld, Zdenek Svitak, and Josef Drbohlav of Praûská vodohospodáská spolenost a.s. (Prague stockholding company), Prague, Czech Republic
- Hugo Bartolin and Fernando Martinez of Polytechnic University of Valencia, Spain

I also thank the following organizations and companies for providing information for this book: American Society of Civil Engineers, American Water Works Association, Azteca Systems, *CE Magazine*, CH2M Hill, Chester Engineers, Computational Hydraulics International, Danish Hydraulic Institute (DHI), Environmental Systems Research Institute, *Geospatial Solutions Magazine*, *GEOWorld Magazine*, Haestad Methods, Hansen Information Technology, *Journal of the American Water Resources Association*, *Journal of the American Water Works Association*, MWH Soft, *Professional Surveyor Magazine*, USFilter, *Water Environment Federation, and Water Environment & Technology Magazine*. Some information presented in this book is based on my collection of papers and articles published in peer-reviewed journals, trade magazines, conference proceedings, and the Internet. The authors and organizations of these publications are too numerous to be thanked individually, so I thank them all collectively without mentioning their names. Their names are, of course, included in the Reference section.

Finally, I would like to thank you for buying the book. I hope you will find the book useful in maximizing the use of GIS in your organization to make things easier to do, increase productivity, and save time and money.

About the Author

Uzair (Sam) M. Shamsi, Ph.D., P.E., DEE is director of the GIS and Information Management Technology division of Chester Engineers, Pittsburgh, Pennsylvania, and an adjunct assistant professor at the University of Pittsburgh, where he teaches GIS and hydrology courses. His areas of specialization include GIS applications and hydrologic and hydraulic (H&H) modeling. He has been continuing education instructor for the American Society of Civil Engineers (ASCE) and an Environmental Systems Research Institute (ESRI)-authorized ArcView® GIS instructor since 1998. He has taught GIS courses to more than 500 professionals throughout the United States, including a course on "GIS Applications in Water, Wastewater, and Stormwater Systems" for ASCE. Sam earned his Ph.D. in civil engineering from the University of Pittsburgh in 1988. He has 20 years of GIS and water and wastewater engineering experience in teaching, research, and consulting. His accomplishments include more than 120 projects and over 100 lectures and publications, mostly in GIS applications. His previous book, *GIS Tools for Water, Wastewater, and Stormwater Systems*, was an ASCE Press best seller. He is the recipient of the ASCE's Excellence in Civil Engineering Education (EXCEED) training and is a licensed professional engineer in Pennsylvania, Ohio, and West Virginia. In addition to ASCE, he is a member of the American Water Resources Association, the Water Environment Foundation, and the American Water Works Association.

GIS is an instrument for implementing geographic thinking.

Jack Dangermond (1998)

Iron rusts from disuse; water loses its purity from stagnation and in cold weather becomes frozen; even so does inaction sap the vigors of the mind.

Leonardo da Vinci (1452–1519)

Life is like a sewer… what you get out of it depends on what you put into it.

Tom Lehrer (1928–)

Times of general calamity and confusion create great minds. The purest ore is produced from the hottest furnace, and the brightest thunderbolt is elicited from the darkest storms.

Charles Caleb Colton (1780–1832)

CHAPTER 1

GIS Applications

Geographic Information System (GIS) is one of the most promising and exciting technology of the decade in our profession. This book will show you that with GIS the possibilities to manage your water, wastewater, and stormwater systems are almost endless.

GIS applications can take you from work frustration to job satisfaction.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand the importance and scope of geographic information system (GIS) applications for water, wastewater, and stormwater systems.

MAJOR TOPICS

- Definition of GIS applications
- History of GIS applications
- Advantages and disadvantages of GIS applications
- Evolving and future GIS applications and trends
- Methods of developing GIS applications

GIS Project Nominated for OCEA Award

American Society of Civil Engineers (ASCE) awards Outstanding Civil Engineering Achievement (OCEA) awards to projects based on their contribution to the well-being of people and communities; resourcefulness in planning and solving design challenges; pioneering in use of materials and methods; innovations in construction; impact on physical environment; and beneficial effects including aesthetic value. The Adam County (Illinois) 2002 GIS Pilot Project was a nominee for the 1997 awards. This project was a 10-year, multiparticipant (Adams County, City of Quincy, Two Rivers Regional Planning Council, and a number of state and local agencies) project to develop an accurate, updated GIS designed to create a more efficient local government.

INTRODUCTION

The water industry** business is growing throughout the world. For example, the U.S. market for water quality systems and services had a total value of $103 billion in 2000. The two largest components of this business are the $31-billion

* Each chapter of this book begins with a list of frequently used acronyms in the chapter. Appendix A provides a complete list of acronyms used in the book.
** In this book, the term *water industry* refers to water, wastewater, and stormwater systems.

public wastewater treatment market and the $29-billion water supply market (Farkas and Berkowitz, 2001).

One of the biggest challenges in the big cities with aging water, wastewater, and stormwater infrastructures is managing information about maintenance of existing infrastructure and construction of new infrastructure. Many utilities tackle infrastructure problems on a react-to-crisis basis that, despite its conventional wisdom, may not be the best strategy. Making informed infrastructure improvement decisions requires a large amount of diverse information on a continuing basis. If information is the key to fixing infrastructure problems, the first step of any infrastructure improvement project should be the development of an information system.

An information system is a framework that provides answers to questions, from a data resource. A GIS is a special type of information system in which the data source is a database of spatially distributed features and procedures to collect, store, retrieve, analyze, and display geographic data (Shamsi, 2002).

More than 80% of all the information used by water and wastewater utilities is geographically referenced.

In other words, a key element of the information used by utilities is its location relative to other geographic features and objects. GIS technology that offers the combined power of both geography and information systems is an ideal solution for effective management of water industry infrastructure. Geotechnology and geospatial technology are alias names of GIS technology.

The days of the slide rule are long gone. Word processors are no longer considered cutting-edge technology. We are living in the information age, which requires us to be more than visionaries who can sketch an efficient infrastructure plan. Today's tech-savvy society expects us to be excellent communicators who can keep all the stakeholders — the public, the regulators, or the clients — "informed." New information and decision support systems have been developed to help us become good communicators. GIS is one such tool that helps us to communicate geographic or spatial information. In fact, a carefully designed GIS map can be worth more than a thousand words. Sometimes the visual language of GIS allows us to communicate without saying a single word, which is the essence of effective communication.

WHAT ARE GIS APPLICATIONS?

An application is an applied use of a technology. For example, online shopping is an application of Internet technology, automobile navigation is an application of GPS technology, and printing driving-direction maps is an application of GIS technology. No matter how noble a technology is, without applied use it is just a theoretical development. Applications bridge the gap between pure science and applied use. Highly effective water and wastewater utilities strive for continuous operational improvements and service excellence. GIS applications have the potential to enhance

the management of our water, wastewater, and stormwater systems and prepare them for the operational challenges of the 21st century.

HISTORY OF GIS APPLICATIONS

GIS technology was conceived in the 1960s as a digital layering system for coregistered overlays. Started in the mid-1960s and still operating today, Canadian GIS is an example of one of the earliest GIS developments. Civilian GIS in the U.S. got a jump start from the military and intelligence imagery programs of the 1960s. The Internet was started in the 1970s by the U.S. Department of Defense to enable computers and researchers at universities to work together. GIS technology was conceived even before the birth of the Internet.

Just as technology has changed our lifestyles and work habits, it has also changed GIS. Though the art of GIS has been in existence since the 1960s, the science was restricted to skilled GIS professionals. The mid-1990s witnessed the inception of a new generation of user-friendly desktop GIS software packages that transferred the power of GIS technology to the average personal computer (PC) user with entry-level computing skills. In the past decade, powerful workstations and sophisticated software brought GIS capability to off-the-shelf PCs. Today, PC-based GIS implementations are much more affordable and have greatly reduced the cost of GIS applications. Today's GIS users are enjoying faster, cheaper, and easier products than ever before, mainly because of the advent of powerful and affordable hardware and software.

There were only a few dozen GIS software vendors before 1988 (Kindleberger, 1992); in 2001, the number had grown to more than 500. This revolution rightfully steered the GIS industry from a focus on the technology itself toward the applications of the technology (Jenkins, 2002). The strength of GIS software is increasing while its learning curve is decreasing. At this time, GIS is one of the fastest growing market sectors of the software industry and for a good reason: GIS applications are valuable for a wide range of users, from city planners to property tax assessors, law enforcement agencies, and utilities. Once the exclusive territory of cartographers and computer-aided drafting (CAD) technicians, today's GIS is infiltrating almost all areas of the water industry.

A GIS article published in *American City and County* in 1992 predicted faster computers and networks and that efficient database management and software will move GIS applications from property recording, assessing, and taxing functions to much more diverse applications during the 1990s (Kindleberger, 1992). This article anticipated future GIS applications to be rich in their use of multimedia, images, and sound. It expected GIS applications to become more closely linked to the 3D world of CAD as used by architects and engineers. Almost all of the GIS applications predicted in 1992 are now available except interacting with GIS data in a "virtual reality" medium wearing helmets and data gloves.

GIS literature is broad due to the wide variety of areas that utilize geographic data. Likewise, the literature describing GIS applications in the water industry is itself very

broad. However, much of this work has been in the area of natural hydrology and large-scale, river-basin hydrology. A recent literature review conducted by Heaney et al. (1999) concluded that GIS applications literature exists in several distinct fields. In the field of water resources, recent conferences focusing on urban stormwater have several papers on GIS. Proceedings from two European conferences on urban stormwater by Butler and Maksimovic (1998), and Seiker and Verworn (1996), have a wealth of current information on GIS. The American Water Resources Association (AWRA) has sponsored specialty conferences on GIS applications in water resources, such as Harlin and Lanfear (1993) and Hallam et al. (1996). These reports have sections devoted to urban stormwater, of which modeling is a recurring theme. The International Association of Hydrological Sciences (IAHS) publishes the proceedings from its many conferences, some of which have dealt specifically with the integration and application of GIS and water resources management (e.g., Kovar and Nachtnebel, 1996).

In the early 1990s, not too many people were very optimistic about the future of GIS applications. This perception was based, in part, on geographic information technologies being relatively new at that time and still near the lower end of the growth curve in terms of (1) applications and (2) their influence as tools on the ways in which scientific inquiries and assessments were conducted (Goodchild, 1996). It was felt that several challenges related to our knowledge of specific processes and scale effects must be overcome to brighten the future of GIS applications (Wilson et al., 2000).

GIS applications for the water industry started evolving in the late 1980s. In the early 1990s, the water industry had started to use GIS in mapping, modeling, facilities management, and work-order management for developing capital improvement programs and operations and maintenance plans (Morgan and Polcari, 1991). In the mid-1990s, GIS started to see wide applicability to drinking water studies. Potential applications identified at that time included (Schock and Clement, 1995):

- GIS can provide the basis for investigating the occurrence of regulated contaminants for estimating the compliance cost or evaluating human health impacts.
- Mapping can be used to investigate process changes for a water utility or to determine the effectiveness of some existing treatment such as corrosion control or chlorination.
- GIS can assist in assessing the feasibility and impact of system expansion.
- GIS can assist in developing wellhead protection plans.

According to the American Water Works Association (AWWA), approximately 90% of the water utilities in the U.S. were using GIS technology by the end of the year 2000.

The use of GIS as a management tool has grown since the late 20th century. In the past 10 years, the number of GIS users has increased substantially. GIS technology has eased previously laborious procedures. Exchange of data between GIS, CAD, supervisory control and data acquisition (SCADA), and hydrologic and hydraulic (H&H) models is becoming much simpler. For example, delineating watersheds and stream networks has been simplified and the difficulty of conducting spatial data management and model parameterization reduced (Miller et al., 2004).

Today GIS is being used in concert with applications such as maintenance management, capital planning, and customer service. Many of us are using GIS applications on the Internet and on wireless devices without even knowing that we are using a GIS. These developments make GIS an excellent tool for managing water, wastewater, and stormwater utility information and for improving the operation of these utilities. Experts believe that in the near future, most water industry professionals will be using GIS in the same way they are now using a word processor or spreadsheet. Except for the computer itself, no technology has so revolutionized the field of water resources (Lanfear, 2000). In the early 1990s, GIS was being debated as the most controversial automation technology for the water industry (Lang, 1992). However, the time has come for all the professionals involved in the planning, design, construction, and operation of water, wastewater, and stormwater systems to enter one of the most promising and exciting technologies of the decade in their profession — GIS applications.

The Environmental Systems Research Institute (ESRI), the leading GIS software company in the world, has been a significant contributor to GIS applications in the water industry. ESRI hosts a large annual international user conference. The proceedings archives from these conferences are available at the ESRI Web site. This Web site also has a homepage for water and wastewater applications.

More information about GIS application books, periodicals, and Internet resources is provided in the author's first GIS book (Shamsi, 2002).

4M APPLICATIONS

Representation and analysis of water-related phenomena by GIS facilitates their management. GIS applications that are of particular importance to water industry professionals are: mapping, monitoring, modeling, and maintenance. These four *M*s define some of the most important activities for efficient management of water, wastewater, and stormwater systems, and are referred to as the "4M applications" in this book. With the help of new methods and case studies, the following chapters will show you how a GIS can be used to implement the 4M applications in the water industry. This book will demonstrate that with GIS the possibilities to map, monitor, model, and maintain your water, wastewater, and stormwater systems are almost endless. It will teach you how to apply the power of GIS and how to realize the full potential of GIS technology in solving water-related problems. This book does not train you in the use of a particular GIS software. It is not intended to help you run a GIS map production shop. Simply stated, this book will enable you to identify and apply GIS applications in your day-to-day operations.

ADVANTAGES AND DISADVANTAGES OF GIS APPLICATIONS

As described in the following subsections, GIS applications offer numerous advantages and a few drawbacks.

Advantages

Thanks to recent advances in GIS applications, we are finally within reach of organizing and applying our knowledge of the Earth in our daily lives. Typical advantages of GIS applications are described in the following subsections.

GIS Applications Save Time and Money

The foremost benefit of GIS technology is increased productivity and quicker turnaround. Increased efficiency saves time, which translates into saving money. GIS applications improve the quality of life because they make things easier to do. GIS allows us to perform routine work, such as keeping records of maintenance work or customer complaints, more efficiently. GIS tools have become user-friendly and easier to use. Local governments, utilities, and their consultants are using GIS to analyze problems and recommend solutions in a fraction of the time previously required.

GIS provides a spatial approach to organizing information about customers and the assets of a water or sewer utility, such as pipes, hydrants, pumps, and treatment equipment. GIS applications help a utility to analyze the spatial information about its customers and assets to improve planning, management, operation, and maintenance of its facilities. Municipalities and utilities that have successfully implemented GIS have seen dramatic improvements in the way in which data are retrieved, analyzed, and maintained. These improvements are allowing municipal and utility personnel to collect information more efficiently, better perform routine activities, and make more informed decisions.

GIS applications can significantly reduce time and costs associated with conventional analysis and evaluation methodologies (EPA, 2000).

GIS Applications Are Critical to Sustaining GIS Departments

Continued development of new applications is critical to sustaining the growth of a new technology. GIS, being a new technology itself, might not survive unless people use it in their routine business operations to make things easier to do, to enhance productivity, and to save both time and money. To justify their existence in an organization, GIS departments should use GIS to develop cost-effective solutions that make people's life easier. Simply stated, GIS applications are the key to garnering the management's financial support for GIS departments. This book shows how to put GIS technology to productive use in the water industry.

Although GIS applications in the water industry are not new, getting beyond basic inventory and mapping functions is often challenging. Unfortunately, mapping efforts alone do not always justify the financial support for a GIS group. Unless a GIS is taken to the operational level, it is nothing but a pretty map. That is why GIS emphasis is now shifting from producing high-quality maps to

enterprise-wide mission-critical applications. The benefit–cost ratio of GIS increases with its functionality and applications. GIS applications of automated mapping return a 1:1 benefit–cost ratio. Benefit–cost ratios of 4:1 can be attained when GIS use expands to all the departments of an organization (Alston and Donelan, 1993).

GIS Applications Provide the Power of Integration

The typical local government office contains hundreds of maps displaying such information as municipal boundaries, property lines, streets, sewer pipes, water mains, voting district boundaries, zoning areas, flood plains, school bus routes, land use, streams, watersheds, wetlands, topography, geology, and soil types, to name a few. Paper maps, after all, have been the traditional method of storing and retrieving geographically referenced information. The sheer number, range of types, and diversity of maps used by municipalities are evidence of the importance geographically referenced information plays in our day-to-day operations. Unfortunately, the wide variety of maps and diversity of their scales and designs at our disposal make it extremely difficult to access, use, and maximize the value of the information they contain. GIS *integrates* all kinds of information and applications with a geographic component into one manageable system.

The real strength of GIS is its ability to integrate information. This integration power makes the scope of GIS applications almost infinite. A GIS can be whatever we want it to be. GIS can organize the geographic information of a municipality or utility into one seamless environment. The unique integration capability of GIS allows disparate data sets to be brought together (*integrated*) to create a complete picture of a situation. GIS technology illustrates relationships, patterns, and connections that are not necessarily obvious in any one data set but are amazingly apparent once the data sets are integrated. The integration capability of GIS technology empowers organizations to make better and informed decisions based on all relevant factors (ESRI, 2003). GIS offers integrated solutions in the areas of planning and engineering, operation and maintenance, and even finance and administration.

GIS Applications Offer a Decision Support Framework

GIS helps decision makers by pulling together crucial bits and pieces of information as a "whole" and showing them the "big" picture. In this regard, GIS can be used as a consensus-building and decision-making tool. By using geography as the common denominator, GIS permits data from a wide range of disparate sources to be combined and analyzed. Therefore, an important benefit of GIS applications is their inherent ability to integrate and analyze all spatial data to support a decision-making process. GIS provides uniformity of data usage and the flexibility to test and evaluate multiple scenarios. The use of a common database eliminates the differences in presentation, evaluation, and decision making based on using different forms and types of data. For example, civil engineers who need

to know the lay of the land to design, build, and maintain projects can learn from the ways in which utilities and municipalities are linking GIS data to every aspect of their computing enterprise (Goldstein, 1997). A GIS provides the opportunity to conduct sensitivity analyses appropriate for the level of accuracy of the input data. This allows engineers, planners, elected officials, and the public to focus on the impacts and analysis of alternatives rather than the accuracy of data. After the planning and decision-making phase has been completed, GIS can continue to support the implementation phase of a project by tracking the success and failures of alternative approaches. Plan performance tracking and testing of new approaches is based on new parameters, new information, and new conditions within or outside the study area (EPA, 2000).

GIS Applications Provide Effective Communication Tools

GIS fosters better communication and cooperation among various stakeholders (e.g., community leaders and the public) of a water industry construction or improvement project. Many people learn better with maps than they do with words or numbers. GIS can be used to communicate with different audiences using visually different views of the same data. For instance, 3D plan views of a water or sewer system improvement project can be used for presentations at town meetings to graphically illustrate necessary improvements. Because GIS is a visual language, it is an excellent communication tool for visual learners. A picture is only worth a thousand words. A map may be worth a thousand numbers. But a GIS is worth a thousand tables.

In the late 1990s, GIS advocates noted that robust citizen participation in ongoing policy making was limited because many groups lacked access to the GIS environment (Obermeyer, 1998). This has started to change over the last 5 years mainly due to availability of browser-based "Internet GIS" technology described in Chapter 6 (Internet Applications). However, the challenge remains to provide citizens with GIS applications that until recently were only available to professionals.

If bottom–up decision making is to succeed, all stakeholders must have access to GIS technology in various forms (Miller et al., 2004).

GIS Applications Are Numerous

GIS is as ubiquitous as it is today because it is a very effective tool for an incredible number of applications (Zimmer, 2001). Today's GIS is limitless! The number of GIS applications is limited only by our own imagination and the availability of data. For instance, the municipal applications alone are numerous, including:

- Water, wastewater, and stormwater operations
- Comprehensive planning

- Vulnerability assessment and security planning
- Permitting and code enforcement
- Building inspections
- Zoning
- Parcel mapping
- Pavement management
- Tracking customer complaints
- Grant applications
- Routing

The magnitude of GIS applications can be appreciated by the fact that this entire book is devoted to one application from the preceding list.

A recent survey conducted by Geospatial Information and Technology Association (GITA) indicates the following top ten applications in the utility industry (Engelhardt, 2001; GITA, 2001):

- Landbase model
- Work management
- Facility model analysis/planning
- Operations and maintenance
- Document management
- Customer information systems
- Workforce automation
- Regulatory reporting
- Environmental testing
- Marketing

The same survey lists the following technologies driving GIS implementation for utilities:

- Nonproprietary programming
- Pen/mobile computing/field data capture
- Internet/intranet
- Data exchange/open GIS
- Document management/workflow
- GPS
- Digital orthophotography
- Satellite imagery

The water industry was found to be focusing on the following applications:

- Work management
- Facility model analysis/planning
- Pen/mobile computing

Water utilities were found to be implementing more pen/mobile systems than any other market segment. It was also found that water utilities were seeking higher landbase accuracy of 5 ft compared with other utilities, for instance, the 50-ft accuracy sought by gas companies.

The major GIS applications for the water industry are summarized in the following list:

- GIS provides the ideal means of describing water and sewer infrastructure facilities, identifying problems and recommending solutions, scheduling and recording maintenance activities, and supporting technical analysis (e.g., hydraulic modeling) of the facilities. For example, GIS can be used for mapping the water mains and identifying water main breaks in terms of location, pressure, soil type, pipe size, pipe material, or pipe age. Such applications are described in Chapter 9 (Mapping Applications), Chapter 10 (Monitoring Applications), and Chapter 15 (Maintenance Applications).
- Various spatial data layers can be combined and manipulated in a GIS to address planning, operation, and management issues. For example, water and sewer line information can be combined with population statistics and ground elevation data to assess the adequacy of water and sewer utilities. The Metropolitan District of Greater Cincinnati (Ohio) uses GIS to locate storm sewer system problem areas. The trouble spots are identified and targeted for preventive maintenance by mapping the relationship between customer complaints and amount of rainfall (Mitchell, 1997). Such applications are described in Chapter 9 (Mapping Applications), and Chapter 15 (Maintenance Applications).
- GIS topology provides information about how the network elements are connected with each other and what is the direction of flow. This capability makes GIS ideally suitable for identifying customers of a utility network affected by service interruption, such as water main leaks and breaks. For instance, the Cherokee Metropolitan District (Colorado) uses a "Water/Wastewater" option on the district's GIS menu to display, plot, and identify the valves to be shut off to repair water system leaks and identify and notify the customers who will be out of water due to the valve closure (Mitchell, 1997). Such applications are described in Chapter 9 (Mapping Applications), and Chapter 15 (Maintenance Applications).
- GIS can be used to satisfy regulatory requirements that are increasingly reliant on computer-generated data and maps. For example, GIS can be used to develop water/sewer system inventory reports and watershed protection/management plans. Such applications are described in Chapter 10 (Monitoring Applications).
- GIS can be used to develop hydrologic and hydraulic (H&H) computer models for water and sewer systems, watersheds, and floodplains. These applications are described in Chapter 11 (Modeling Applications), Chapter 12 (Water Models), and Chapter 13 (Sewer Models).
- GIS can be used to design efficient meter-reading routes. This can be accomplished by linking the customer account database to the streets GIS layer. This application is described in Chapter 9 (Mapping Applications).
- GIS topology can help us to simulate the route of materials along a linear network. For example, we can assign direction and speed to a streams layer to simulate the fate of an accidental contaminant release by a factory through the stream network.
- GIS can be integrated with automated mapping/facilities management (AM/FM) systems to automate inspection, maintenance, and monitoring of water and sewer systems. Sample applications include:
  - Preparing work orders for inspection and maintenance activities
  - Scheduling TV inspection and cleaning of sewers
  - Identifying the valves that must be closed to repair a broken water pipe
  - Keeping track of leak detection survey for a water system

  - Creating a map of customer complaints, pipe breaks, and basement flooding and identifying the reasons
  - Improving management of labor resources through more efficient deployment of field crews. AM/FM applications are described in Chapter 14 (AM/FM/GIS Applications), and Chapter 15 (Maintenance Applications).
- GIS analyses can be used to develop a decision support system for the efficient operation and management of stormwater, best management practices (BMPs), floodplains, combined sewer overflows (CSOs), and sanitary sewer overflows (SSOs). Such applications are described in various chapters of this book.
- GIS can be used to integrate related technologies, such as relational database management systems (RDBMSs), the Internet, wireless communications, CAD, GPS, and remote sensing (satellite imagery). The integrated platform provides the best of all worlds. Such applications are described in various chapters of this book.

Disadvantages

As with any new technology, GIS has some drawbacks. The first issue is the substantial time and cost required to compile and analyze the necessary data. High initial costs are generally incurred in purchasing the necessary hardware, software, and for ongoing maintenance. Though the advantages of GIS applications are dramatic, the failure to effectively implement GIS can lead to disappointment and disillusionment with the technology. Improperly designed and planned GIS applications can result in costly and time-consuming efforts. GIS applications are disadvantageous when one fails to define a vision, understand the vision requirements, define the tools needed to attain the vision, and select appropriate technology to integrate those tools. Only when a GIS is fully understood with proper training and education should one expect its applications to be limitless. Needs analysis, described in Chapter 2, can be used to avoid this pitfall.

Another common pitfall in GIS application development is capturing more data than required by the application. This approach is called a "data-driven" or "bottom–up" approach. For example, a nonpoint source modeling project spent substantial time and effort to capture detailed soils series survey data from the U.S. Natural Resources Conservation Service (EPA, 2000). However, the final application ended up using the Universal Soil Loss Equation for erosion modeling, which required the simpler soil associations data instead of the detailed soils series data. Considerable money could have been saved if an appropriate model and its data requirements had been identified before starting the data conversion process. The use of inappropriate data in GIS applications may lead to misleading results. The data must be of appropriate scale and resolution and highly documented to be useful in GIS applications. Users must be extremely conscious of the nature of the source information to avoid abusive extrapolations and generalizations.

The GIS learning curve, privacy issues, and periodic shortage of skilled personnel are some other challenges of GIS implementation. However, as the *San Diego Union-Tribune* (1998) reports, "Those who overcome such hurdles soon find GIS applications

breathtaking in scope and far-reaching in the potential to affect, if not shape and change, everyday lives."

SUCCESS STORIES

Some compelling examples demonstrating the benefits of GIS applications are described in the following subsections.

San Diego

The City of San Diego was an early convert to GIS technology and is considered a leader in GIS implementation. Having the motto, "We have San Diego covered," SanGIS is a joint agency of the City and the County of San Diego, responsible for maintenance of and access to regional geographic databases for one of the nation's largest county jurisdictions covering more than 4200 mi^2. SanGIS spent approximately $12 million during a 14-year period from 1984 to 1998 to collect GIS data. The conventional surveying approach would have cost them about $50 million (the *San Diego Union-Tribune*, 1998). The GIS/GPS approach has saved the City and the County of San Diego millions of dollars.

If we define a "savings factor" as the ratio of conventional approach (non-GIS) cost (or time) to GIS approach cost (or time), San Diego's success story resulted in a savings factor of 4.2 (50/12) or 420% cost savings.

Boston

The Massachusetts Water Resources Authority (MWRA) provides water and wastewater services to 2.5 million people in 60 municipalities of the Greater Boston area. The MWRA service area spans more than 800 mi^2 that contains several treatment plants, 780 mi of large-size pipelines, and dozens of pumping stations and tunnels. The MWRA recognized the potential for GIS to save ratepayers' money and initiated a GIS program in 1989. As the GIS data have been used repeatedly by individual communities to protect their water resources, the investment continues to pay off years later. For example, their geologic database "gBase" contains information on deep rock borings for the many tunnel and dam projects designed over the past 100 years. Ready access to this information guides current geologic exploration and enables MWRA to better locate new borings, which can cost $20,000 to $50,000 each (Estes-Smargiassi, 1998).

Cincinnati

Faced with a $10-billion network of aging infrastructure that included a water system with a capacity of 50 billion gallons a year, the City of Cincinnati, Ohio, conducted an in-depth feasibility study. The study showed that a GIS would save the City $11 million over a 15-year period, with payback anticipated within 8 years of implementation (American City & Country, 1993).

Knoxville

A $5.5-million GIS project that was started in 1986 jointly by the City of Knoxville, Knox County, and the Knoxville Utility Board (Tennessee) expected to pay for itself within 8 years (Dorris, 1989). In 1992, General Waterworks (King of Prussia, Pennsylvania) owned and managed 34 small- and medium-size water utility companies. The company's GIS experience indicated that a GIS at a medium-size water company can pay for itself in as little as 3 years (Goubert and Newton, 1992).

Dover

The planners in the City of Dover (New Hampshire) used GIS from Intergraph to determine where and how much solid waste needed to be collected and removed. Without GIS, collecting this information would have taken approximately 6 months. Using GIS, it only took a few weeks. This information was provided to bidders to help them base their bids on facts rather than assumptions. This application resulted in lower-priced bids (Thompson, 1991). *This success story resulted in a savings factor of 12 or 1200% cost savings.*

Charlotte

The City of Charlotte and Mecklenburg County of North Carolina, which are among the fastest growing metropolitan areas of the U.S., have developed a Watershed Information System called WISE that integrates data management, GIS, and standard hydrologic and hydraulic (H&H) programs such as HEC-1, HEC2, HEC-HMS, and HEC-RAS. Using this information technology (IT)–based integration method, the existing H&H models can be updated at a fraction (less than $100,000) of the cost of developing a new model (more than $1 million) (Edelman et al., 2001). *This success story resulted in a savings factor of 10 or 1000% cost savings.*

Elsewhere, an ArcInfo GIS software interface with H&H modeling packages HEC-1 and HEC-2 was found to offer substantial cost savings. It was determined that if the H&H models were not linked to the GIS, manual calculations would be required that would take at least five times longer than using the GIS linkage (Phipps, 1995). *This success story resulted in a savings factor of 5 or 500% cost savings.*

Thanks to a GIS approach, planning tasks previously requiring months to complete now take only days in Albany County, Wyoming.

Albany County

Albany County, located in southeastern Wyoming, covers 4,400 mi^2, a student-based population of 30,000, and 1,600 mi of roads. For rural communities like Albany County, building a GIS from scratch can be an expensive endeavor due to a lack of resources. For example, the cost associated with updating the county's existing digital aerial photography was estimated to exceed $100,000. A geographic-imaging

approach consisting of GIS and satellite imagery, on the other hand, allowed the county to have high-resolution and up-to-date views of the entire county for $32,000. Thanks to the GIS approach, planning tasks previously requiring months to complete now take only days (Frank, 2001). *This success story resulted in a savings factor of over 3 or 300% cost savings.*

GIS Applications Around the World

Although most of the GIS application examples in this book are from the U.S., GIS applications for water and wastewater systems are growing throughout the world. In the early 1990s, the United Nations Institute for Training and Research (UNITAR) started to provide GIS training to specialists from developing countries with the broader goal that each participant would eventually establish a foundation for GIS technology in his or her own country. Established in 1992, the Center for Environment and Development for the Arab Region and Europe (CEDARE) recognized that GIS was a key tool for efficient collection, management, and analysis of environmental data in the Middle East. Recognized as one of the best GIS implementations in the world, the Environment Department of the State of Qatar developed a GIS in the mid-1990s and integrated it with their environment management tasks. Fueled by high-resolution satellite imagery from the Indian Remote Sensing (IRS) satellite IRS-1C, the GIS/GPS technology saw a boom in the late 1990s.

The Sistema de Agua Potabley Alcantarillado de León (SAPAL) in León, Mexico, began its GIS implementation in 1993 and built a complete inventory of their water system, including fittings, pipes, and pumps, using ESRI's ArcView and ArcInfo GIS software packages. The Center for Preparation and Implementation of International Projects, Moscow, implemented several environmental management GISs in the Yaroslavl, Vologda, Kostroma, and Ivanovo regions of Russia. The South Australian Water Corporation (SA Water) developed the Digitized Facilities Information System (DFIS) to extract digital data for conceptual design of more than 32,000 km of water and wastewater mains. SA Water's DFIS was used to develop a Water Master Plan for the Indonesian province of West Java for the design, construction, and operation of wastewater treatment, water supply, water storage, and flood control facilities. South Africa's Working for Water organization developed a prototype ArcView GIS-based project information management system to track more than 250 water resources management projects across the country (ArcNews, 2001).

EVOLVING GIS APPLICATIONS AND TRENDS

GIS technology is changing rapidly. New GIS applications are evolving frequently mainly due to the successful marriage of GIS and the Internet. GIS applications are being fueled by the recent advances in wireless, the Internet, networking, and satellite technologies. The cost of spatial data is falling rapidly due to competition in data acquisition, processing, and distribution. More intuitive and simpler interfaces are taking GIS beyond the world of the computer geeks, techno wizards, and GIS gurus. User interfaces are becoming friendlier, wizards are replacing obscure command

lines, and the use of GIS by semiskilled end users is growing (Limp, 2001). These factors are resulting in the evolution of new GIS applications at unprecedented speed. Major evolving GIS applications and trends are listed in the following list:

- Storing both the geographic and the attribute data in one database
- Representing real-world features as objects rather than as geometric entities (e.g., points, lines, and polygons)
- Convergence of image processing and GIS into the large umbrella of information technologies (Limp, 2001)
- Using high-resolution submeter satellite imagery as base maps
- Capturing high-resolution images suitable for photogrammetric analysis using inexpensive and powerful digital cameras
- Using GPS technology for better locations of mobile sensor platforms and ground control points
- Accessing geographic data through wireless application protocol (WAP)–enabled devices, such as cellular phones, personal digital assistants (PDAs), mobile terminals, and pocket personal computers
- Using GIS and hydraulic modeling for vulnerability assessment and security planning to safeguard the water industry against sabotage and potential terrorist attacks
- Integration of computer, video camera, and GPS referred to as "video mapping" to document smoke tests and TV inspection of pipes
- Creation of an accurate virtual reality representation of landscape and infrastructure with the help of stereo imagery and automatic extraction of 3D information
- Rapid emergence of Extensible Markup Language (XML) as the *lingua franca* for data encoding and wireless Web applications
- Evolution of Geography Markup Language (GML) from XML for accurate and effective representation of GIS data in Web browsers (Waters, 2001)
- Evolution of a spatial Network Query Language (NQL) from the structured query language (SQL) for serving GIS data over the Internet, wireless, and PDAs (Waters, 2001)
- Migration from Unix workstations to Microsoft Windows desktop environment

FUTURE APPLICATIONS AND TRENDS

It is a rainy day on May 1, 2010, and it is Chrysa's first day on her new job. Chrysa is a newly hired sewer system maintenance person for a large city. She has a few years of prior sewer maintenance experience, but she is not thoroughly familiar with the sewer system of this city. As she is arranging her modular work space, the customer service department forwards her a basement flooding complaint. She talks to the customer, hangs up the phone, and slips on a headset as she leaves the office. The headset provides an enhanced reality system that combines glasses, earphones, and a tiny microphone, but weighs a little more than a pair of current sunglasses (Turner, 2001). When Chrysa reaches the subject property, she issues a simple voice command to view the buildings and sewer lines superimposed on a 3D wire-frame display of the landscape around her. As she walks around the property, her virtual reality display changes to show what is in front of her. From the 3D displays Chrysa notices that the basement of the subject property is only

slightly higher than the sanitary sewer serving the property. She then uses her wireless and GPS-enabled PDA to connect to and query the City's centralized enterprise database. The GPS automatically identifies the Lot ID, and the database tells her that the subject property's service lateral does not have a backflow prevention valve.

Chrysa's display also appears simultaneously on the office computer and PDA of her supervisor, Brian. Brian sees a shopping center upstream of the property and clicks on it. The computer indicates that the shopping center construction was completed last month. Brian concludes that the new flow from the shopping center is overloading the sanitary sewer and causing the basement flooding. Brian also authorizes Chrysa to make arrangements for the installation of a backflow prevention valve. Chrysa clicks on the service lateral of the property and creates a work order with a few clicks on her PDA. Before leaving the property, she e-mails the work order to the City's sewer maintenance contractor and copies the same to Mr. Jones, the owner of the property.

Such scenarios may seem like science fiction, but much of the technology to support them already is under development or available in prototype form, including high-speed wireless, GPS, and mobile GIS.

Experts believe that in the near future most water industry professionals will be using GIS in the same way they have used a word processor or spreadsheet.

Around the mid-1990s, not too many people were too optimistic about the future of GIS applications. Today, the future of GIS looks bright. GIS is experiencing rapid growth as an information management tool for local and regional governments and utilities because of its powerful productivity and communication capabilities. Many current and evolving GIS applications have been described in the preceding text. Other potential applications will be discovered in the future, as GIS technology and regulatory requirements continue to evolve. All sectors of business and government that depend on accurate geographical information will continue to benefit from GIS applications (Robertson, 2001). In 1999, core worldwide GIS business (hardware, software, services) revenue grew by 10.6% to an estimated $1.5 billion (Daratech, 2000). In 2001, this revenue jumped to $7.3 billion. The world will be very different a decade from now. Advances already underway in IT, communications infrastructure, microelectronics, and related technologies will provide unprecedented opportunities for information discovery and management (Turner, 2001). Looking beyond 2005, GIS-related technologies (e.g., wireless, Internet, networking, GPS, and remote sensing) are expected to do even better. Integration of photogrammetry with other geospatial technologies is opening new doors for exploring and developing alternative spatial applications. The commercial remote sensing market is flourishing and is poised for revenues of $2.7 billion within 3 to 4 years. Location-based wireless services revenues in North America alone are expected to reach $3.9 billion by 2004 (Geospatial Solutions, 2001). A growing GIS market has resulted in lower GIS implementation costs, increased data accuracy, and continued improvement in GIS hardware and software. These developments will help us to develop broader GIS applications (Robertson, 2001).

Future prognosis is a popular hobby of GIS gurus. Most GIS experts believe that the future of GIS looks bright thanks to recent advances in GIS-related technologies. Due to GIS-related innovations, future GIS applications are expected to be centered around commercial remote sensing, location-based services (LBS), mobile GIS, and the Internet. The early 21st century will bring Web-based client/server solutions, interoperability, on-demand data, and software download via the Internet on a pay-per-use basis, and an abundance of online data that can be processed in the field using wireless Web-savvy devices (Waters, 2001). Instead of purchasing GIS data permanently, future GIS users will be able to subscribe to pay-per-view type plans and pay based on the extent and duration of their usage. The technology is moving so fast that you may be using some of these applications by the time you read this book.

Though GIS has come far, big changes are still in the works (Lanfear, 2000).

To some it may appear that the future of GIS is already here; but it is not. Though GIS has come far, big changes are still in the works (Lanfear, 2000). Based on the predictions of some GIS industry experts (Lanfear, 2000; Geospatial, 2001; Engelbrecht, 2001), the following trends are expected in future GIS applications:

- Spatial data will become more widely accepted, unit costs of spatial data will fall, and GIS applications will become more affordable.
- The explosion of spatially enabled consumer products will benefit the entire GIS applications industry. Soon GPS will reside inside our wrist watches. Location information via GPS will become as common as timekeeping on a wrist watch. The new generation of low-cost consumer GPS products and spatially enabled mobile phones and PDAs will provide consistent accuracies of 10 m or better — sufficient to navigate people to their destination.
- As the bandwidth of the Internet improves, it will enable us to deliver information-rich geospatial content directly to end users.
- Wireless Internet use will surpass wired use. By 2005, over 60% of world population will have wireless Internet connections.
- Billions of people will use a Web-enabled mobile device, and millions of those devices will be equipped with LBS capabilities, either through GPS, a wireless network, or a hybrid solution (Barnes, 2001). LBS will combine GIS applications with user-friendly mobile devices to provide needed information at any time or place. LBS devices paired with wireless technologies will provide on-demand geospatial information.
- High-resolution local GIS data will be merged with federal data inventories.
- In addition to GIS input (raw data), the World Wide Web clearinghouses will share the GIS output (processed data) and the processing tools themselves.
- The new generation of raster imaging tools will allow processing of satellite imagery inside spreadsheets and word processors.
- Commercial remote sensing companies will be selling more than satellite images; they will be offering subscription-based monitoring services for change detection and vegetation indices, etc.
- Maps of dubious accuracy will not be digitized into a GIS. Contemporary imagery will be obtained for each unique application or solution.

- There will be a digital database of land-cover imagery and vectors that will include the major landmasses of the entire world.
- Laser imaging detection and ranging (LIDAR) will become a true GIS tool and produce new varieties of GIS data products. Enhanced interpretation of the strength of airborne laser signals will enable automatic creation of low-grade digital orthophotos.
- GIS databases will be connected with real time sensor data inputs, which will provide new opportunities for mapmakers and resellers of GIS products and services. New markets will be developed to expand our selection of data sets.
- Last but not least, the future may create a new set of degree, licensing, and certification programs in the field of GIS.

GIS APPLICATION DEVELOPMENT PROCEDURE

As shown in Figure 1.1, developing GIS applications generally requires six typical steps:

1. Needs analysis (strategic planning)
2. Specifications (system design)
3. Application programming
4. Testing (pilot project)
5. Installation (hardware, software, and data)
6. Ongoing operation and maintenance (includes training)

Most of these activities are generally conducted in a needs analysis study as described in Chapter 2 (Needs Analysis). Step No. 3 requires software development as described in the following text. Step No. 4 is highly recommended because it provides an opportunity to test the system design for a small pilot project area and fine-tune the design and computer programs, if necessary. Pilot testing allows system designers and programmers to tweak the design to meet user needs. Pilot testing can even save money because the data or software can be changed before full

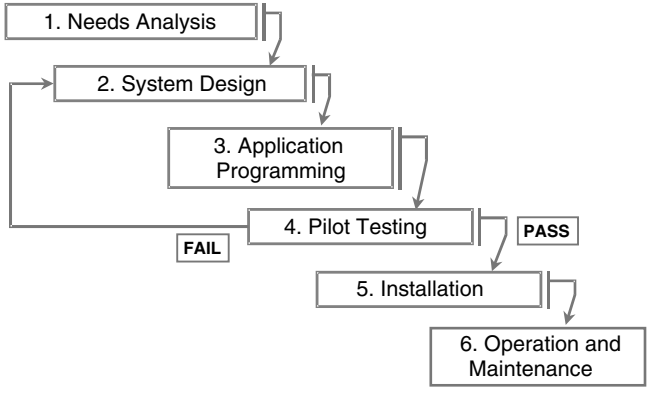

Figure 1.1 Six typical steps for developing GIS applications.

systemwide implementation, at which time it might be too expensive to make major changes.

APPLICATION PROGRAMMING

Application programming means writing the computer programs for GIS applications. Creative application developers strive to develop GIS applications to streamline the operations of their water industry business. They can find something useful in a GIS package and turn it into an innovative application. There are two methods of application programming:

1. GIS-based approach
2. Application-based approach

GIS-Based Approach

The easiest way to develop GIS applications is by extending the core capabilities of a GIS software. In this method, application functions are incorporated in a GIS. Application programs can be developed in a GIS or called from a GIS. This approach provides more GIS capability than the application-based approach. Application capability depends on the GIS software and the method of developing and integrating the application. The flexibility, adaptability, and openness of a GIS software are key to developing applications for that GIS platform. Depending on the complexity of the application, the GIS-based approach can be implemented using one or more of the following four methods:

1. GIS customization
2. Scripting
3. Extensions
4. External programs

GIS Customization

When supported by a GIS package, this method is implemented by customizing the GIS software's graphical user interface (GUI). Examples include adding or deleting a button or pull-down menu. For example, the buttons or menus that are irrelevant to a particular application can be deleted to simplify the learning process and prevent unwanted edits. New buttons or menus can be added to display helpful tips and messages. This method is more suitable for supporting applications rather than developing them. For example, it can be used to add a button that runs another program or script. This method is not very useful when used alone; it is therefore used in conjunction with the other methods described below. When used alone, it does not require computer programming.

Scripting

Scripting is suitable for simple applications such as creating a link to an H&H model. This method requires programming using a scripting language. Scripts are

small computer programs written in a scripting language. A scripting language is a programming language that is (usually) embedded in another product, such as Microsoft's Visual Basic or Autodesk's AutoLISP. ESRI's ArcGIS software (Version 8 and higher) allows programming using Visual Basic for Applications (VBA). Older versions of ESRI's ArcInfo and ArcView software allow programming using Arc Macro Language (AML) and Avenue scripts, respectively. Avenue is ArcView's native scripting language built into ArcView. Avenue's full integration with ArcView benefits the user in two ways: first, by eliminating the need to learn a new interface; second, by letting the user work with Avenue without exiting ArcView (ESRI, 1995). A sample Avenue script for displaying sewer TV inspection video movies in ArcView GIS is given in the following text.

```
theVal = SELF
if (not (theVal.IsNull)) then
if (File.Exists(theVal.AsFileName)) then
 System.Execute("C:\Program Files\Windows Media
Player\MPLAYER2.EXE "+theVal)
else
 MsgBox.Warning("File "+theVal+" not found.,""Hot Link")
end
end
```

This "Movie&ImageHotLink" script enables users to click on a sewer line in the GIS map to play the digital movie of the sewer defect. It receives the movie filename, checks to see if the file exists, and then opens it with a user-specified movie player such as Windows Media Player. The reason for the small size of the script is the fact that it takes advantage of an existing program (i.e., it uses Media Player). Figure 1.2 shows an ArcView screenshot displaying the results of running this script. As the user click on a collapsed pipe, its video file starts playing in the Media Player window.

Figure 1.3 shows the integrated VBA programming interface of ArcGIS 8.3. The left window shows VBA code to automatically assign polygon feature IDs to point features (Lundeen, 2003). For example, this script can be used to create parcel IDs for water meters or to create basin names for manholes. The right window shows the water system layers and parcels in ArcMap. ESRI's ArcScripts Web site is a good place to find downloadable scripts for ESRI GIS software.

Extensions

Extensions are suitable for developing complex applications such as adding raster GIS capability to support hydrologic modeling. Scripts should be compiled and linked to GIS software before they can be executed, which is cumbersome. A set of scripts can be converted to an extension for faster and user-friendly installation and execution. Extensions are special scripts that are loaded into the GIS software to

Figure 1.2 Sample application that plays sewer TV inspection videos in ArcView GIS.

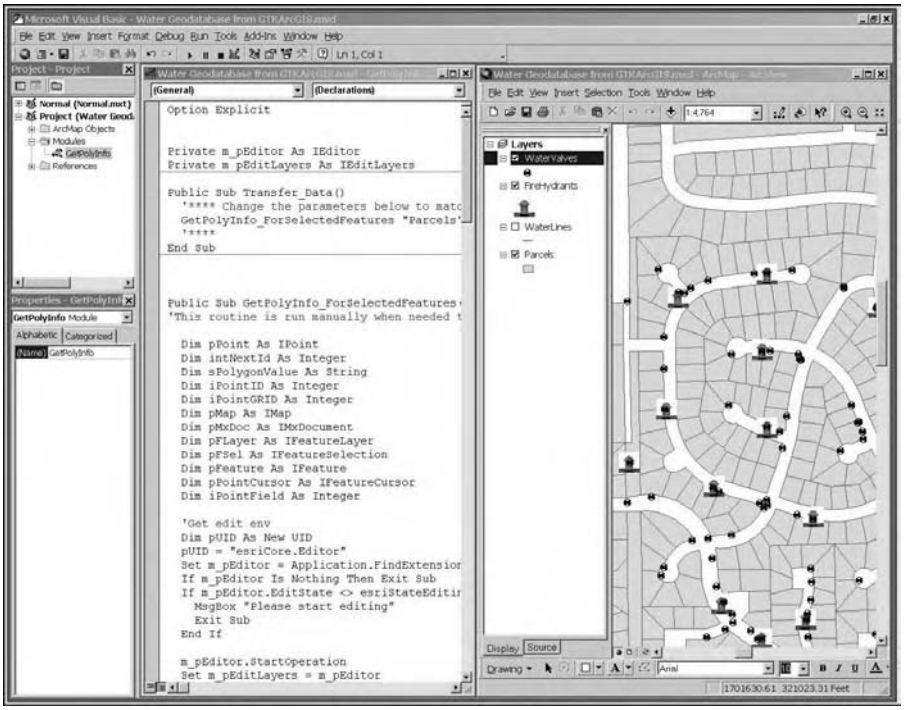

Figure 1.3 Integrated application development environment of ArcGIS (Version 8.3).

increase its capabilities. For example, ArcView 3.2 extensions can be loaded (or unloaded) by selecting them from the File\Extensions pull-down menu. Small basic extensions, such as the "hydro" (hydrology) extension are included with the ArcView software. Hundreds of free basic extensions written by the ESRI software user community can be downloaded from the ArcScripts Web site. Complex special-purpose extensions, such as Spatial Analyst Extension (adds raster GIS capability to ArcGIS) or 3D Analyst Extension (adds 3D capability to ArcGIS) should be purchased separately.

External Programs

Some scripting languages are not suitable for programming mathematically complex algorithms. For many applications (e.g., H&H modeling), the computer code is written and maintained by government agencies. Converting an existing code to a script might be error prone and cumbersome. In these situations, external programs can be called in from inside a GIS. The Movie&ImageHotLink script described earlier uses this method when it uses the external Media Player program. ArcGIS allows developing cross-platform applications with C++ or Java languages.

A dynamic link library (DLL) is an executable module that contains functions or procedures that can be called from an external program. For example, each major

component of the Windows operating system is a DLL. Custom DLLs can be created using languages such as C and C++. Many GIS packages such as ArcView 3.x support DLLs that can be used to provide efficient interfacing with third-party external programs. Functions in DLLs can be called directly from Avenue, and data can be passed back and forth.

Application-Based Approach

In this method, GIS (mapping) functions are incorporated in existing applications. GIS functions are developed in, or are called from, an existing application. This method offers limited GIS and complete application functions. For instance, ESRI MapObjects and ArcObjects software provide programmable objects that can be plugged into VBA applications. RJN Group's CASSView module is an example of this approach. CASSView integrates an infrastructure maintenance management system in MapObjects environment. It requires the RJN CASS WORKS system and a minimum of a geo-coded street centerline to operate. CASSView provides CASS WORKS users with access to maintenance information, as-built records, maps, and GIS data. The end result is a database-driven desktop mapping application that provides visual data on demand.

In-house development of applications requires computer programming skills. It is often difficult to find people skilled in GIS-specific programming languages such as Avenue and AML. For advanced applications, the purchase price of commercial packages is usually less than the labor cost of in-house software development. A large variety of third-party applications from facilities management to H&H modeling is available for purchase from commercial vendors. Most commercially available software is listed in the "Business Partner" page of the GIS software Web site or advertised in the periodicals of the GIS software company.

CHAPTER SUMMARY

This chapter showed that with GIS the possibilities to manage your water, wastewater, and stormwater systems are almost endless. It provides an ideal platform to integrate various business operations and technologies. GIS applications increase worker productivity and save time and money, and are critical to garnering financial support for the GIS departments of an organization. They equip us with better communication and decision-making tools. GIS applications are so numerous that the possibilities can be limited only by our own imagination. The following chapters

will describe the procedures for and examples of developing GIS applications for the typical needs in the water industry. In particular, we will focus on the four areas of applications: mapping, monitoring, modeling, and maintenance. Referred to as the 4M applications, these are most critical to the effective operation and management of water, wastewater, and stormwater systems. Due to recent advances in Internet and wireless technologies, new GIS applications are evolving at an unprecedented rate. It is expected that future GIS applications will be even more exciting than those that have been listed in this chapter. The effect of these new applications will be profound. They will be inexpensive, user friendly, and ubiquitous, and will support the integration of GIS and related technologies in ways unlike anything current water industry professionals have ever envisioned.

CHAPTER QUESTIONS

1. What are GIS applications and how are they developed?
2. What are the pros and cons of GIS applications? How can you avoid the potential pitfalls of GIS applications?
3. What technologies are fueling the popularity of GIS applications?
4. List your ten favorite GIS applications.
5. How will your current GIS needs benefit from potential future GIS applications?

CHAPTER 2

Needs Analysis

A careful needs analysis is critical to successful GIS implementation and should be the first task of any GIS project.

Needs analysis requires a thorough analysis of existing data sources.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand the value and methodology of needs analysis for GIS application projects.

MAJOR TOPICS

- Definition of needs analysis
- Needs analysis steps
- Needs analysis case studies

RDBMS Relational Database Management System

OCEAN COUNTY'S STRATEGIC PLAN

Ocean County Utilities Authority, located in central New Jersey, serves 36 municipalities through three wastewater treatment plants with a combined capacity of 80 MGD. The sewage collection system consists of 200 mi of sewer lines and 40 pumping stations. The Authority developed a GIS program as an integral part of its information technology (IT) strategy. Instead of treating the GIS as a stand-alone system, the Authority envisioned using it as integrated part of its other enterprise systems such as the SAP Maintenance Management System. Authority's IT-based approach included the following steps (Stupar et al., 2002):

- Needs analysis: This step identified goals of the GIS as they related to the Authority's business needs.
- Spatial database design: The objective of this step was to treat GIS data as an enterprise asset. ESRI's geodatabase data model was used to design the database.
- Data conversion: This step involved collecting the needed data and converting it to a geodatabase.
- Application development: This step designed and implemented applications for the GIS.

INTRODUCTION

Needs analysis (or needs assessment) identifies and quantifies the GIS needs of an organization and its stakeholders. Performing a needs analysis is the crucial first step to a successful GIS project. Needs analysis is analogous to strategic planning; it is a blueprint for funding, implementing, and managing a GIS. Like strategic planning, a careful needs analysis is critical to a successful GIS implementation and

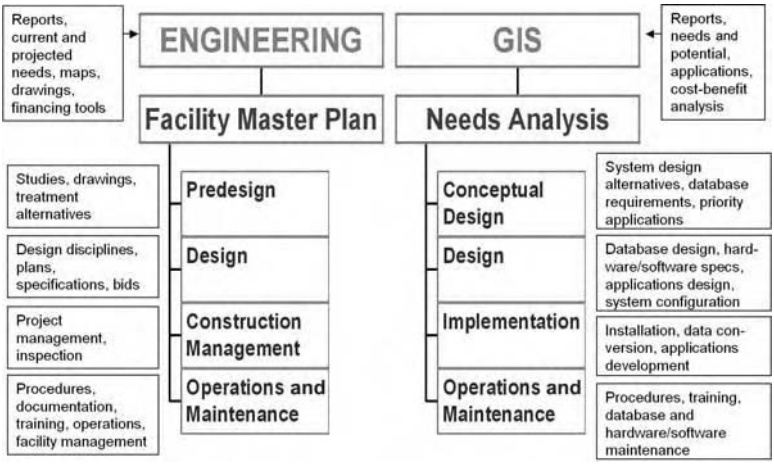

Figure 2.1 Comparison of needs-analysis study and facility master plan.

should be the first task of any GIS project. Needs analysis clarifies the project's specific needs and defines how a GIS will benefit an organization by relating specific organizational resources and needs to specific GIS capabilities (Wells, 1991). There are three major goals of needs analysis:

1. To define current work processes, data, and IT resources in place
2. To determine how the organization hopes to use GIS to streamline its operations
3. To make recommendations defining the path to meet these hopes

Needs analysis identifies potential applications that can be performed more efficiently using GIS technology. The applications are identified through stakeholder interviews and through an inventory of potential data resources.

The needs analysis findings are presented in a needs analysis study or needs assessment report. Depending on the size of the city or the organization, these studies can be generally completed in 6 to 12 months for $25,000 to $100,000. In certain ways, a GIS needs analysis study is analogous to a facility master plan in engineering. Figure 2.1 shows a comparison of the two documents. A facility plan provides information on the design, construction, and operations and maintenance of a structure. A needs analysis study provides the same information for a GIS application.

Table 2.1 lists the potential applications for the Borough of Ramsey, NJ, identified in a 1994 needs analysis study completed by Chester Engineers (Pittsburgh, Pennsylvania). This needs analysis study was completed in 1 year at a cost of $40,000.

NEEDS ANALYSIS STEPS

There are eight typical needs analysis steps:

1. Identify stakeholders
2. Talk to stakeholders

Table 2.1 Potential Applications of GIS Technology

Department	Representative Applications
Public works (responsible for operation and maintenance of the sewer system)	Emergency repair Utility markout Asset management Maintenance tracking and scheduling One-call support Critical water user location Wellhead protection
Engineering and planning	Generation of 200-ft notification lists Demographic analysis Planning review Permit approval Green space analysis Floodplain mapping Drainage management (storm sewer maps)
Tax office	Parcel location and data retrieval Tax-map production Property photo storage and retrieval Automated public access
Public safety	Fire hazard locations Hazardous-materials inventory Hydrant flow data retrieval Preferred hydrant location Crime location analysis

3. Inventory resources
4. Establish need priorities
5. Create system design
6. Conduct a pilot project
7. Prepare an implementation plan
8. Conduct the final presentation

Step 1. Stakeholder Identification

Stakeholders include all the people who can affect or can be affected by a GIS project, such as users, executives, and GIS team members. A broader classification can include users, managers, IT personnel, customers, clients, policymakers, elected officials, politicians, regulators, partners, and funding experts.

Step 2. Stakeholder Communication

This step requires talking with and listening to stakeholders to identify their GIS needs. Some or all of the following formal communication methods can be employed:

1. Introductory seminar
2. Work sessions
3. Focus groups
4. Interviews

The first three methods are optional and can be used depending on the size, scope, and budget of the project. The last method is almost always necessary to perform a comprehensive needs analysis study.

Introductory Seminar

An introductory seminar is warranted if most of the stakeholders are new to GIS. It should focus on three critical questions:

1. What is GIS?
2. Why use GIS?
3. Who else is using GIS?

The first item defines GIS for those new to it. This part should be done in layperson's language. Avoid technical terms and acronyms typically found in a college lecture on GIS-101. The second item answers the question of why GIS is important. It should emphasize that GIS benefits people, it makes things easier to do, and it increases productivity and reduces the cost of business functions. The third item presents compelling examples and success stories from other communities and organizations, such as:

- By using GIS, Charlotte, North Carolina, completed an H&H modeling project initially estimated at $1 million for less than $100,000.
- By using GIS and LIDAR elevation data, Chatham County, Georgia, saved $7 million in construction cost.
- By using GIS, Cincinnati, Ohio, expects to save $11 million in 15 years on a water infrastructure improvement project.

Success stories and associated savings factors presented in Chapter 1 (GIS Applications) can be used to answer questions 2 and 3.

Work Sessions and Focus Groups

These 1- to 2-h management level focus group sessions are conducted to gain a top–down view of the issues confronting the organization. They also allow capture of the business processes that can be enhanced using GIS applications. The discussions lead to establishing goals that can be forged into benchmarks for GIS implementation, such as:

- Creation of a map showing sewer pipes and manholes on an aerial photograph
- Creation of a map showing water mains, fire hydrants, and valves on city streets
- An application running on field (mobile) computers capable of identifying valves that should be closed to isolate a broken water main for repair

Interviews

This is often considered the single most important step in the development of a GIS plan (Henstridge, 1998). A number of selected stakeholders should be interviewed to identify the needs, uses, problems, and requirements the organization has

for GIS and its applications. The interviews should attempt to quantify the cost and effort that can be reduced by implementing GIS. People with good communication skills should conduct this step. You should listen, learn, and encourage audience participation. Prepare a list of questions but avoid distributing a long questionnaire. Do not organize the interviews like a pop-up quiz. The typical interview duration is 1 to 2 h. The key questions that should be explored are:

- Do they want a GIS?
- Do they need a GIS?
- What is their wish list?
- What functions (operations) need to be improved?
- Do these functions need GIS?
- Can GIS improve these functions?
- What are the need priorities?

A GIS vision can evolve during the above communication steps. For large GIS projects, articulating a vision statement is highly recommended because, in the famous words of Yogi Berra, "If you don't know where you're going, you might not get there." The vision should reflect how users envision the business processes working in an ideal way. Most vision statements reflect easy access to accurate information (Zimmer, 2001).

When communicating with stakeholders, remember the famous metaphor, "to a man with a hammer, every problem looks like a nail." GIS cannot and will not solve every problem in an organization.

We sometimes set ourselves up for failure by creating unrealistic expectations of what GIS will do for us. Before the commencement of a needs analysis, some unscrupulous or unknowledgeable salespeople might make unsuspecting users believe that all applications will function flawlessly regardless of the quality or even existence of data. A GIS project's success is measured against expectations. Managing these expectations helps to achieve project goals and claim success. A mismatch between expectations and resources is often a source of GIS failure. Some GIS experts believe that an ill-defined scope and unrealistic expectations are the most common causes of GIS project failures (Somers, 1999; Davis, 2000; Meyers, 2002). Stakeholder communications provide an excellent opportunity to clearly define the scope of a GIS project and manage end-user expectations.

Step 3. Resource Inventory

This step requires inventorying GIS-related resources, such as maps and drawings, spatial and tabular data, databases, IT resources (hardware, software, and network), and the staff skills and interests. This step describes the as-is condition of the organization.

Lehigh County Authority located in Allentown, Pennsylvania, provides water and wastewater services to 12,000 customers in a service area of approximately 50 mi^2. In 1999, the Authority hired a consultant to complete a combined needs assessment and GIS strategic implementation plan. The needs analysis study included a complete

inventory of the Authority's digital and hard-copy data sources and compiled the following list (Babbitt, 2002):

- A 1-in. = 800-ft schematic map
- A series of valve maps for each development
- Some CAD files
- Approximately 900 as-built drawings
- A valve and hydrant database in Microsoft Access
- An in-house customer information system in the ADMINS language

Step 4. Need Priorities

Because it is not feasible to implement a large number of applications simultaneously, the needs identified in Step 1 should be prioritized. This can be done by assigning a priority ranking to needs, such as mission critical, most urgent, very high, high, medium, and low. For example, Lehigh County Authority's needs analysis study identified 34 potential applications. Of these, five were considered high priority based on organization-wide use and business process improvements (Babbitt, 2002).

Remember that the people who are paying for your GIS project would be anxious to see the return on their investment. Applications that can be developed quickly (e.g., digital orthophotos) should, therefore, be given a higher priority to help show early progress during the implementation phase. The applications that are least costly or those that give the "biggest bang for the buck" (e.g., downloadable digital elevation models) can also be assigned a higher priority.

A common approach to implementing this step is to summarize and correlate the interview results into a matrix with priorities assigned to each need. Table 2.2 shows a popular method to quantify the needs by preparing a matrix of needs (applications) and the departments that need those applications. The last column shows the total score of each identified need as the sum of departments requiring that need.

Step 5. System Design

This step recommends a GIS to support the applications identified in the previous steps. It should evaluate the as-is state of the organization relative to key business functions and identify the required elements needed to create the desired improvements. System design includes determining specifications for the following components:

- Data conversion (mapping)
- Database
- Software
- Hardware
- User interface

Data Conversion (Mapping)

Approximately 75% of typical GIS costs are related to data conversion and creation. This component includes data conversion methods (scanning, digitization, etc.)

Table 2.2 Sample Departmental Needs Matrix

	Departments									
Needs (Applications)	**Administration**	**Plants**	**Customer Service**	**Lab**	**Engineering**	**Collection System**	**Shop/Purchasing**	**Pretreatment**	**Solids**	**Total Score**
Public access/general GIS data viewing	☑	☑	☑	☑	☑	☑	☑	☑	☑	9
Emergency management response	☑	☑	☑	—	☑	—	—	—	—	4
Special notification	☑	☑	☑	—	☑	—	—	—	—	4
Customer location and service verification	—	—	☑	—	☑	—	—	—	—	2
Customer service/complaint tracking	☑	—	☑	—	☑	☑	—	—	—	4
Sample point monitoring and tracking	—	☑	—	☑	☑	—	—	—	—	3
As-built indexing	—	—	—	—	☑	☑	—	—	—	2
Work order management	☑	☑	☑	—	☑	☑	☑	☑	☑	8
Project management tracking	☑	—	—	—	☑	—	—	—	—	2
Link TV inspections to GIS/work order management	—	—	—	—	☑	☑	—	—	—	2
Pretreatment tracking	—	—	☑	—	☑	☑	—	☑	—	4
Biosolids tracking	—	—	☑	—	☑	—	—	—	☑	3

and the source, resolution, and scale of the maps or map layers. Needs-driven design is particularly critical for data conversion and database components. The design and content of the mapping and database components determine the fundamental capabilities of the entire GIS. These components can be considered to be the foundation of the system. Once actual implementation has begun, extensive changes to either the mapping or the database design can be very costly. Additional information for this component is provided in Chapter 8 (Mapping).

Database

A GIS database stores descriptive information about map features as attributes. For example, a water system database includes attributes for pipes, valves, meters, hydrants, and so on; and a sewer system database contains attributes for pipes, manholes, catch basins, outfalls, and so on. The creation of an appropriate GIS database is the most difficult and expensive part of developing GIS applications. Successful GIS applications require a database that provides appropriate information in a useful and accessible form. The design of the database is, therefore, driven by application needs.

For data storage and manipulation, a database management system (DBMS) uses a data model, such as a hierarchical, network, or relational data model. Conventional GIS databases consist of graphic features with links or pointers (usually facility identification numbers, or IDs) to related attribute or tabular data. In the late 1990s, a new object-oriented (rule-based) data model was introduced that stores attributes as an intrinsic part of the graphics feature. These modern databases do not require links between features and attributes because they can store both the graphic features and attributes inside a single relational DBMS (RDBMS).

Database design involves three steps: (1) conceptual design, (2) logical design, and (3) physical design (Shamsi, 2002). Conceptual design does not depend on hardware or software. Logical design depends on software only. Physical design depends on hardware and provides a detailed definition of the structure and content of the database. Database design is presented with the help of a data dictionary, which documents the logical and physical structure of the layers of the GIS. Table 2.3 shows a sample data dictionary for a 2000 sewer mapping project in the city of Monongahela, Pennsylvania.

Table 2.3 Sample Data Dictionary

Layer	Name	Class	Attribute	Description
Study area	STUDY	Lines	none	Defines general study area and clips other layers
City boundary	BOUNDARY	Lines	none	Municipal boundary
Roads	ROADS	Lines	none	City streets from CAD file
Railroads	RAILS	Lines	none	Railroads from TIGER file
Surface water	RIVERS	Lines	none	River and creeks from CAD file
Subarea	SUBAREA	Lines	none	Digitized sewershed boundaries
		Polygons	Subarea_id	Subarea identification (ID) number
			Acres	Area in acres
			Mn_percimp	Mean percentage imperviousness
			Pop	Population
			Mn_popden	Mean population density
			Houses	Number of houses
			Mn_famsize	Mean family size
			Mn_mktval	Mean market value
			Mn_medinc	Mean median family income
Sewers	SEWERS	Lines	None	Collection system sewers
Interceptor	INTERCEP	Lines	None	Interceptor sewers
Treatment plant	TREATMNT	Lines	None	Treatment plant footprint
CSO discharge point	CSO	Points	Cso_id	ID Number of combined sewer overflow (CSO) discharge points

For detailed information on water, wastewater, and wastewater system database design, please refer to the author's companion book *GIS Tools for Water, Wastewater, and Stormwater Systems* (Shamsi, 2002).

Software Selection

GIS software represents less than 10% of the total GIS cost in most cases, yet people spend a lot of time in selecting the best software for their GIS applications. Many users are so proficient (and sometimes loyal) in using a given software that they will lose interest in GIS if they are not allowed to use their favorite GIS software. Because user needs are key to the success of a GIS project, their preferences should be taken seriously. Thus, despite its relatively lower cost, GIS software can have a significant impact on the success of a GIS project.

GIS software should have an "open" architecture. An open GIS allows for sharing of geographic data and integration among various GIS, GIS-related (e.g., remote sensing), and even non-GIS (e.g., hydraulic modeling) technologies. An open GIS can operate on different operating systems, platforms, and database management systems. It can be scaled to support a wide range of application needs, from an office engineer using GIS on a desktop, to a mobile field technician using a handheld device, to hundreds of users working on an enterprise system across multiple departments.

Today, GIS development software used for data conversion work is almost always a commercial off-the-shelf (COTS) program because custom development would be simply too expensive. Many commercial packages are available for implementing common GIS applications, such as work order management. Thus, no software development is necessary for data conversion or application software because reinventing the wheel is "penny-wise and pound-foolish." Some U.S. government agencies that invested in developing their own home-grown GIS packages did not see a return on their investment (Henstridge, 1998a). Custom development is warranted if COTS packages are not available for an application or if they are too expensive. As described in the following text, creation of a custom user interface also requires software development.

Custom software can be developed in-house if computer programmers skilled in the GIS-specific programming languages are available. If this is not possible, consultants can be hired. Development and (often overlooked) maintenance costs are the major disadvantages of in-house development. For some organizations (e.g., consultants) an advantage of the in-house software is the competitive edge of proprietary packages.

A needs analysis must carefully select an appropriate GIS software for the GIS needs of an organization. Fortunately, the field has narrowed and there are only a few major vendors today (Henstridge, 1998a). Some needs analysis studies utilize a decision matrix of user needs (applications) and available software capabilities to help select the most appropriate software. For example, Table 2.4 shows a sample decision matrix for various applications of a typical water utility that uses an ESRI GIS platform. This table indicates that ArcView, ArcInfo, and Spatial Database Engine (SDE) should be given high priority because they are required to implement all the GIS applications of the organization.

Table 2.4 Software Selection Matrix Example

Application	AV	SA	NA	3DA	AI	SDE	AO
Planning and engineering	🖫	—	—	🖫	🖫	🖫	🖫
Operations and maintenance	🖫	—	🖫	—	🖫	🖫	🖫
Construction	🖫	—	🖫	—	🖫	🖫	🖫
Infrastructure management	🖫	—	🖫	—	🖫	🖫	🖫
Water resources and hydrology	🖫	🖫	—	—	🖫	🖫	—
Finance and administration	🖫	—	—	—	🖫	🖫	—

Notes: AV = ArcView; SA = Spatial Analyst; NA = Network Analyst; 3DA = 3D Analyst; AI = ArcInfo; SDE = Spatial Database Engine; and AO = ArcObjects.

Hardware Selection

The selection of appropriate GIS hardware depends on the scope of the GIS application project and the available resources. GIS hardware can be set up as a stand-alone workstation or in a network configuration. Typical hardware requirements are listed in the following text:

- Computer with fast processor, large memory, and extensive disk space
- DVD drive
- Large-screen, high-resolution, color monitor (21 in. minimum)
- Backup and storage device, such as a CD or DVD burner
- Color printer
- Large-format (wide-format) color plotter
- Digitizer
- Large-format scanner
- High-speed Internet connection (T1, cable, or DSL)
- GPS receiver
- Computer server (for networked configurations)

Hardware can be expensive, but like the GIS software, the hardware for a typical municipal GIS accounts for less than 10% of the total GIS investment. Thus, cost alone should not be used in hardware selection. The following additional factors should also be considered: service and support, capacity for growth (storage and memory), connectivity with peripheral devices (plotters, scanners, digitizers, GPS equipment, and field computers), and connectivity with Internet and networks (intranets and extranets). When comparing prices and hardware features, remember the golden rule: You get what you pay for. Another valuable advice for hardware procurement is: Try before you buy.

Today's laptops are just as powerful as desktops. For certain users, like a GIS manager who must commute between different offices, a laptop computer might be more suitable than a desktop computer. The laptops cost more but are worth the extra money for mobile users. As of 2003, the minimum requirements for a laptop to be able to run GIS software are: a 1.7 GHz processor; 512 MB memory; 60 GB hard drive; 1280 x 1024 resolution, 32-bit color XGA screen; DVD R/RW drive; Internal 56K modem; and an Ethernet or wireless Local Area Network (LAN) (Thrall, 2003).

Client/server architecture is a common computer system configuration in which one main server stores and distributes all data. Workstation users, called "clients," access and manipulate server data using client software installed on the workstation computer. A network-based design is necessary if more than one person will need to access the same GIS data, i.e., when a team rather than an individual is working on a project. For an individual researcher doing a thesis or term project, a personal workstation is sufficient. However, in real-world projects the entire project team must share the data, which requires a client/server architecture. Server maintenance is absolutely necessary. Without a dedicated technician, the client/server architecture is difficult to maintain.

Wide- or large-format plotters allow printing on 24- to 60-in. rolls. Today's wide-format plotters are available in both ink and laser technology. The cost depends on resolution, color, and speed. Common inkjet plotters range from $2,500 to $25,000. Common laser plotters range from $15,000 to $175,000. When budgeting for hardware cost, do not forget to include the maintenance cost; for example, supplies for printer and scanner such as toner, ink cartridge, paper rolls, etc. Compare the up-front cost of a laser printer to the savings of not replacing cartridges (approximately $40 each). The maintenance cost can range $100 to $500 per month based on usage. Thus, when pricing a plotter, do not forget the cost of media and ink. Compare the plotters using a cost-per-page figure for different media types. Make sure that the plotter you choose can handle a large number of plots per day at the quality you prefer. Request for a demonstration and plot your own maps before making the final selection. Some manufacturers like Hewlett Packard allow trading in the old plotter toward the purchase of a new one and have lease options starting at less than $100 per month.

As of 2000, ESRI software runs on many platforms including Digital Tru64 UNIX and Alpha Windows NT, IBM, AIX, HP-UX, Microsoft Windows 95/98/NT/2000, NEC EWS-UX, SGI IRIX, and Sun Solaris. Linux is being evaluated and tested as a viable platform (ESRI, 2000).

Orange County Geomatics/Land Information Office started to provide enterprise-wide access to GIS data in 1997 using hardware and software from Intergraph. Their Oracle database containing 7 GB of attribute information resided on a 200 MHz Quad Pentium Pro with 256 MB of RAM. The data could be viewed using Intergraph's MGE product suite (Goldstein, 1997).

Table 2.5 provides sample hardware and software specifications for a single-user installation specified in a 1994 needs analysis study for the Borough of Ramsey, New Jersey. The 1994 cost for this setup was approximately $3000. Table 2.6 provides hardware and software specifications and the approximate cost specified in 2000 for a four-seat, server-based GIS laboratory. The 2000 cost for this setup was approximately $145,000. A comparison of Table 2.5 and Table 2.6 indicates that computer hardware has changed substantially within the period of 6 years from 1994 to 2000.

User Interface

A user interface is a computer program that acts as an interpreter between the user and a computer. It generally operates on top of a GIS package as a menu-driven shell to the software's commands. A graphical user interface (GUI) is a popular

Table 2.5 Single-User Hardware and Software Specifications (Year 1994 Example)

Component	Recommended Specifications
CPU	Intel Pentium, 256 KB RAM cache
Video card	VL-bus Windows accelerator capable of 72 Hz vertical refresh rate at 1024 x 768 resolution with 256 simultaneous colors, noninterlaced
Monitor	17 in. size, performance to match video card, 0.28 mm dot pitch
RAM	16 MB, expandable to 32 MB, 36-bit SIMMs
Hard drive	500 MB IDE
Floppy drives	One 3.5 in. (1.44 MB), one 5.25 in (1.2 MB)
Expansion slots	Eight ISA slots, including two VL-bus slots
Drive bays	Total of five half-height bays, three with front access
Fax modem	14,400 bps Hayes compatible, internal
Printer/plotter	HP 650C DesignJet
Software	DOS 6.0, Windows 3.1, ArcView

type of user interface that replaces difficult-to-remember text commands by interactive computer graphics consisting of menus, dialogue boxes, input and output windows, and icons (Shamsi, 1997). For example, Internet Explorer™ is a GUI for the World Wide Web.

Creation of a custom GUI is optional. It is recommended when the GIS functions are very complex and/or the end users are complete novices. A custom GUI provides access (links) to all the GIS functions of an organization from a single program (screen) that bears the organization name and corporate logo. A custom GUI can also be used for user authentication using passwords.

Table 2.6 Hardware and Software Specifications, and Cost of a Four-User GIS Laboratory (Year 2000 Example)

Item	Year 2000 Cost ($)
One 400 MHz Pentium II NT server with 256 MB 100 MHz SDRAM, 3 x 4 GB hot swap hard drives, and Uninterruptible Power Supply (UPS)	9,000
Four Pentium II personal workstations (400 MHz, 128 MB RAM, 4.3 GB hard disk, writeable CD-ROM) with 21 in. monitors ($4,000 per workstation)	16,000
UPS backup for all personal workstations ($300 each)	1,200
Large-format color scanner with floor stand Calcomp ScanPlus III 800C (A–E size, 800 dpi max resolution)	20,000
Flatbed desktop scanner	100
Digitizer (42 x 60 in.) with floor stand. Must be WinTab compliant. Calcomp Summagrid V or GTCO Accutab.	10,000
Color plotter. Must be E size (36 in. wide). HP DesignJet 750C Plus (36-in.-wide sheet roll)	7,500
B&W LaserJet printer (HP LaserJet 5 or better)	500
Color inkjet desktop printer (HP DeskJet 1600C or better)	500
Iomega 2 GB Jaz drive for backup	500
ARC/INFO NT bundle 4 seats (includes ARC/INFO, ArcView, and ArcView extensions) ($20,000 each)	80,000
Total Cost	**145,300**

Some GIS packages allow customization of their default interfaces with little or no programming to meet user-specific needs. When available, this feature can be used to create simple GUIs. Custom GUIs for complex applications require computer programming or scripting. Custom GUI development needs will be gradually reduced and eventually eliminated as GIS packages complete their migration from a command-based to an interface-based environment.

Step 6. Pilot Project

This is a very important step. Inclusion of a pilot project in a GIS implementation plan allows the project team to test an initial strategy before committing to a specific course of action. For example, database design determines the fundamental capabilities of the entire GIS. Once actual implementation has begun, extensive changes to database design are very costly. Thus, before a systemwide implementation, the initial database design and data conversion methodology should be evaluated for a small portion of the project area (pilot area). The pilot project allows you to test the system design, evaluate the results, and modify the system design if necessary. It provides an opportunity to refine the proposed approach to full-scale data conversion and implementation. This step should also produce a working demonstration of the intended applications for the pilot area.

The Washington Suburban Sanitary Authority (WSSC) is among the ten largest water and wastewater utilities in the U.S. According to the 2003 records, it serves 420,000 customer accounts, provides water and sewer services to 1.6 million residents in a nearly 1000 mi^2 area, and employs more than 1500 people. In the early 1990s, WSSC undertook GIS implementation as a cooperative effort with five other regional agencies. The interagency organization called Geographic Information System for Montgomery and Prince George's Counties (GeoMaP) proceeded with studies to assess needs, analyze requirements, and evaluate alternatives. A detailed GIS system design was then completed for specifications of database, data conversion, hardware, software, and communications network. A pilot project was completed to evaluate the system design prior to full-scale implementation. The pilot was intended to be the first phase of GIS implementation rather than a separate experimental effort or prototype. The pilot project developed all components of the proposed database design for sample areas and designed and developed a sample set of GIS applications. The water and sewer facility layers were structured as ARC/INFO network coverages to support network analysis applications as well as to provide standard water and sewer reference maps. The sewer layer was found much easier to develop than the water layer (Cannistra et al., 1992).

Mohawk Valley Water (MVW) is a water utility serving more than 125,000 people in approximately 150 mi^2 area in central New York. MVW completed a 6-month pilot project in 2002 to develop a water distribution system geodatabase using ESRI's ArcGIS, ArcIMS, and ArcSDE software and a hydraulic model using Haestad Method's WaterCAD software. The pilot project covered approximately 5% of the representative distribution system area including three storage tanks and two pumping stations. The database design used ESRI's Water Distribution Data Model. A major goal of the pilot project was to estimate the time and money required to

implement GIS and hydraulic modeling in the entire system (DeGironimo and Schoenberg, 2002). Another pilot project example, for the Borough of Ramsey, is described later in this chapter.

Step 7. Implementation Plan

An implementation plan identifies specific actions and resources required to implement a GIS. It provides information on schedule, cost, staffing, training, and operation and maintenance. It is used by a project or program manager to build the GIS, so it should be as detailed as possible. Phased implementation is preferable. The phases should be designed to distribute the cost evenly and to allow a comfortable pace over the project duration. Schedule success into your project schedule. Create your implementation plan with a few small but early successes to help you sustain the momentum over potential rough spots. Plan for early success by first implementing quick and high-impact applications that can be put to use right away. GIS integration with other information systems and applications (e.g., hydraulic modeling) is beneficial but technically complex. Because clearly identifiable benefits should be achieved in the earlier phases of an implementation plan, integration tasks should be scheduled for later phases where possible.

A successful implementation plan should be based on a holistic approach that achieves balance among stakeholders, technology, time, and budget.

Define key success factors before starting. Treat the success factors — such as acquiring hardware, installing and testing software, conducting training and workshops, populating the database, testing the database, and developing applications — as milestones. Project milestones provide a ruler against which success can be measured. Hitting these milestones will show the success of your GIS in clearly demonstrable ways and will allow you to measure success in small steps along the way. The milestones should specify the data sets, applications, and user access. A milestone like "Hydraulic Modeling by January 2004" leaves too much room for interpretation and, thus, dissatisfaction. A more useful milestone would be "Linking the water layer to EPANET model for the Engineering Department by January 2004."

User involvement is a key factor in the success of a GIS project. They should be incorporated in all stages of GIS development, rather than only in the needs analysis interviews. User training is paramount to the success of a GIS application project after it has been implemented.

The implementation plan should identify GIS staffing needs. This requires understanding the composition of the user community. When considering the best approach to GIS staffing and expertise investments, four factors should be evaluated: GIS expertise requirements, GIS project situation (e.g., early or later project phases), internal environment (e.g., hiring policies and procedures), and external environment (e.g., job market) (Somers, 1999a). All alternatives to fulfill GIS staffing needs including training existing staff, hiring new personnel, and using contractors and consultants should be evaluated. In-house projects do not require capital funds, and internal staff is more

familiar with source documents. Contractors can usually complete the projects faster because they have specialized experience, more workers, and higher productivity.

The long-term viability of a GIS requires ongoing maintenance. Maintenance activities include updating the GIS data layers to reflect changes such as new streets, subdivisions, or sewer lines. Such routine maintenance activities can be contracted out on an hourly basis. The typical data maintenance cost for medium-size communities is $3000 to $5000 per year. The implementation plan should provide the maintenance procedure and responsibility for each layer in the GIS. For example, standards for site plans from developers and engineers should be developed so that changes can be easily incorporated into the GIS. Today, most plans are available in AutoCAD DXF or DWG file format and might require a data conversion effort for incorporating them into a GIS. For ESRI users, the Shapefile will be a more suitable format for accepting the site plans. If required, multiple-user editing of GIS layers should be provided by selecting appropriate GIS software. Separate operations and maintenance (O&M) manuals should be developed for large installations.

Procedures for obtaining ongoing operations support should be recommended. Today, annual software support can be easily purchased with the software. On-site

Table 2.7 Implementation Priorities and Project Phases

Needs (Applications)	Total Score	Cost to Implement	Difficulty to Implement	Mission Critical	Project Phase	Data Type
Public access/general GIS data viewing	9	L	L	VH	1	Core, facility, department
Work order management	8	M	L	VH	1	Core, facility
Emergency management response	4	M	L	H	1	Core, facility
Special notification	4	L	L	M	1	Core, facility
Customer service/complaint tracking	4	M/L	L	H	1	Core, facility
Pretreatment tracking	4	L	L	M	2	Core, facility, department
Sample point monitoring and tracking	3	L	L	L	2	Core, facility, department
Biosolids tracking	3	L	L	L	2	Core, facility, department
Customer location and service verification	2	M/L	M	H	1	Core, facility
As-built indexing	2	M	M	M	1	Core, facility
Project management tracking	2	M	M/L	M/L	2	Core, facility, department
Link TV inspections to GIS/work order management	2	M/H	M/H	M	1	Core, facility, department

Notes: L = low; M = medium; H = high; VH = very high; M/L = medium/low; and M/H = medium/high.

troubleshooting support can be obtained from consultants on an hourly or incident basis.

Finally, perceptions and expectations and hence the needs of people often change with time. A GIS implementation plan, especially if it is a long one, should be flexible to accommodate changes in organizations, people, and technology.

Table 2.7 shows a sample implementation plan summary. The first two columns show the needs and their scores from Table 2.2. Columns 3 to 5 assign rankings based on cost, implementation difficulty, and mission criticality, respectively. The sixth column assigns a project phase based on columns 2 to 5. The last column shows the data type required for each identified need.

Step 8. Final Presentation

This presentation should be conducted for the same audience that attended the introductory seminar. It should summarize the findings of the needs analysis study. The presentation should also include a live demonstration of the pilot project.

NEEDS ANALYSIS EXAMPLES

Some needs analysis examples are given in the following subsections that demonstrate the results of conducting various needs analysis steps described in the preceding text.

Pittsburgh, Pennsylvania

The city of Pittsburgh performed an in-house needs analysis in 1984 that spanned a period of 4 years and took 18 months of staff time (Wells, 1991). The heart of this needs analysis was a comprehensive inventory of existing files and maps. The needs analysis listed major functions and responsibilities of each city department. The major GIS applications included:

- Maintaining infrastructure maps and inventories
- Allowing network tracing and analysis for water, sewer, and stormwater systems
- A water and sewer facilities management system
- Computing shortest routes for emergency response and work crews
- Permit processing
- Address matching
- Producing maps
- Enhancing property and business tax administration
- Automating acquisition, maintenance, and disposal of tax-delinquent properties
- Integrating census and municipal data for community planning and budget analysis
- Facilitating production of routine reports, tables, form letters, and mailing lists
- Creating and maintaining disaster preparedness map layers (hazardous-material sites, hospitals, group care facilities, etc.)

Once the needs analysis was completed, the city hired a consultant (PlanGraphics, Inc.) to procure a GIS implementation project. The consultant translated the city's GIS needs into the following technical specifications:

- Database structure
- Data entry
- Graphic data manipulation
- Database query
- Data output and display
- User-directed software development
- System operation
- Applications
- System configuration and hardware

The consultant prepared a Request for Qualifications (RFQ) and Request for Proposals (RFP). The RFQ was sent to 80 firms and the RFP was sent to 11 firms. The proposals were submitted by five vendors.

Borough of Ramsey, New Jersey

The Ramsey Board of Public Works is responsible for the operation and maintenance of water distribution and sanitary sewer collection systems throughout the Borough of Ramsey. These operations necessitate the daily use of a variety of map products and associated geographically referenced (or "georeferenced") information resources, which describe or are related to a specific location, such as a land parcel, manhole, sewer segment, or building. In an effort to more efficiently manage its geographically referenced data, the board started to explore the benefits and applications of GIS technology and computer mapping in early 1993. As a first step, with the assistance of Chester Engineers, Inc. (Pittsburgh, Pennsylvania), they started a GIS pilot project (Shamsi et al., 1996). The goals of the pilot project were to:

- Thoroughly evaluate the benefits and costs of a GIS
- Develop specifications for GIS implementation
- Confirm the suitability of tasks selected for GIS automation
- Demonstrate GIS functional capabilities
- Firmly quantify unit costs of GIS implementation
- Demonstrate GIS benefits to the departments not participating in the pilot project
- Identify any technical problems
- Provide immediate tangible benefits
- Assess the quality of existing records and procedures

The GIS pilot project produced a GIS Needs Assessment Report, a GIS Implementation Plan, and a functioning GIS demonstration system for a selected portion of the borough. With the knowledge and experience gained from the pilot project, the board was prepared to pursue a broader implementation of GIS technology. The geographic limits of the pilot project area were selected on the basis of two criteria:

- Size: large enough to allow realistic evaluation, small enough to be affordable
- Location: encompassing a portion of the borough where activities supported by priority applications are likely to occur

The selected pilot area measuring approximately 2600 ft × 2600 ft was located in the central portion of Ramsey. The pilot project was completed in 1 year for approximately $40,000 (in 1994 dollars).

From the applications listed in Table 2.1, the following two priority applications were selected for pilot testing:

1. Public Works Department: Management of infrastructure asset location information to support emergency repair and utility markout functions. The GIS will automate the storage and retrieval of location and maintenance data for water and sewer infrastructure. Expected benefits include more rapid emergency repair response, more efficient utility markouts, and more efficient scheduling of routine maintenance.
2. Planning Department: Generation of 200-ft notification lists as part of plan review process. GIS automation will generate a 200-ft buffer, identify affected parcels, retrieve lot and block numbers, retrieve property owner names and addresses, and print a notification list. GIS benefits are expected to dramatically reduce the time required to complete these tasks.

The City of Bloomington, Indiana

The City of Bloomington (with a population of approximately 60,000) started their GIS strategy with a needs analysis in 1989. They completed their base map by the end of 1993, and got the system fully functional in the next year. They stored the GIS map and Oracle RDBMS data on workstations located at Bloomington's Utilities Service Center and distributed them through a fiber-optic network to city hall and to police and fire departments. The GIS software was loaded on ten Unix workstation host machines, most of which supported a number of X-terminal and P users across the network (Goldstein, 1997).

San Mateo County, California

San Mateo County, also referred to as the "Gateway to Silicon Valley," has approximately 200,000 property parcels and covers 552 mi^2. In 2001, the county started development of an enterprise-wide GIS base map. A success factor for the project was that all aspects of its development were planned and agreed on by all the stakeholders before the project started. A GIS Steering Committee, in consultation with a larger group of county departments, hired a consultant (GIS Consultants, Inc.) to conduct a needs analysis, which resulted in a strategic plan. Thereafter, a specific implementation plan was designed for base-map construction, followed by detailed and complete specifications and preliminary cost estimates. Formal needs analysis efforts were credited for the timely completion of base-map creation, hardware and software purchase, and training (Joffe et al., 2001).

CHAPTER SUMMARY

This chapter described the importance and benefits of a needs analysis prior to implementing a full-scale GIS project. Various steps involved in needs analysis were explained. When carefully done, needs analysis clarifies the project's specific needs,

provides a process for arriving at interdepartmental understandings about the objectives and limits of a project, and establishes a detailed basis for developing GIS maps and applications.

CHAPTER QUESTIONS

1. What is needs analysis? How does it compare to strategic planning and facility master planning?
2. What steps are recommended for needs analysis? Which step is most critical?
3. What is a pilot project? What are the benefits of conducting a pilot project?
4. How would you prepare a needs analysis study for a water system mapping project?
5. You are tasked with integrating a large city's H&H model with the city's GIS. What will be your first step and why?

CHAPTER 3

Remote Sensing Applications

Can a satellite 400 miles above the ground surface help you locate a leaking pipe? Read this chapter to find out.

The Landsat 7 Enhanced Thematic Mapper (ETM+) scene of the lower Chesapeake Bay region acquired on July 5, 1999 (Image courtesy of USGS).

LEARNING OBJECTIVE

The learning objective of this chapter is to comprehend the applications of remote sensing technology in the water industry.

MAJOR TOPICS

- Remote sensing satellites
- Applications of satellite imagery
- Types of remote sensing data
- Digital orthophotos
- Using remote sensing for land-use classification
- Image processing software
- Anticipated future trends

LIST OF CHAPTER ACRONYMS

DEM Digital Elevation Model
DOP Digital Orthophoto
DOQ Digital Orthophoto Quadrangle
DOQQ Digital Orthophoto Quarter Quadrangle
LIDAR Laser Imaging Detection and Ranging
LULC Land Use/Land Cover
TM Thematic Mapper (onboard Landsat satellite)
USGS United States Geological Survey

ALBANY COUNTY'S REMOTE SENSING APPLICATION

Public-domain digital aerial photography data, such as USGS digital orthophoto quadrangles (DOQs) and digital orthophoto quarter quadrangles (DOQQs), usually become outdated in rapidly developing areas. For such areas, high-resolution satellite imagery may be a cost-effective source of more recent overhead images.

Albany County, located in southeastern Wyoming, covers 4,400 mi^2, has a student-based population of 30,000, and has 1,600 mi of roads. For rural communities such as Albany County, building a GIS from scratch can be an expensive endeavor due to lack of resources. The County's day-to-day mapping functions required a data layer of imagery for the entire county. Various data options were reviewed, including aerial flights, existing DOQs, and satellite imagery. New aerial imagery was eliminated because it was too expensive. Existing DOQs were not suitable because they were 7 years old and did not reflect recent county growth trends. In addition, costs associated with updating the County's existing digital aerial photography exceeded $100,000. High-resolution satellite imagery, on the other hand, allowed the County to have high-resolution up-to-date views of the entire county for $32,000. For 85 mi^2 of populated areas, the County selected 1-m pan-sharpened IKONOS satellite imagery (described later in this chapter). For the rest of the county, 90 quads of

CARTERRA DOQ 5-m black and white (B&W) imagery was selected. Both products were produced by Space Imaging (Thornton, Colorado). Thanks to this geographic-imaging approach, planning tasks previously requiring months to complete took only days after the County implemented this project (Frank, 2001).

In the Albany County of Wyoming, addition of high-resolution up-to-date imagery to GIS data reduced the completion of typical planning tasks from months to a few days.

INTRODUCTION

The technologies that are commonly used in conjunction with GIS are commonly referred to as GIS-related technologies. Examples include remote sensing, global positioning system (GPS) surveying, the Internet, and wireless technologies. This chapter will focus on remote sensing, one of the most successful GIS-related-technologies. Other related technologies are described elsewhere in the book.

Remote sensing allows obtaining data of a process from a location far away from the user. Remote sensing can, therefore, be defined as a data collection method that does not require direct observation by people. Remote sensing is the process of detection, identification, and analysis of objects through the use of sensors located remotely from the object. Three types of remote sensing systems are useful in the water industry:

1. Aerial photographs
2. Satellite imagery
3. Radar imagery

The data from these systems are commonly referred to as remote sensing or remotely sensed data. Sometimes, remote sensing data are incorrectly confused with supervisory control and data acquisition (SCADA) data used to operate water and wastewater treatment plants. Remote sensing data collected using airplanes are called aerial photographs or aerial photos. Digital remote sensing data collected from satellites are called satellite imagery or images. Digital pictures of the Earth are taken by satellites from 400 to 500 mi above the ground compared with aerial photographs that are taken by aircraft from 1 mi above the ground (for low-altitude photography) to 7 to 8 mi above the ground (for high-altitude photography). The chart in Figure 3.1 shows the altitude difference between the aircraft- and satellite-type remote sensing systems. Radar imagery or images are another type of remote sensing data but their usage is not widespread in the water industry. Although the definition of remote sensing includes aerial photos and radar data, remote sensing is often considered synonymous with satellite imagery.

The American Society for Photogrammetry and Remote Sensing (ASPRS) values the U.S. remote sensing industry at about $1.3 billion (as of 2001) and forecasts 13% annual growth, giving values of $3.4 billion by 2005 and $6 billion by 2010. The industry currently consists of about 220 core companies employing about 200,000 employees in the areas of remote sensing, photogrammetry, and GIS imaging. A 2001

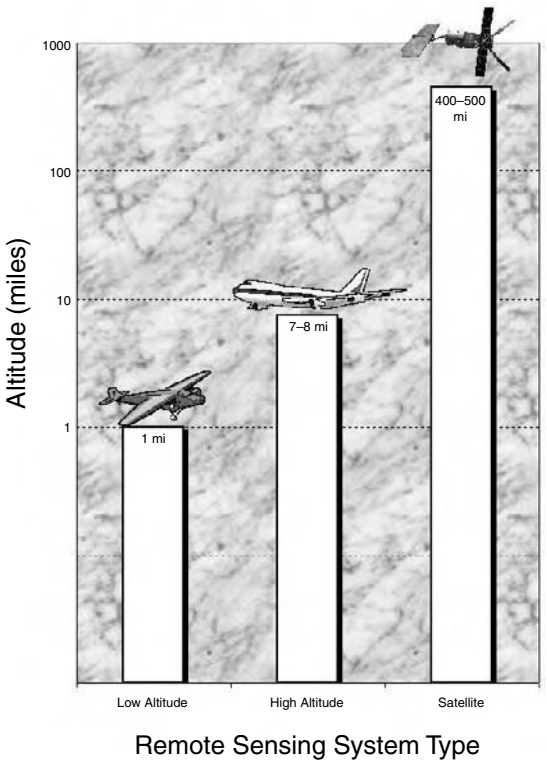

Figure 3.1 Altitude difference in aerial photography and satellite imagery.

ASPRS study concludes that utilities are one of the greatest untapped potential markets and that a shortage of trained workers is one of the greatest challenges to the growth of the remote sensing industry (Barnes, 2001a).

Although vector GIS data are still an important and vital tool for many water industry applications, the newer raster GIS applications of satellite imagery are beginning to make a major move into the GIS and mapping market. The benefits of satellite imagery are (Schultz, 1988):

1. They enable aerial measurements in place of point measurements.
2. They offer high spatial and/or temporal resolution.
3. All information is collected and stored at one place.
4. Data are available in digital form.
5. Data acquisition does not interfere with data observation.
6. Data can be gathered for remote areas that are otherwise inaccessible.
7. Once the remote sensing networks are installed, data measurement is relatively inexpensive.

Satellite imagery is stored in a pixel (raster) format that makes it ideally suited for incorporation into a GIS (Engman, 1993). Thus, satellite imagery can be treated as raster-type GIS data. Image processing equipment and methods can be used to

extract useful information from hard copy and digital images and combine it with other data layers in a GIS. Image data sources including scanned paper maps, aerial photographs, and satellite imagery can be used in a GIS when reprojected as image maps. Projected images can be used as a background or as a base map upon which other vector layers are overlaid.

Casual GIS users can easily import remote sensing imagery into their GIS projects as an image theme (or layer). However, advanced remote sensing applications and image analyses require formal remote sensing training and digital image processing skills. The incorporation of remote sensing data in a GIS requires a digital image processing software such as ERDAS IMAGINE, Geomatica, ER Mapper, or ENVI, or a raster GIS software with image processing capability, such as ArcGRID or IDRISI. Such programs are described later in this chapter.

These are exciting times both for the GIS and the remote sensing industries, thanks to dramatic price and performance breakthroughs in GIS hardware and software. The increasing use of GIS is contributing to a renewed interest in satellite imagery by nongeographers, such as civil and environmental engineers. Although GIS technology is promoting the use of satellite imagery, satellite imagery is also in turn advancing the use of GIS. Although non-GIS stand-alone image processing software can be used for exploring satellite imagery, those with GIS capabilities are more suitable because they can combine imagery with additional information, such as demographic and topographic data (Corbley, 2000).

REMOTE SENSING APPLICATIONS

Satellite imagery is not restricted to the visible (0.4 to 0.7 μm wavelength) part of the electromagnetic spectrum. Satellite sensors can record Earth images at wavelengths not visible to the human eye, such as near-infrared and thermal-infrared bands. Different satellite bands provide information about different objects and conditions of the Earth. For example, thermal-infrared band (10.4 to 12.5 μm wavelength) data are useful for soil–moisture discrimination. These bands of satellite data can be used as different data layers in a GIS for further analysis.

Remote sensing applications in the water industry are as diverse and numerous as the GIS applications themselves. Typical examples are listed below:

1. Satellite remote sensing has contributed to water resources applications and research for three decades (Jackson, 2000). Remote sensing data are especially useful in watershed hydrologic modeling. Satellite imagery can be used to estimate input parameters for both the lumped-parameter and distributed-type hydrologic models.
2. Satellite imagery can be used for delineating watersheds and streams. For example, SPOT satellite's stereographic capability can generate topographic data. Terra satellite can provide digital elevation models (DEMs) from stereo images. (These and other satellites are discussed later in this chapter.) Topographic and DEM data collected by satellites can be processed in GIS for automatic delineation of watershed boundaries and streams.
3. Remote sensing data are used for land-use classification. GIS can help to refine or verify the imagery-based land-use classes.

4. Satellite and radar data can be used to estimate the area and intensity of rainfall.
5. Remote sensing can produce surface temperature data through thermal-infrared images.
6. Microwave remote sensing can produce soil-moisture data.
7. Remotely sensed temperature and moisture data can be combined to estimate evaporation and evapotranspiration rates.
8. Remote sensing data are used to estimate vegetation indices and the leaf area index. These parameters can be combined to delineate areas where a subsurface supply of water is available for vegetation.
9. Remote sensing can be used in real time flood forecasting with a distributed hydrologic model into which radar rainfall data can be input.
10. Other applications (Singh, 1995; ASCE, 1999) are:
    - Utility routing
    - Weather forecasting
    - Environmental impact assessment of large water resources projects
    - Snow and ice conditions (microwave region)
    - Forecasting seasonal and short-term snowmelt runoff
    - Evaluation of watershed management strategies for conservation planning
    - Inventory surface water, such as rivers, lakes, reservoirs, swamps, and flooded areas
    - Water quality parameters such as algae, chlorophyll, and aquatic life
    - Thermal and chemical pollution and oil spills
    - Drought assessment and forecasting
    - Geologic and geomorphologic information
    - Groundwater mapping

REMOTE SENSING SATELLITES

Satellite data became available to water industry professionals in 1972 when the U.S. government launched the first Landsat satellite, which was specifically designed to provide imagery of the Earth (Miotto, 2000). In the late 1970s and early 1980s, a second generation of Landsat satellites was developed. Landsats 4 and 5 were launched in July 1982 and March 1984, respectively. They were equipped with two instruments:

- Multispectral scanner (MSS) having 80-m resolution and 4 spectral bands
- Thematic mapper (TM) having 30-m resolution and 7 spectral bands

MSS sensors capture imagery at different wavelengths of light to produce color images. Landsat 4 was retired in 1991, and Landsat 5's MSS sensor failed in October 1993. The successor satellite, Landsat 6, failed to achieve orbit in 1993. To keep the imagery flowing, Landsat 7 was launched on April 15, 1999.

Popular satellite-based sensors and platforms include Landsat MSS and TM, AVHRR, AVIRIS, SPOT XS, GOES, SEASAT, SIR, RADARSAT, SRTM, TOPSAT, ERS-1 and 2, and JERS-1 (Luce, 2001; Lunetta and Elvidge, 1998). The remote sensors that provide hydrologically useful data include aerial photographs, scanning radiometers, spectrometers, and microwave radars. The satellites that provide hydrologically useful data are the NOAA series, TIROS N, SPOT, Landsat, and the

geostationary satellites GOES, GMS, and Meteosat. Satellites can capture imagery in areas where conventional aircraft cannot fly. However, bad weather, especially cloud cover, can prevent satellites from capturing imagery (Robertson, 2001).

SPATIAL RESOLUTION

The spatial resolution of an image is defined as the size of the smallest feature that can be discerned on the image. Spatial coverage is defined as the area of the Earth's surface captured by the image. In general, the higher the spatial resolution, the smaller is the spatial coverage. For example, NASA's Terra Satellite MODIS sensor has 36 spectral channels at 250 m, 500 m, and 1 km. A standard MODIS image covers 1200 km × 1200 km, whereas a standard IKONOS satellite image covers 11 km × 11 km. At such a large spatial coverage, MODIS spatial resolution is more than 50 times coarser than the IKONOS imagery (Space Imaging, 2001). In 2001, the approximate number of 30-m (or better) resolution satellites in the world was 30, and the number of 10-m (or better) resolution satellites was 14 (Limp, 2001).

Figure 3.2 provides a comparison of image resolution. It shows five images at various resolutions for the same geographic area (Gish, 2001). The top-left image, with the highest resolution, is a 0.15-m (0.5-ft) B&W orthophoto taken in 1993. The top-right image is a 0.6-m (2-ft) 1998 B&W orthophoto. The center-left image is a 1-m (3.28-ft) 1999 color-infrared orthophoto taken in invisible light in the infrared bands. The center-right image is a simulated B&W SPOT image with a 10-m (32.8-ft) resolution. Finally, the bottom image has the lowest resolution of 30 m (98.4 ft) and consists of Landsat 7 TM color imagery taken in 2000.

In remote sensing, B&W or gray-scale imagery is called *panchromatic* and color imagery is called *multispectral*. Panchromatic satellite-imagery resolution varies from 15 m (49 ft) for the Landsat 7 satellite, 10 m (33 ft) for the French SPOT satellite series, 5 m (16 ft) for the Indian Remote Sensing series, 1 m (3.2 ft) for the IKONOS satellite (Gilbrook, 1999), to 60 cm (2 ft) for the QuickBird-22 satellite. Until recently, satellite images tended to have very low resolutions. In January 2000, IKONOS high-resolution satellite imagery became available in the commercial marketplace for the first time.

Based on their spatial resolution, remote sensing data can be divided into three categories:

1. Low-resolution data corresponding to imagery with a resolution greater than 30 m
2. Medium-resolution data corresponding to imagery with a resolution between 5 and 30 m
3. High-resolution data corresponding to imagery with a resolution less than 5 m

Low-Resolution Satellite Data

The United States Earth Observing System (EOS) satellites are an excellent source of low- and medium-resolution satellite data. There are four EOS satellites currently in orbit: Landsat 7, QuickSAT, ACRIMSAT, and Terra. Terra, launched by NASA in December 1999, has three remote sensing instruments that could be

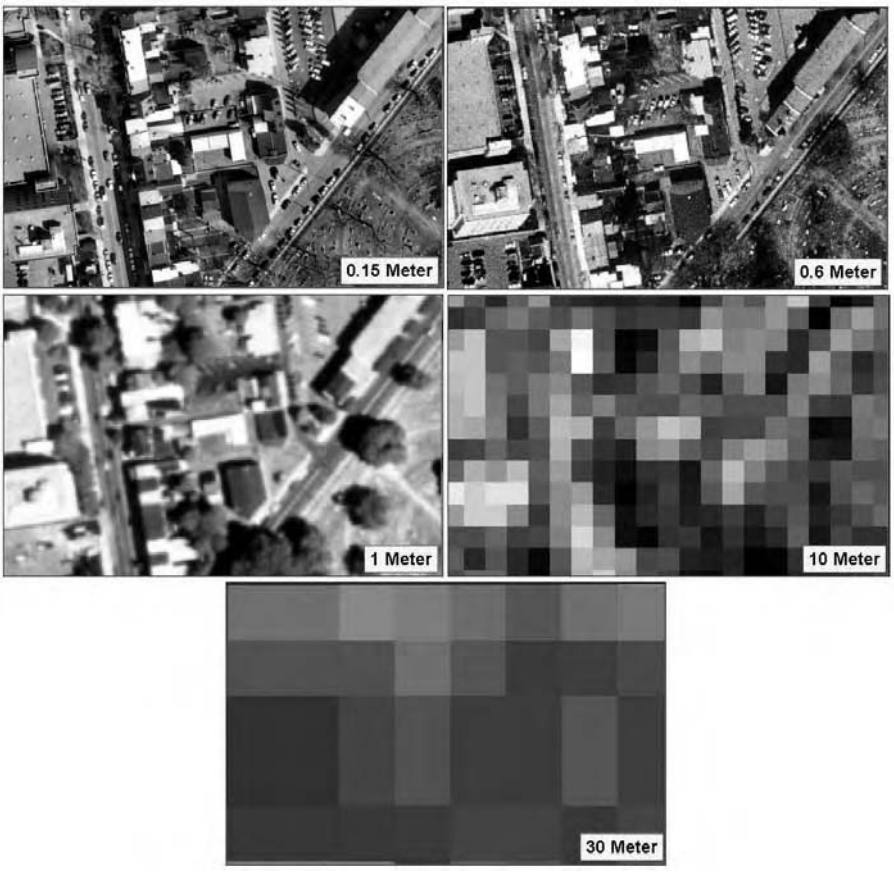

Figure 3.2 Image resolution comparison. Top left: 0.15-m B&W orthophoto (1993); top right: 0.6-m B&W orthophoto (1998); center left: 1-m color infrared orthophoto (1999); center right: 10-m simulated SPOT; bottom: 30-m Landsat TM (2000).

useful for certain water resources applications: Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Moderate Resolution Imaging Spectroradiometer (MODIS), and Multiangle Imaging Spectroradiometer (MISR). ASTER provides digital elevation maps prepared from stereo images. MODIS provides data on cloud- and snow-cover characteristics. MISR data can distinguish different types of clouds, land cover, and vegetation canopy. Although low-resolution satellite imagery works well for regional level studies, it is not very useful in water industry applications.

Medium-Resolution Satellite Data

Table 3.1 provides a summary of medium-resolution satellites. Landsat 7 is the most recent satellite in the Landsat series. By May 2001, Landsat 7 had captured more than 200,000 15-m scenes throughout the world. The Enhanced Thematic

Table 3.1 List of Major Medium-Resolution Satellites

Feature	Landsat 7	SPOT 4	IRS-1C
Company	USGS	French Government	Indian Government
Launch date	April 15, 1999	1998	December 28, 1995
B&W resolution	15	10	5
Color resolution	30	20	23
Swath width (km)	185	120	70
Global cover repeat days	16	26	24

Mapper Plus (ETM+) sensor onboard Landsat 7 provides 15-m panchromatic and 30-m multispectral resolutions. Landsat 7 offers imagery of the highest resolution and lowest price of any Landsat. The USGS ground-receiving station in Sioux Falls, South Dakota, records 250 Landsat scenes a day that are available online within 24 hours. Landsat 7 is expected to have a design life of 5 years. Each Landsat image covers about 10,000 mi^2. Landsat 7 is very useful in water resources applications.

Figure 3.3 shows a modified Landsat TM image for southwestern Pennsylvania, which can be used in a GIS to consistently map land use/land cover (LULC) throughout the state. These images, called Terrabyte, are extracted from the 30-m resolution TM data using an extractive process based on a research trust at Penn State University under cooperation between the Office for Remote Sensing of Earth Resources in the Environmental Resources Research Institute and the Center for

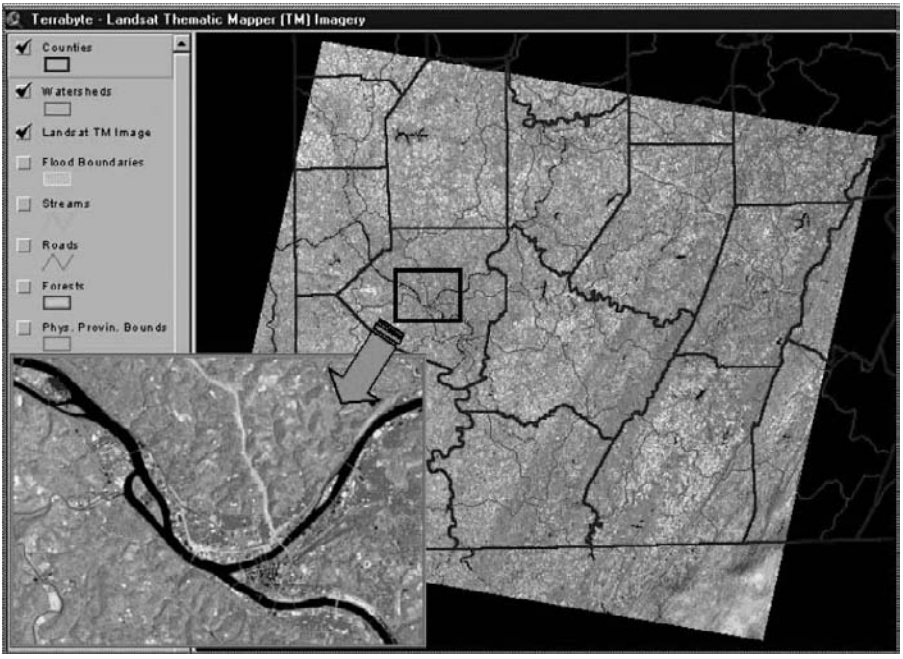

Figure 3.3 Terrabyte Landsat Thematic Mapper image for southwestern Pennsylvania.

Statistical Ecology and Environmental Statistics in the Department of Statistics, with sponsorship from the National Science Foundation and the Environmental Protection Agency. The Terrabyte images are not intended to provide fine detail such as individual buildings at the site level, but rather to convey a sense of landscape organization. Each pixel record occupies one byte; hence the name Terrabyte. Terrabyte condensations for ten satellite scenes will fit on one CD-ROM, whereas two scenes of original satellite data would more than fill one CD-ROM. Terrabyte CD-ROMs of Pennsylvania data have been distributed by Pennsylvania Mapping and Geographic Information Consortium (PaMAGIC) (www.pamagic.org).

In addition to the EOS satellites, France's SPOT 4 satellite provides 10-m panchromatic and 20-m color imagery. In the U.S., 60 × 60 km SPOT scenes cost $750 (pre-1998) to $1500 (post-1998). India's Indian Remote Sensing (IRS) satellite IRS-1C provides 5-m panchromatic and 23-m or 188-m color imagery. Commercial companies and government agencies around the world had plans to launch more than 25 medium-resolution (30 m or better) satellites by the end of 2003.

High-Resolution Satellite Data

High-resolution data correspond to imagery whose resolution is less than 5 m. Traditionally, water industry professionals have purchased aerial photography services on an as-needed basis, which is costly and time-consuming. Now, thousands of square miles of GIS-ready seamless imagery is available in various formats with the promise to bring remote sensing data to any desktop (Robertson, 2001). Until recently, some water industry professionals used 5-m panchromatic imagery from India's IRS-1C satellite or 10-m panchromatic imagery from France's SPOT 4 satellite for their high-resolution data needs. The recent launches of IKONOS (1-m) and QuickBird-2 (60-cm) satellites have changed this by starting to provide high-resolution panchromatic imagery, which meets the U.S. National Map Accuracy Standards for 1:5000-scale maps. 1-m imagery represents an accuracy level commensurate with 1:2400 mapping, which is more than adequate for many planning and H&H modeling applications.

GIS applications are poised to bring the recently available high-resolution satellite imagery directly to the dispatch office of a water, wastewater, or stormwater utility.

High-Resolution Satellites

There are three major satellites that are providing high-resolution satellite imagery today: IKONOS, OrbView, and QuickBird. Table 3.2 provides more information about high-resolution satellites.

High-resolution imagery shows detailed features, such as houses, schools, street centerlines, rights-of-way, trees, parks, highways, and building facilities. They can be used for base-map and land-registry updates, infrastructure mapping analysis and management, natural resource inventories, ecological assessments, transportation mapping, and planning the construction of new highways, bridges, and buildings (Murphy, 2000).

Table 3.2 List of Major High-Resolution Satellites

Feature	QuickBird-2	IKONOS	OrbView-3
Company	DigitalGlobe	Space Imaging	ORBIMAGE
Launch date	October 18, 2001	September 24, 1999	June 26, 2003
B&W resolution (m)	0.61	1	1

Global cover repeat days	148	247	3
Standard scene size	40 km × 40 km	13 km ×13 km	User defined
Web site	digitalglobe.com	spaceimaging.com	orbimage.com

DigitalGlobe's (formerly Earth Watch) QuickBird-1, designed for 1-m panchromatic and 4-m color resolution, failed to achieve its proper orbit after being launched from Plesetsk, Russia, on November 20, 2000. QuickBird-1's unfortunate failure is a good example of a "beneficial loss." QuickBird-2 was launched on October 18, 2001, on a Boeing Delta II rocket from Vanderberg Air Force Base in California. At the time of this writing, QuickBird-2 provides the only commercial satellite imagery of resolution less than 1 m. Figure 3.4 shows the sample QuickBird imagery taken in 2002 and a photograph of the San Diego Convention Center area in California that hosts the world's largest GIS conference (ESRI Annual User Conference) every year. Note that the boats at the marina and the north and south towers of the Marriot

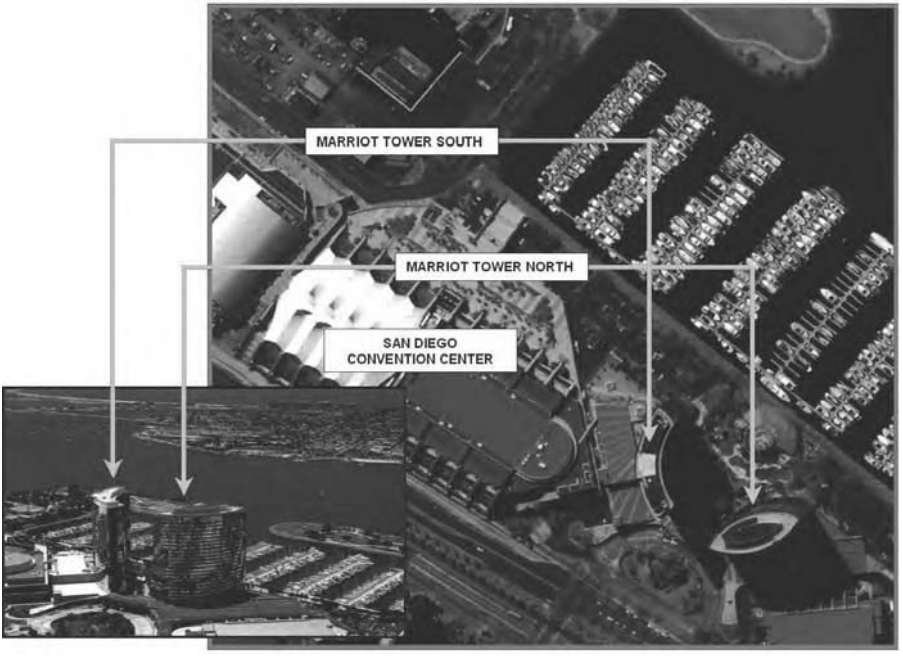

Figure 3.4 Sample QuickBird imagery for San Diego, California. (Image courtesy of DigitalGlobe.)

Hotel adjacent to the convention center are clearly visible on the imagery. DigitalGlobe is planning to launch another satellite dubbed WorldView in 2006, which will be capable of collecting 50-cm panchromatic and 2-m multispectral imagery. WorldView's 800-km-high orbit will allow the satellite to visit imagery collection sites more frequently, letting users repeat their image acquisition about once a day.

IKONOS provides 1-m panchromatic and 4-m multispectral (color) imagery. The satellite weighs 1600 lb and orbits 438 mi above the ground surface. IKONOS products are available under the CARTERRA™ brand name in TIFF and GeoTIFF format. CARTERRA also provides DOQ — B&W, color, or false color IR 5-m imagery, cut into a convenient 7.5-min USGS quadrangle format. Orthorectified CARTERRA DOQs provide an image map suitable for water resources management, urban and rural planning, change detection, and map creation and revision.

High-Resolution Imagery Applications

GIS applications are poised to bring the recently available high-resolution satellite imagery directly to the dispatch office of a water, wastewater, or stormwater utility. For years, aerial photography has been used in many utility GISs, and that use will continue because of its submeter resolution. High-resolution satellite imagery is now available commercially at a reasonable cost. Therefore, when a 1-m resolution is sufficient, satellite imagery can be used as a base map instead of orthorectified digital orthophotos. High-resolution satellite imagery provides digital data at a fraction of the cost people pay for aerial photographs of the same level of accuracy. There is no question that the launch of high-resolution satellites marks a new era in the remote sensing industry.

Typical applications of high-resolution satellite imagery for the water industry are described in the following list:

- High-resolution satellite imagery can enable the water and wastewater system utilities to gather information quickly and inexpensively, allowing them to perform daily operations more efficiently.
- Multispectral imagery can detect vegetation stress before it is visible to the naked eye. Watermain leaks and manhole overflows can impact the soil and vegetation conditions around them. These potential indicators may be used to identify leaks and overflows. *Thus, although satellites cannot directly locate leaking pipes, they can provide the surrogate data that can lead to locating them.*
- High-resolution imagery is especially useful in remote areas of the world where there are no governments and commercial archives and where cost and regulatory hurdles preclude aerial missions.
- Medium-resolution imagery cannot capture some landscape characteristics, such as distribution of shrubs vs. bare ground or gaps in the forest crown (Space Imaging, 2001). High-resolution imagery bridges the gap between field measurements and medium-resolution imagery, providing a continuum from point measurements to medium resolution. High-resolution imagery can also be used to "ground truth" the low- and medium-resolution imagery.
- High-resolution imagery can be used to study urban growth and detailed urban land-use mapping. It can be used to identify growth trends in order to develop the necessary infrastructure in advance.

- Damage from natural disasters (earthquakes, hurricanes, fires, and floods) can be analyzed and response plans prepared. High-resolution imagery can be used to prepare more accurate flood-prediction computer models, monitor stormwater runoff, and study erosion and sedimentation.
- Right-of-way encroachments can be identified by periodically running automated change-detection routines on new imagery.
- Inexpensive pipeline siting and corridor selection can be performed using least-cost path analysis.
- Ecological assessments can be conducted.

Data Sources

TerraServer was started as a joint research project by Aerial Images, Microsoft, USGS, and Compaq. It is considered one of the world's largest online atlases of high-resolution satellite imagery and aerial photography (Thoen, 2001).

In 2001, USGS, PCI Geomatics, Oracle, and Sun Microsystems teamed up to provide a new data delivery service called Real-time Acquisition and Processing of Imagery Data (RAPID). It provides same day service for conversion of TM imagery into easy-to-use data that can be downloaded using an Internet connection. Using RAPID, users can have georeferenced, GIS-ready processed imagery within 10 min of receipt from USGS.

Some consumer-oriented companies are also selling high-resolution satellite imagery. For example, Eastman Kodak Company's CITIPIX imagery database consists of 95 major North American metropolitan areas, including 7000 cities and towns and 600 U.S. and Canadian counties. This ready-to-use "Earth Imaging Products" consist of orthorectified imagery in 6-in., 1-ft, 2-ft, and 1-m resolutions. Kodak's 24-bit color images exceed National Map Accuracy Standards' accuracy requirement at 1:1200. These products are intended for applications in architecture, engineering, construction, telecommunication, utilities, insurance, and real-estate industries as well as local, state, and provincial governments.

The cost of spatial data is falling rapidly due to competition in data acquisition, processing, and distribution. As satellite imagery has become more widely accepted, its unit cost has started to decline. For example, Landsat-4 and -5 imagery used to cost $4400 per scene; now the same scene costs $600. After the launch of QuickBird-2 and OrbView-3 satellites, the price of IKONOS imagery has come down from $62/km^2 to $29/km^2 (with a 100 km^2 minimum order) — a decrease of over 50%.

DIGITAL ORTHOPHOTOS

Digital orthophotos are a special type of high-resolution remote sensing imagery. Traditional aerial photos contain image displacements caused by camera lens distortion, camera tip and tilt, terrain (topographic) relief, and scale (Michael, 1994). Because of these problems, an aerial photograph does not have a uniform scale, and therefore, it is not a map. The distortions are removed through a rectification process to create a computer file referred to as a digital orthophoto (DOP). The image rectification is done with the help of geodetic surveying and photogrammetry. A DOP

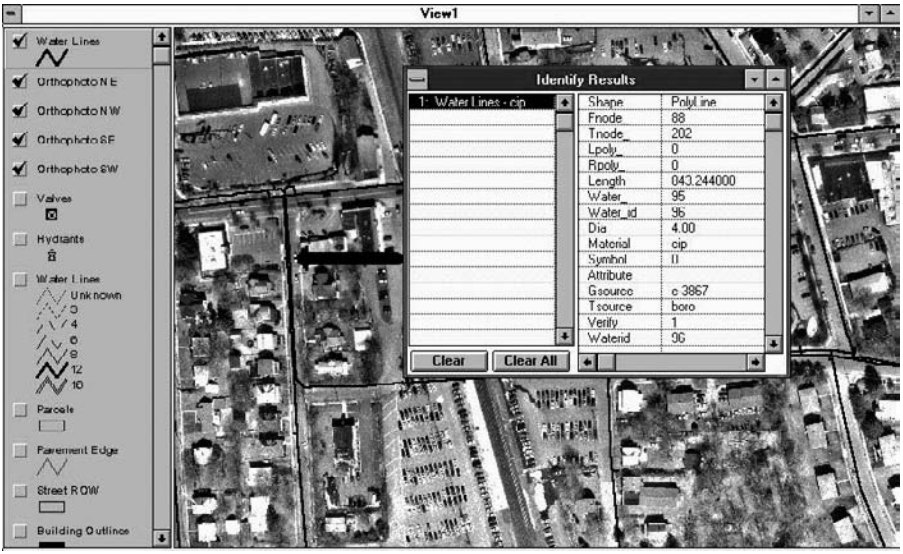

Figure 3.5 Digital orthophoto base map for water system mapping.

is a uniform-scale photographic image and can be considered a photographic map. As the name implies, orthophotos are orthographic photographs or simply photo maps.

DOPs are very detailed, can be easily interpreted, and provide excellent accuracy that can be easily quantified and verified. DOPs are a valuable source for developing an accurate landbase in a GIS mapping project. Because it is a photographic image, the DOP displays features that may be omitted or generalized on other cartographic maps. This makes the digital orthophoto valuable as a base map layer in a GIS. Figure 3.5 shows a DOP base map for a water distribution system mapping project. The DOP has been processed to remove scale distortion and create an accurate and true-to-scale base map with an accuracy of ±1.25 ft. Waterlines have also been plotted on the digital orthophoto.

USGS Digital Orthophotos

A digital orthophoto quadrangle (DOQ) is an orthorectified raster image of a low-altitude USGS aerial photograph in Universal Transverse Mercator (UTM) projection in North American Datum of 1983 (NAD83). DOQs have the geometric properties of a map and meet the National Map Accuracy Standards. DOQs are based on the 1:80,000-scale National High Altitude Photography (NHAP) aerial photos with an altitude of 40,000 ft. They cover an area equal to 7.5 min (1:24,000) USGS quads (quadrangles); hence their name. They have a resolution of 2 m and an accuracy of 40 ft. They are available as 5-MB compressed JPEG files that can be purchased for $35.5 per county CD.

Digital orthophoto quarter quadrangles (DOQQs) are based on the 1:40,000-scale National Aerial Photography Program (NAPP) aerial photos with an altitude

Figure 3.6 USGS digital orthophoto quarter quadrangle (DOQQ) for Washington, D.C. (Image courtesy of USGS.)

of 20,000 ft. They cover an area equal to a quarter of a 7.5-min USGS quads (3.75 min of latitude by 3.75 min of longitude in geographic extent); hence their name. They have a resolution of 1 m and an accuracy of 33 ft. DOQQs also have a UTM map projection system and NAD83 datum. A sample DOQQ image for Washington, D.C., is shown in Figure 3.6.

DOQQs are available as 40 to 50 MB uncompressed files that can be purchased for $60 per file on CD-ROM from the USGS EarthExplorer Web site. State or regional mapping and spatial data clearinghouse Web sites are the most valuable source of free local spatial data. For example, Pennsylvania Spatial Data Access system (PASDA), Pennsylvania's official geospatial information clearinghouse and Pennsylvania's node on the National Spatial Data Infrastructure (NSDI), provides free downloads of DOQQ and other spatial data.

Because DOQQs are based on the NAD83 datum, most U.S. ArcView 3.x users who want to use DOQQs in their GIS projects will have to reproject their NAD27 vector themes into NAD83. NAD83 is an Earth-centered datum (GRS 80 ellipsoid) unlike NAD27, which is based on an arbitrary starting point in Meades Ranch (Kansas). The positions or points or features based on these reference datums will differ considerably. Though reprojected themes will line up reasonably well with features in DOQQs, a more precise alignment can be achieved by adjusting the false easting and northing values to "tweak" the theme (Miller, 2000).

Like DOPs, DOQs and DOQQs also can be used as GIS base maps to overlay other thematic data layers. DOQs can be used in land management, habitat analysis, evacuation planning, and in many other areas (Miller, 2000).

Case Study: Draping DOQQ Imagery on DEM Data

The city of Ventura, California, is located 70 mi north of Los Angeles, covers almost 21 mi^2, and is home to 105,000 people. In an effort to redefine its GIS, the City acquired 11 USGS DOQQs in 1999. The DOQQs were mosaicked and reprojected to California State Plane with ERDAS IMAGINE software and compressed with LizardTech's MrSID software to create a seamless image. They also created a panoramic view of the city using IMAGINE VirtualGIS software by draping the DOQQ mosaic over 10-m DEMs obtained from USGS and Intermap Technologies (Ottawa, Ontario, Canada). The image draping demonstrated the value of orthorectified imagery and helped the City to derive other GIS data layers, such as slope, aspect, and shaded relief (ERDAS, 2001a).

EXAMPLES OF REMOTE SENSING APPLICATIONS

A USGS project helping to restore the original water flow of Everglades is a good example of blending various types of remote sensing data. This project uses aerial videography, laser imaging detection and ranging (LIDAR)*-based topography, and Landsat-based vegetation to create hydrodynamic models of water flow (Miotto, 2000).

The Arizona Department of Water Resources (ADWR) uses satellite data (Landsat and SPOT) and GIS software (ERDAS IMAGINE and ArcInfo) to monitor water use, regulate water rights, and enforce limits on irrigated acreage expansion. ADWR purchases growing-season imagery at an annual cost of $15,000. An investigation is started if the images show crop growth that does not correspond to water rights (McKinnon and Souby, 1999).

A 1997 USGS study for the California Gulch Superfund Site in Leadville, Colorado, demonstrated an application of remote sensing in locating and pinpointing sources of acid mine drainage and a tremendous variety of other surface materials. Mineral maps produced by the study helped expedite the cleaning of hazardous material and reduced the cleanup cost. These maps were produced using a new tool called imaging spectroscopy, the latest in remote sensing science.

Satellite imagery can be used for irrigation monitoring and assessment, or to evaluate erosion potential or landslides. Other remote sensing applications for the water industry include land-use classification, soil moisture mapping, and estimation of meteorological data. These applications are described in the following subsections.

LULC Classification

The San Diego Association of Governments (SANDAG) deals with one of the nation's largest county jurisdictions covering more than 4200 mi^2. Before 1988, SANDAG used costly and time-consuming aerial-photography and photo-interpretation techniques to create LULC maps and updated them only once every 5 years. To meet

* LIDAR is a new remote sensing technology that measures ground surface elevation from an airplane to create DEM data. Additional information is provided in Chapter 4 (DEM Applications).

the special challenge of keeping track of this rapidly changing area in a cost-effective manner, SANDAG turned to GIS. It used raster GIS and image processing software ERDAS, vector GIS software ArcInfo from ESRI, color-infrared aerial photographs, and satellite imagery. Switching to satellite imagery and GIS as a land inventory tool allowed SANDAG to see the region in a new way and permitted rapid change detection. The GIS-based LULC-mapping approach provided SANDAG with current and verified LULC data for modeling transportation, infrastructure, and water needs (Kindleberger, 1992).

In 2003, a digital database of land-cover imagery and vectors was created that includes the major landmasses of the entire world. Called GeoCover LC (Land Cover), this was the first worldwide LULC database prepared using medium-resolution Landsat 7 TM imagery.

LULC classification is one of the most common applications of satellite imagery. Remote sensing data are a valuable source of information for land-use modeling. Derivation of LULC classes from low-level aerial photography is referred to as the *conventional* method compared with the remote sensing techniques that employ satellite imagery. Studies have shown that the remote sensing techniques for LULC classification are more cost-effective. The cost benefits have been estimated on the order of 6 to 1 in favor of the satellite imagery approach. Although remote sensing-based land-use statistics may not be as detailed as those derived using the conventional manual method, many computed parameters such as runoff curve numbers and discharges are nearly the same (Engman, 1993).

The choice of sensors for LULC applications is dictated by the time and space resolution needed for interpretation. The sensor chosen must permit a suitable classification of LULC. The quality of this classification will depend on the LULC types, the quantity of images available, and the dates on which they were taken as well as the classification technique used. Ambiguities in interpretation can be reduced by using field information (ground truthing) to improve classifications. The number of LULC categories depends on the intended application. For example, in watershed nutrient modeling this number must permit the estimation of total nutrient export from a subwatershed and to compare the possible effects of land-use changes. At a minimum, urban, agricultural, grasslands, and forested areas must be clearly distinguished. A distinction between types of farming will provide better nutrient estimates (Payraudeau et al., 2000).

When collecting LULC data, keep in mind the four "Cs": currency, construction, categories, and consistency. Currency determines how current your LULC data are. Construction pertains to new developments that can significantly alter land use and affect soil erosion, sedimentation, and even water quality. Categories represent the LULC classes (polygons). One may not want to have an "agricultural" class created by lumping together cropland, pasture, and dairy farms. And, finally, consistency determines how consistent in time, scale, resolution, and classification various sources of LULC data are (Slawecki et al., 2001).

Vegetation is an important part of a watershed's ecosystem. To preserve and maintain the watershed ecosystems, resource managers need high-quality vegetation maps to monitor temporal vegetative changes and to pinpoint habitats and species likely to be affected by management decisions. Based on the spectral return from

the infrared imagery and using classification techniques of a remote sensing software package, people can identify trees and other vegetation growing in a watershed and even determine the total irrigated area. California Department of Forestry and Fire Protection (Sacramento, California) updates California's LULC mapping and monitoring program on a 5-year cycle. The program utilizes image classification and GIS modeling to generate data that describe the condition and extent of various land-cover types, as well as the magnitude and cause of such changes. Data sources include DOQs, aerial photographs, and satellite images from Landsat TM, Indian Remote Sensing, and SPOT. LULC layers are produced using automated image classification of satellite imagery. This approach efficiently and consistently maps large areas at a low cost. Next, the LULC layer is converted to vector format and hand-edited with high-resolution DOQ as a backdrop. GIS models are run in ESRI's ArcInfo GRID program to label each LULC polygon with a vegetation type. The updated LULC map is created by adding the new 5-year LULC change layer to the old LULC map (Rosenberg et al., 2001).

Dry- and wet-weather flows from sewersheds depend on land use. The hydrologic and environmental effects of land do not depend on the amount of land-use change alone. The location of land-use change is equally important. For example, a development adjacent to a water body might produce a greater impact on water quantity and quality. GIS and remote sensing are ideally suited to studying the temporal and spatial variation of land use. Remote sensing has been recently recognized as a tool that holds great promise for water quality monitoring activities. In 2003, three U.S. agencies, the Environmental Protection Agency (EPA), National Aeronautic and Space Administration (NASA), and the National Oceanic and Atmospheric Administration (NOAA) entered into a partnership to more fully explore how remote sensing may support state water quality management activities (Mehan, 2003).

Digital LULC data are used to derive several watershed parameters, such as the percent imperviousness and runoff curve number, as described in Chapter 11 (Modeling Applications) and Chapter 13 (Sewer Models). This runoff-coefficient estimation technique is a good example of maximizing the capabilities of remote sensing. The LULC layer can be developed from supervised (interactive) or unsupervised (automatic) classification of satellite imagery. GIS can be used to reclassify or aggregate the usually large number of imagery-based LULC classes into a small number of user-specified LULC classes. GIS can also help to refine or verify the imagery-based LULC classes. For example, population-density and unit-type (single or multiple family) attributes of census GIS data (e.g., census blocks) can be used to reclassify the typical residential land-use classes (e.g., low-, medium-, and high-density residential) into single-family residential and multifamily residential land-use classes.

LULC changes observed in remote sensing imagery are of interest to planners, ecologists, hydrologists, and atmospheric scientists. Remote sensing imagery taken at different times can be compared to detect changes in LULC using a process called *change detection*. Remote sensing change detection can also be used for near-real-time detection and mapping of fires, power outages, and floods. Remote sensing change detection techniques can also be adapted for assessing the differences between modeled and observed images for validation of distributed hydrologic and ecosystem models (Luce, 2001; Lunetta and Elvidge, 1998).

Standard multispectral data provide only a grid of numbers that literally reflect the amount of electromagnetic energy measured at a specified small square on the Earth's surface. The most common and pervasive problem in any spectral classification of these data is the presence of mixed cells called "mixels." A 10 m × 10 m location on the ground may be half lawn and shrub and half rooftop. Obviously, because the spectral reflectance value for this cell cannot show two half-values, the value becomes the average of the two surface types, statistically dissimilar from both vegetation and urban areas. Taking into consideration the fact that cells are not spectrally divided into only two distinct surface types but every possible combination, the difficulties in spectrally based classification procedures become apparent. A key challenge to using multispectral satellite imagery data is to "unmix" (usually urban) land-use areas that contain numerous mixed pixels due to a highly variable landscape. High-spectral (or hyperspectral) imagery that divides the electromagnetic spectrum into a large number of segments for a finer classification of the Earth's surface is an important evolving trend. The mixel problem can be eliminated by using hyperspectral data from new satellites, such as NASA's Earth Observing-1 (EO-1) and Orbimage's OrbView 3. One-and-a-half months after its launch aboard the EO-1 spacecraft Hyperion, NASA's first hyperspectral imager was transmitting 30-m resolution images of the Earth in 220 spectral bands from the visible to shortwave infrared. Hyperion captures 7.5 km × 180 km images with high radiometric accuracy. NASA's ASTER is capable of collecting 14 bands of data at 15- to 19-m resolutions. The next OrbView launch is expected to provide a 200-band hyperspectral capability with 8-m resolution. The hyperspectral analysis software packages such as ENVI use special techniques like spectral angle mapping or linear spectral unmixing to isolate different contributions to a single pixel. The IMAGINE software from ERDAS provides a subpixel classifier to handle the mixed cells (ERDAS, 2001).

Note that local governments are usually the best sources of LULC data because they are involved most directly in land-planning activities. Many cities maintain accurate, aerial photo-based parcel maps for tax assessment. Local LULC data can include outlines of buildings, driveways, and pavements, which are excellent sources of data for applications that require highly accurate parameters, such as estimation of percent imperviousness by LULC classes and urban runoff modeling (Slawecki et al., 2001). Before using GIS and remote sensing techniques to create LULC data, one should check with local governments and regional organizations in the study area to determine if existing LULC maps or data are available.

Soil Moisture Mapping

Recent developments have opened the doors for exploring remotely sensed data in the microwave region. The strength of the microwave signal is directly related to the amount of water present below the target surface. This feature makes microwave remote sensing particularly attractive in water resources studies. Microwave sensors can produce soil-moisture data that measure the surface dielectric properties. Daily soil-moisture maps can be composed to establish antecedent conditions for runoff modeling. NASA's Tropical Rainfall Mapping Mission (TRMM) Microwave Imager has been used to establish soil moisture over a 140 km × 280 km region in Oklahoma.

Estimating Meteorological Data

Many watersheds, especially those smaller than 1000 km^2, do not have recording rain gauges. These data gaps can be filled by the rainfall data provided by weather satellites and radars. Detailed applications of remote sensing data in rainfall measurement are provided in Chapter 10 (Monitoring Applications).

Evapotranspiration data are critical in water budget computations of a watershed. Evapotranspiration measurements require expensive instruments for an area no larger than a field. Estimation of evapotranspiration for large areas using computer models may be difficult and time consuming. Research hydrologists at the University of Nebraska-Lincoln have developed a way to measure watershed evapotranspiration using vegetative productivity (greenness) extracted from satellite imagery. Because producing green matter involves using a specific amount of water, evapotranspiration can be calculated for large areas. Evapotranspiration estimates are used to determine irrigation-water and groundwater recharge, two of the most difficult-to-estimate parameters in most water budget computations.

GEOGRAPHIC IMAGING AND IMAGE PROCESSING SOFTWARE

In recent days, geographic imaging has become an essential part of GIS applications. Without geographic imaging capability, a GIS software is like a car without a spare wheel, or a computer without a modem, or a pizza without toppings. Imagine tens or hundreds of image tiles that have unbalanced color, brightness, or contrast, which must be manually adjusted to plot nicely. Imagine a GIS project involving 6-in. resolution images for an entire county and the user waiting for the computer to redraw the screen as he or she zooms in and out. Geographic-imaging and image processing products solve these problems by helping users to visualize, manipulate, analyze, measure, and integrate geographic imagery and geospatial information. These programs can be classified in two categories:

1. Preprocessors: These programs (such as MrSID described in the following text), help to preprocess raster data for GIS applications. Some preprocessing programs can join multiple images to provide georeferenced color-balanced mosaics. They combine multiple frames of scanned film, digital photos, or satellite images into a single picture and apply mapping-coordinates information to the mosaicked image for spectral and spatial analysis.
2. GIS Extensions: These programs add image processing capability to a GIS software. For example, Image Analysis is an extension that adds image processing capability to ArcView GIS software.

Representative software are listed in Table 3.3 and described in the following subsections.

ERDAS Software Products

ERDAS, Inc. (Atlanta, Georgia), is a leading geographic imaging and image processing software company. The company's software products help organizations

visualize, manipulate, analyze, measure, and integrate geographic imagery and geospatial information into 2D and 3D environments. In July 2001, ERDAS's geographic imaging software division was acquired by Leica Geosystems (Heerbrugg, Switzerland) to form a new GIS and mapping division. In the GIS community, Leica Geosystems is known for its GPS and field data collection related equipment.

The ERDAS flagship product is called IMAGINE (previously known as ERDAS; the latest version is 8.7); it provides remote sensing capabilities and a broad range of geographic imaging tools. It contains tools to make data production faster and easier, such as on-the-fly reprojection, a batch wizard to automate routine procedures, the ability to create and edit ESRI Shapefiles, and faster and easier map production capabilities. It also provides enhanced mosaicking capabilities for creating seamless output images. Using specialized color-balancing procedures to remove "hot spots" from aerial photographs and satellite imagery, IMAGINE's simple but powerful mosaicking tool can run in an automated mode or allow users to intervene for quality assurance. For example, its cropping feature removes an image's rough edges, and the Exclude Areas tool can be used to define pixel groups likely to skew the image histogram and cause erroneous mosaicking artifacts.

The ERDAS IMAGINE product suite consists of three components that can be combined to create a scaleable solution for project-specific needs:

- IMAGINE Essentials: A mapping and visualization tool that allows different types of geographic data to be combined with imagery and organized for a mapping project.
- IMAGINE Advantage: This component builds upon the geographic imaging capabilities of IMAGINE Essentials by adding more precise mapping and image processing capabilities. It analyzes data from imagery via image mosaicking, surface interpolation, and advanced image interpretation and orthorectification tools.
- IMAGINE Professional: This is a suite of sophisticated tools for remote sensing and complex image analysis. It contains all the capabilities of IMAGINE Essentials and IMAGINE Advantage and adds radar analysis and advanced classification tools like the IMAGINE Expert Classifier. It also includes graphical spatial data modeling, an advanced feature for geographic data analysis.

ERDAS MapSheets is a mapping and geographic presentation software package. Because of it's compatibility with Microsoft Office, MapSheets allows using Object Linking and Embedding (OLE) technology to incorporate maps and images into reports, presentations, and spreadsheets. Reportedly, it is as easy to use as a word processor or a spreadsheet because it works directly with Microsoft Office software. It allows adding a map to a Microsoft Word report, using Excel to query the map attributes, using corporate data with Microsoft Access, and making presentations in PowerPoint. MapSheets allows reshaping images and drawings that have different projections. Its change-detection feature allows viewing changes from one image or drawing to another.

ERDAS Software Application Example

With a population of over 500,000 people, Colorado Springs, Colorado, is the U.S.' 18th-fastest growing city. In 1999, the Water Resources Department of Colorado

Springs Utilities (CSU) embarked on a pipeline-mapping project using high-resolution aerial photographs. CSU used 6-in. resolution DOPs of the Rockies to accurately, quickly, and inexpensively create a base map of two water pipelines that stretch approximately 130 mi. The resulting data were combined with GPS and ArcInfo GIS data to create an accurate set of detailed pipeline maps at a scale of 1 in. = 200 ft. CSU utilized ERDAS' Stereo Analyst, IMAGINE Virtual GIS, and IMAGINE OrthoBASE geographic imaging software products. The compatibility between ERDAS and ESRI products allowed CSU to leverage its existing ArcInfo data to analyze pipeline accessibility, maintenance history and schedules, and future water needs. CSU also used high-resolution aerial photographs to create a detailed map of its water treatment plant in about 2 weeks. The ability to process more high-resolution imagery in-house in less time helped CSU to cost-effectively and efficiently maintain its GIS and save an estimated $1.8 million in mapping cost (ArcNews, 2001a).

ArcView Image Analysis Extension

ArcView Image Analysis Extension was developed as a collaborative effort between ESRI and ERDAS. It provides a direct path from IMAGINE to ArcView for users with complex geographic imaging and processing needs and provides readily available image and remote sensing data. It allows georeferencing imagery to Shapefiles, coverages, global positioning system points, or reference images; image enhancement; automatic mapping of feature boundaries; change detection for continuous and thematic imagery; multispectral categorizations for LULC mapping and data extraction; vegetation greenness mapping; and mosaicking imagery from different sources and different resolutions. One of the most useful tools in Image Analysis Extension is the Image Align tool designed to coregister image data to vector layers. The intuitive point-marking scheme is designed to make image rectification simple for novices. In addition to the standard rectification process from user-specified control points and GPS-collected points, the software also displays selected satellite data types in proper map position automatically. This capability is called image calibration, and is based on positional information (ephemeris) provided in commercial data sources. Image Analysis' spectral-categorization capabilities include unsupervised image classification with ISODATA classifier and finding like areas for single-class identification. These capabilities can be used for automatic LULC classification from satellite imagery.

ERDAS Stereo Analyst is another ArcView extension. It allows users to collect and visualize spatial data in true stereo and to roam with real-time pan and zoom. Features include the ability to collect and edit 3D Shapefiles and visualization of terrain information, tree stands, and watersheds.

MrSID

Water system and sewer system GIS data generally have DOP base maps that are stored in extremely large files. For example, the City of Loveland, Colorado, had four aerial photo images of 1.3 gigabytes (GB) each (Murphy, 2000a). The recent explosion of high-resolution imagery has dramatically increased the size of

raster data. Raster images are storage-hungry but compressed images lose resolution because there is a trade-off between image size and resolution. Large image files take a long time to display on the computer. Fortunately, the data-reading capacity of image processing software has increased from a few gigabytes to the terabyte range. Image-compression techniques have played a critical role in storing large raster data sets in compressed file formats, such as Earth Resource Mapping's ECW format and LizardTech's MrSID format.

Multiresolution Seamless Image Database (MrSID) is a relatively new image file type (SID) from LizardTech. It encodes large, high-resolution images to a fraction of their original file size while maintaining the original image quality. Images become scalable and can be reduced, enlarged, zoomed, panned, or printed without compromising integrity. MrSID's selective decompression and bandwidth-optimization capabilities also increase the file transfer speed. MrSID provides the world's highest compression ratios that average at about 40 but can be as high as 100. For example, Mecklenburg County, North Carolina, had 708 sheets of 1-in. = 1000-ft B&W digital orthophotos for 538 mi^2 of the entire county. The scanned 9 in. × 9 in. films at a resolution of 1-ft to 1-pixel created approximately 23 MB georeferenced TIFF files. This procedure created 16 GB of imagery stored on 27 CD-ROMs. Delivering a compression ratio of 1:28, MrSID took 14 hours on a Pentium PC with 512 MB of RAM to compress 16 GB of imagery to a single 608 MB MrSID Portable Image Format that could be stored on a single 650 MB CD-ROM (Kuppe, 1999). Similarly, MrSID was able to compress 18 GB of Washington, D.C., DOPs onto one CD-ROM.

MrSID allows fast viewing of massive images. For instance, displaying a 50 MB TIFF image can take several minutes, whereas it requires only a few seconds to open the same image in the MrSID format. Reportedly, MrSID software can automatically mosaic hundreds of image tiles of virtually any size into a single, seamless image that is geometrically and geographically accurate with all georeferencing data intact. MrSID images can be viewed in most popular GIS software packages, such as ESRI's ArcInfo, ArcView, MapObjects, ArcIMS, ArcExplorer, and ArcPad; Autodesk, Intergraph, and GE Smallworld. MrSID ArcView GIS extension allows MrSID images to be instantly decompressed and displayed within ArcView GIS. It takes advantage of MrSID's image-compression and retrieval capability and offsets the problems of working with large images in ArcView GIS. MrSID's ArcView GIS extension gives users the ability to work with raster images of any size while providing instantaneous, seamless, multiresolution browsing of large raster images in ArcView.

PCI Geomatics

PCI Geomatics (Ontario, Canada) provides a suite of image processing, remote sensing, orthophoto, and GIS software tools. In 2001, PCI Geomatics software was used to produce "ImageMap USA," the first seamless color satellite image of the continental U.S. at 15-m spatial resolution. This mosaic is composed of approximately 450 individual Landsat 7 satellite scenes. PCI Geomatics' software products are described below.

Geomatica™ unites previously separate technologies that were dedicated to remote sensing, image processing, GIS (both vector and raster), cartography, and

desktop photogrammetry into a single integrated environment. Geomatica represents the most aggressive movement toward the integration of GIS and image processing functions in one software package (Limp, 2001). Although Geomatica is available in several configurations, all have a consistent user interface and data structure.

EASI/PACE desktop remote sensing software allows working with Landsat, SPOT, air photos, or radar data in one image processing package. Users can use data from GIS databases and extract information for resource analysis, mapping and environmental applications. It can also be used to make image maps and update GIS data.

ImageWorks is a GUI-based software that incorporates the most frequently needed image-display, enhancement, and data management tools in a user-friendly interface. The software provides integrated raster and vector display capability.

OrthoEngine Suite provides capabilities for producing map-accurate imagery. It can orthorectify many types of image data, including aerial photos, digital camera frames, and Landsat, SPOT, IRS, IKONOS, RADARSAT, ERS, and JERS imagery. It allows DEM generations from SPOT, IRS, or RADARSAT imagery. It also provides manual and automatic mosaicking tools to create seamless mosaics of multiple images.

FLY! is a terrain-visualization tool that drapes imagery and vectors over DEM data to create 3D perspective scenes in near real-time. An intuitive point-and-click user interface enables users to control flight speed, direction, elevation, and perspective parameters interactively during flight.

Radar imagery from satellites and aircraft has become a significant tool for a wide range of remote sensing applications. Data from sources such as RADARSAT, ERS, and JERS provide timely and consistent sources of information, regardless of weather conditions or illumination. With the expanding use of radar-imaging systems comes the need for new processing tools to extract useful information. Imaging radar data requires special handling and analysis techniques. PCI Geomatics has developed RADARSOFT to meet these needs.

PAMAP is a full-featured GIS software that combines an easy-to-use interface with increased interactivity and dynamic links to many industry-standard external databases for efficient storage of attribute data. It uses PCI Geomatics' Generic Database (GDB) technology, which supports over 50 different raster and vector data types facilitating easy exchange of spatial and attribute data.

GeoGateway allows users to visualize large data files, reproject them into any of the over 25 supported projection systems (or define a new projection system), subset the files into smaller windows of data, and write the resulting data out to a different, more distributable format, or even to an enterprise relational database such as Oracle.

Blue Marble Geographics

Blue Marble Geographics provides a host of geographic imaging, image processing, and map-projection software tools and utilities. The Geographic Transformer allows users to establish an "image-to-world" relationship between image and map coordinates and reproject an image into a georeferenced image map. It is a simple software to georeference, reproject, tile, and mosaic images. The Geographic Transformer AVX is an ArcView extension that integrates these functions directly into the ArcView GIS environment. Geographic Calculator is a stand-alone

utility than can convert coordinates from one system to another. It offers more than 12,000 predefined coordinate systems as well as user-defined systems, datums, and units. Geographic Calculator supports DXF, DWG, SHP, MIF, and TAB files.

FUTURE DIRECTIONS

Remote sensing has dramatically improved our ability to forecast weather, monitor pollution, and respond to natural disasters. As we continue to transition into the information age, we will uncover even more remote sensing applications. According to industry experts, QuickBird and LIDAR are only the tip of the iceberg. There are several new developments in the remote sensing field that will have a significantly positive impact on future applications in the water industry (Merry, 2000). These include the launch of the EOS series of satellites, the availability of satellite hyperspectral remote sensing data, and high-resolution commercial remote sensing data. Hyperspectral sensors examine hundreds of individual bands of the electromagnetic spectrum to reveal extremely subtle characteristics of the Earth's surface. The EOS time-series data is organized in an information system that will allow direct assimilation of remote sensing data into computer models for calibration purposes. New sensors, particularly in the microwave region, promise great potential for hydrologic applications. The U.S. Navy's scheduled launch of the Naval Earth Map Observer (NEMO) will provide data on shallow-water bathymetry, bottom type composition, currents, oil slicks, atmospheric visibility, beach characteristics, and near-shore soil and vegetation (Lillesand and Kiefer, 1999).

In the future, maps of dubious accuracy will not be digitized into a GIS. Contemporary imagery will be obtained for each unique application or solution. The new technology will enable improved analysis of reflected laser signals of LIDAR systems. Enhanced interpretation of the strength of the laser signals will enable automatic creation of low-grade DOPs. LIDAR technology one day will become so accurate that it will be possible to distinguish between different types of trees. As our ability to develop DEMs increases, the potential uses of LIDAR technology will multiply.

The human eye is accustomed to seeing objects such as tanks and ponds, whereas remote sensing data recognize nothing but pixels. This limitation creates the pixel problem described earlier in the chapter, which can be eliminated using the latest hyperspectral imagery. In addition to this solution, new remote sensing techniques are being developed to enable identification of objects. In such applications, the spatial and textural properties of the image are used along with the spectral properties of a single pixel to extract real-world objects from remotely sensed data (Limp, 2001). Geographic imaging software companies like ERDAS are developing hyperspectral analysis tools that will provide task-oriented, wizard-based capabilities to simplify and automate numerous preprocessing steps for analyzing hyperspectral imagery.

Autonomous aerial imaging combines the advantages of both aerial and satellite imaging. Autonomous imaging is already available for military missions, and it is anticipated that it will soon become available for commercial applications. On April 23, 2001, the U.S. Air Force's Global Hawk became the first autonomous powered aircraft to cross the Pacific Ocean. The result of a collaboration between the U.S. Air

Force and the Australian Defence Organization, Global Hawk can fly at altitudes of 65,000 ft and image 40,000 mi^2 in less than 24 hours. For commercial applications, the aircraft could be quickly deployed to an area of interest (or crisis) and data could be downloaded and processed in near real-time-like satellite imagery, but with a higher pixel resolution. This technology can reduce overhead cost on pilot and technician hours and make real-time high-resolution imagery affordable to water industry professionals.

CHAPTER SUMMARY

The increasing use of GIS is contributing to a renewed interest in remote sensing — the process of observing and mapping from a distance. GIS technology is promoting the use of remote sensing data such as aerial photographs, satellite imagery, and radar data. Remote sensing technology offers numerous applications in the water industry. Space-based satellite imagery in GIS-ready format can be used as cost-effective base maps for mapping water industry systems. It can be used for land-use classification, watershed delineation, and measuring rainfall. Remote sensing data are available in various resolutions; not all of which are suitable for water industry applications. The recent availability of high-resolution (0.5 to 5 m) satellite imagery is poised to bring remote sensing technology to a water utility near you. For additional information, the famous Lillesand and Kiefer (1999) textbook *Remote Sensing and Image Interpretation* is suggested.

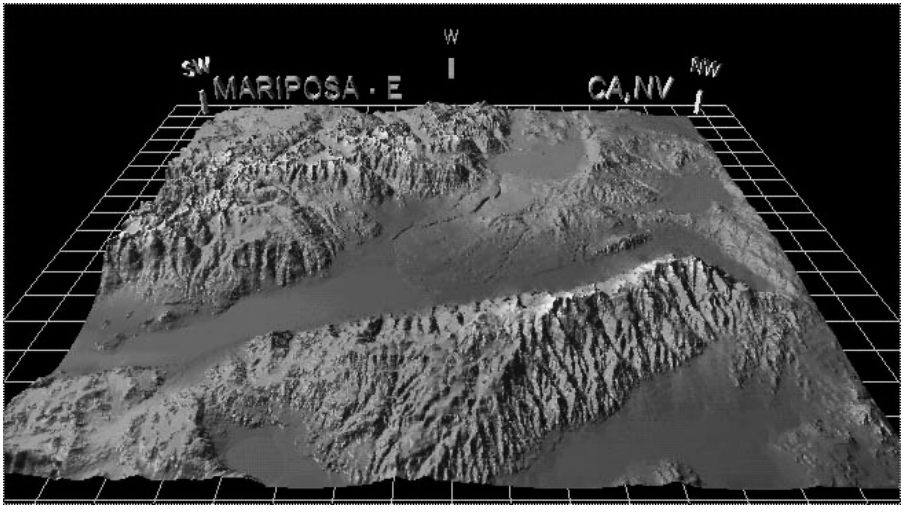
CHAPTER QUESTIONS

1. What is remote sensing and how is it related to satellite imagery?
2. How is remote sensing related to GIS and how is it used in GIS applications?
3. What is a digital orthophoto and how is it used in GIS?
4. How are remote sensing data used for land-use classification?
5. What type of software is required for using remote sensing data?

CHAPTER 4

DEM Applications

Can a laser device mounted in an airplane create a GIS-ready ground surface elevation map of your study area or measure the elevation of your manholes? Read this chapter to find out.



1:250,000 USGS DEM for Mariposa East, California (plotted using DEM3D viewer software from USGS).

LEARNING OBJECTIVE

The learning objective of this chapter is to learn how to use digital elevation models (DEM) in GIS for water industry applications.

MAJOR TOPICS

- DEM basics
- DEM data resolution and accuracy
- USGS DEM data
- DEM data from remote sensing technology
- DEM data from LIDAR and IFSAR technologies
- DEM analysis techniques and software packages
- DEM application case studies and examples

LIST OF CHAPTER ACRONYMS

DEM Digital Elevation Model
DTM Digital Terrain Model
ERDAS Earth Resource Data Analysis System
IFSAR Interferometric Synthetic Aperture Radar
LIDAR Laser Imaging Detection and Ranging/Light Imaging Detection and Ranging
NED National Elevation Detection and Ranging
TIN Triangular Irregular Network

HYDROLOGIC MODELING OF THE BUFFALO BAYOU USING GIS AND DEM DATA

In the 1970s, the Hydrologic Engineering Center (HEC) of the U.S. Army Corps of Engineers participated in developing some of the earliest GIS applications to meet the H&H modeling needs in water resources. In the 1990s, HEC became aware of the phenomenal growth and advancement in GIS. The capability of obtaining spatial data from the Internet coupled with powerful algorithms in software and hardware made GIS an attractive tool for water resources projects. The Buffalo Bayou Watershed covers most of the Houston metropolitan area in Texas. The first recorded flood in 1929 in the watershed devastated the city of Houston. Since then, other flooding events of similar vigor and intensity have occurred. During 1998 to 1999, the hydrologic modeling of this watershed was conducted using the Hydrologic Modeling System (HMS) with inputs derived from GIS. The watersheds and streams were delineated from the USGS DEM data at 30-m cell resolution, stream data from USGS digital line graph (DLG), and EPA river reach file (RF1). When used separately, software packages such as ArcInfo, ArcView, and Data Storage System (DSS)

were found to be time consuming, requiring the combined efforts of many people. HEC integrated these existing software tools with new programs developed in this project into a comprehensive GIS software package called HEC-GeoHMS. The low-relief terrain of the study area required human interpretation of drainage paths, urban drainage facilities, and man-made hydraulic structures (e.g., culverts and storm drains), which dictated flow patterns that could not be derived from DEM terrain representation. To resolve this issue, the project team took advantage of the flexibility in HMS to correct drainage patterns according to human interpretations and local knowledge (Doan, 1999).

DEM BASICS

Topography influences many processes associated with the geography of the Earth, such as temperature and precipitation. GIS application professionals must be able to represent the Earth's surface accurately because any inaccuracies can lead to poor decisions that may adversely impact the Earth's environment. A DEM is a numerical representation of terrain elevation. It stores terrain data in a grid format for coordinates and corresponding elevation values. DEM data files contain information for the digital representation of elevation values in a raster form. Cell-based raster data sets, or grids, are very suitable for representing geographic phenomena that vary continuously over space such as elevation, slope, precipitation, etc. Grids are also ideal for spatial modeling and analysis of data trends that can be represented by continuous surfaces, such as rainfall and stormwater runoff.

DEM data are generally stored using one of the following three data structures:

- Grid structures
- Triangular irregular network (TIN) structures
- Contour-based structures

Regardless of the underlying data structure, most DEMs can be defined in terms of (x,y,z) data values, where x and y represent the location coordinates and z represents the elevation values. Grid DEMs consist of a sampled array of elevations for a number of ground positions at regularly spaced intervals. This data structure creates a square grid matrix with the elevation of each grid square, called a pixel, stored in a matrix format. Figure 4.1 shows a 3D plot of grid-type DEM data. As shown in Figure 4.2, TINs represent a surface as a set of nonoverlapping contiguous triangular facets, of irregular size and shape. Digital terrain models (DTMs) and digital surface models (DSMs) are different varieties of DEM. The focus of this chapter is on grid-type DEMs.

Usually, some interpolation is required to determine the elevation value from a DEM for a given point. The DEM-based point elevations are most accurate in relatively flat areas with smooth slopes. DEMs produce low-accuracy point elevation values in areas with large and abrupt changes in elevation, such as cliffs and road cuts (Walski et al., 2001).

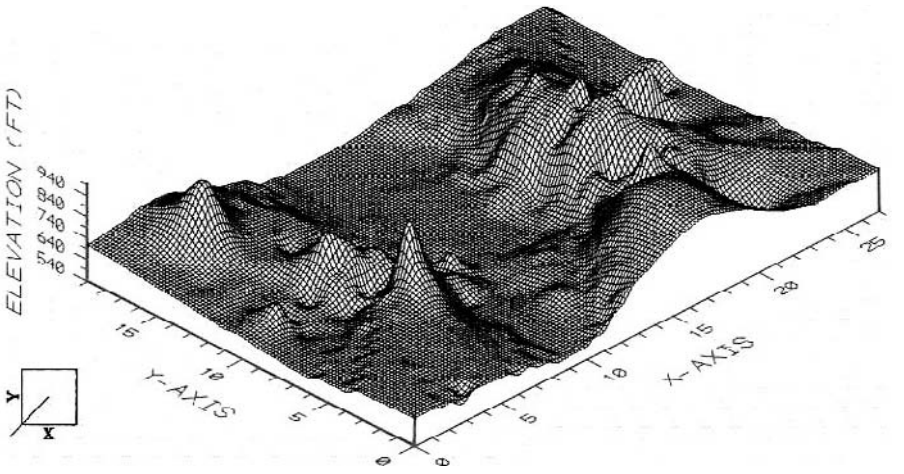

Figure 4.1 Grid-type DEM.

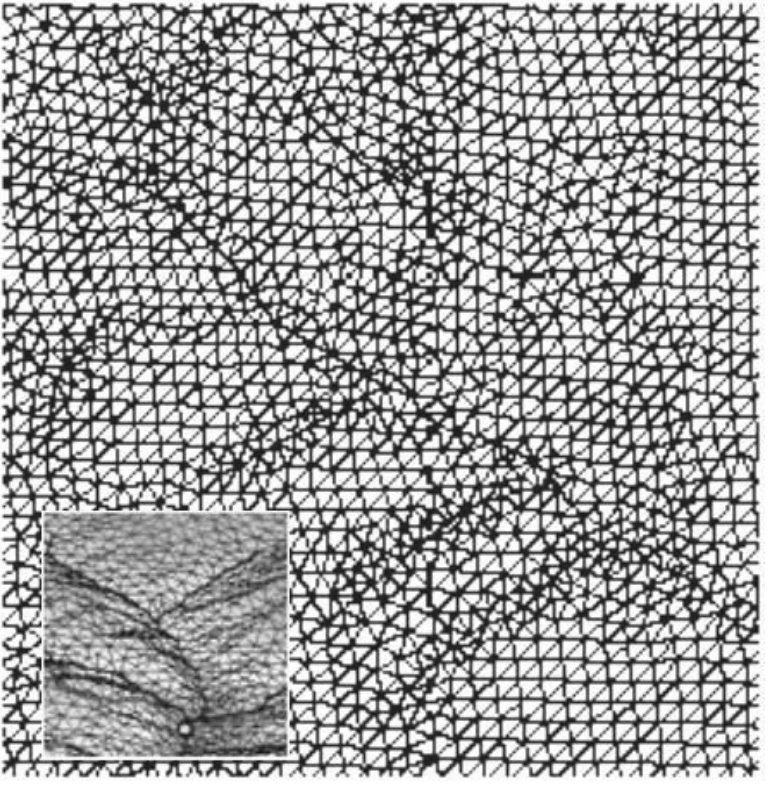

Figure 4.2 TIN-type DEM.

DEM APPLICATIONS

Major DEM applications include (USGS, 2000):

- Delineating watershed boundaries and streams
- Developing parameters for hydrologic models
- Modeling terrain gravity data for use in locating energy resources
- Determining the volume of proposed reservoirs
- Calculating the amount of material removed during strip mining
- Determining landslide probability

Jenson and Dominique (1988) demonstrated that drainage characteristics could be defined from a DEM. DEMs can be used for automatic delineation of watershed and sewershed boundaries. DEM data can be processed to calculate various watershed and sewershed characteristics that are used for H&H modeling of watersheds and sewersheds. DEMs can create shaded relief maps that can be used as base maps in a GIS for overlaying vector layers such as water and sewer lines. DEM files may be used in the generation of graphics such as isometric projections displaying slope, direction of slope (aspect), and terrain profiles between designated points. This aspect identifies the steepest downslope direction from each cell to its neighbors.

Raster GIS software packages can convert the DEMs into image maps for visual display as layers in a GIS. DEMs can be used as source data for digital orthophotos. They can be used to create digital orthophotos by orthorectification of aerial photos, as described in Chapter 3 (Remote Sensing Applications). DEMs can also serve as tools for many activities including volumetric analysis and site location of towers. DEM data may also be combined with other data types such as stream locations and weather data to assist in forest fire control, or they may be combined with remote sensing data to aid in the classification of vegetation.

Three-Dimensional (3D) Visualization

Over the past decade, 3D computer modeling has evolved in most of the engineering disciplines including, but not limited to, layout, design, and construction of industrial and commercial facilities; landscaping; highway, bridge, and embankment design; geotechnical engineering; earthquake analysis; site planning; hazardous-waste management; and digital terrain modeling. The 3D visualization can be used for landscape visualizing or fly-through animation movies of the project area. 3D animations are highly effective tools for public- and town-meeting presentations. GIS can be used to create accurate topographic elevation models and generate precise 3D data. A DEM is a powerful tool and is usually as close as most GISs get to 3D modeling.

3D graphics are commonly used as a visual communication tool to display a 3D view of an object on two-dimensional (2D) media (e.g., a paper map). Until the early 1980s, a large mainframe computer was needed to view, analyze, and print objects in 3D graphics format. Hardware and software are now available for 3D modeling of terrain and utility networks on personal computers. Although DEMs are raster images, they can be imported into 3D visualizations packages. Affordable and user-friendly software tools are bringing more users into the world of GIS.

These software tools and 3D data can be used to create accurate virtual reality representations of landscape and infrastructure with the help of stereo imagery and automatic extraction of 3D information. For example, Skyline Software System's (www.skylinesoft.com) TerraExplorer provides realistic, interactive, photo-based 3D maps of many locations and cities of the world on the Internet.

Satellite imagery is also driving new 3D GIS applications. GIS can be used to precisely identify a geographic location in 3D space and link that location and its attributes through the integration of photogrammetry, remote sensing, GIS, and 3D visualization. 3D geographic imaging is being used to create orthorectified imagery, DEMs, stereo models, and 3D features.

DEM RESOLUTION AND ACCURACY

The accuracy of a DEM is dependent upon its source and the spatial resolution (grid spacing). DEMs are classified by the method with which they were prepared and the corresponding accuracy standard. Accuracy is measured as the root mean square error (RMSE) of linearly interpolated elevations from the DEM, compared with known elevations. According to RMSE classification, there are three levels of DEM accuracy (Walski et al., 2001):

- Level 1: Based on high-altitude photography, these DEMs have the lowest accuracy. The vertical RMSE is 7 m and the maximum permitted RMSE is 15 m.
- Level 2: These are based on hypsographic and hydrographic digitization, followed by editing to remove obvious errors. These DEMs have medium accuracy. The maximum permitted RMSE is one half of the contour interval.
- Level 3: These are based on USGS digital line graph (DLGs) data (Shamsi, 2002). The maximum permitted RMSE is one third of the contour interval.

The vertical accuracy of 7.5-min DEMs is greater than or equal to 15 m. Thus, the 7.5-min DEMs are suitable for projects at 1:24,000 scale or smaller (Zimmer, 2001a). A minimum of 28 test points per DEM are required (20 interior points and 8 edge points). The accuracy of the 7.5-min DEM data, together with the data spacing, adequately support computer applications that analyze hypsographic features to a level of detail similar to manual interpretations of information as printed at map scales not larger than 1:24,000. Early DEMs derived from USGS quadrangles suffered from mismatches at boundaries (Lanfear, 2000).

DEM selection for a particular application is generally driven by data availability, judgment, experience, and test applications (ASCE, 1999). For example, because no firm guidelines are available for selection of DEM characteristics for hydrologic modeling, a hydrologic model might need 30-m resolution DEM data but might have to be run with 100-m data if that is the best available data for the study area. In the U.S., regional-scale models have been developed at scales of 1:250,000 to 1:2,000,000 (Laurent et al., 1998). Seybert (1996) concluded that modeled watershed runoff peak flow values are more sensitive to changes in spatial resolution than modeled runoff volumes. An overall subbasin area to grid–cell area ratio of 10^2 was found to produce reasonable model results.

Table 4.1 DEM Applications

DEM Resolution	Approximate Cell Size	Watershed Area (km²)	Typical Application
1 sec	30 m	5	Urban watersheds
3 sec	100 m	40	Rural watersheds
15 sec	500 m	1,000	River basins, States
30 sec	1 km	4,000	Nations
3 min	5 km	150,000	Continents
5 min	10 km	400,000	World

The grid size and time resolution used for developing distributed hydrologic models for large watersheds is a compromise between the required accuracy, available data accuracy, and computer run-time. Finer grid size requires more computing time, more extensive data, and more detailed boundary conditions. Chang et al. (2000) conducted numerical experiments to determine an adequate grid size for modeling large watersheds in Taiwan where 40 m × 40 m resolution DEM data are available. They investigated the effect of grid size on the relative error of peak discharge and computing time. Simulated outlet hydrographs showed higher peak discharge as the computational grid size was increased. In a study, for a watershed of 526 km² located in Taiwan, a grid resolution of 200 m × 200 m was determined to be adequate.

Table 4.1 shows suggested DEM resolutions for various applications (Maidment, 1998). Large (30-m) DEMs are recommended for water distribution modeling (Walski et al., 2001).

The size of a DEM file depends on the DEM resolution, i.e., the finer the DEM resolution, the smaller the grid, and the larger the DEM file. For example, if the grid size is reduced by one third, the file size will increase nine times. Plotting and analysis of high-resolution DEM files are slower because of their large file sizes.

USGS DEMS

In the U.S., the USGS provides DEM data for the entire country as part of the National Mapping Program. The National Mapping Division of USGS has scanned all its paper maps into digital files, and all 1:24,000-scale quadrangle maps now have DEMs (Limp, 2001).

USGS DEMs are the (x,y,z) triplets of terrain elevations at the grid nodes of the Universal Transverse Mercator (UTM) coordinate system referenced to the North American Datum of 1927 (NAD27) or 1983 (NAD83) (Shamsi, 1991). USGS DEMs provide distance in meters, and elevation values are given in meters or feet relative to the National Geodetic Vertical Datum (NGVD) of 1929. The USGS DEMs are available in 7.5-min, 15-min, 2-arc-sec (also known as 30-min), and 1° units. The 7.5- and 15-min DEMs are included in the large-scale category, whereas 2-arc-sec DEMs fall within the intermediate-scale category and 1° DEMs fall within the small-scale category. Table 4.2 summarizes the USGS DEM data types.

This chapter is mostly based on applications of 7.5-min USGS DEMs. The DEM data for 7.5-min units correspond to the USGS 1:24,000-scale topographic quadrangle map series for all of the U.S. and its territories. Thus, each 7.5-min

Table 4.2 USGS DEM Data Formats

DEM Type	Scale	Block Size	Grid Spacing
Large	1:24,000	7.5 ft × 7.5 ft	30 m
Intermediate	Between large and small	30 ft × 30 ft	2 sec
Small	1:250,000	1° × 1°	3 sec

by 7.5-min block provides the same coverage as the standard USGS 7.5-min map series. Each 7.5-min DEM is based on 30-m by 30-m data spacing; therefore, the raster grid for the 7.5-min USGS quads are 30 m by 30 m. That is, each 900 m^2 of land surface is represented by a single elevation value. USGS is now moving toward acquisition of 10-m accuracy (Murphy, 2000).

USGS DEM Formats

USGS DEMs are available in two formats:

1. DEM file format: This older file format stores DEM data as ASCII text, as shown in Figure 4.3. These files have a file extension of dem (e.g., lewisburg_PA.dem). These files have three types of records (Walski et al., 2001):
   - Type A: This record contains information about the DEM, including name, boundaries, and units of measurements.

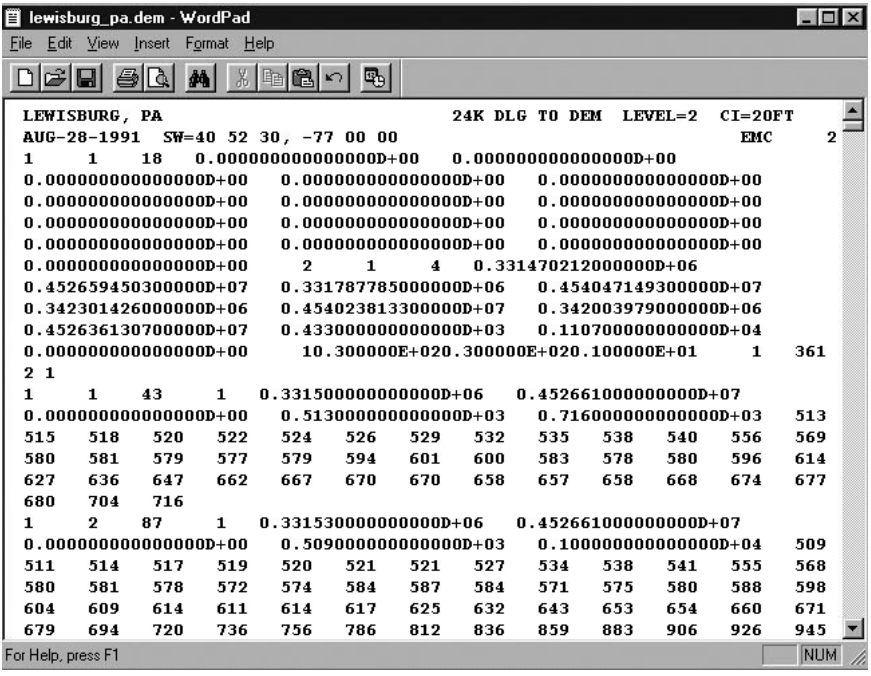

Figure 4.3 USGS DEM file.

- Type B: These records contain elevation data arranged in "profiles" from south to north, with the profiles organized from west to east. There is one Type-B record for each south–north profile.
- Type C: This record contains statistical information on the accuracy of DEM.

2. Spatial Data Transfer Standard (SDTS): This is the latest DEM file format that has compressed data for faster downloads. SDTS is a robust way of transferring georeferenced spatial data between dissimilar computer systems and has the potential for transfer with no information loss. It is a transfer standard that embraces the philosophy of self-contained transfers, i.e., spatial data, attribute, georeferencing, data quality report, data dictionary, and other supporting metadata; all are included in the transfer. SDTS DEM data are available as tar.gz compressed files. Each compressed file contains 18 ddf files and two readme text files. For further analysis, the compressed SDTS files should be unzipped (uncompressed). Standard zip programs, such as PKZIP, can be used for this purpose.

Some DEM analysis software may not read the new SDTS data. For such programs, the user should translate the SDTS data to a DEM file format. SDTS translator utilities, like SDTS2DEM or MicroDEM, are available from the GeoCommunity's SDTS Web site to convert the SDTS data to other file formats.

National Elevation Dataset (NED)

Early DEMs were derived from USGS quadrangles, and mismatches at boundaries continued to plague the use of derived drainage networks for larger areas (Lanfear, 2000). The NED produced by USGS in 1999 is the new generation of seamless DEM that largely eliminates problems of quadrangle boundaries and other artifacts. Users can now select DEM data for their area of interest.

The NED has been developed by merging the highest resolution, best-quality elevation data available across the U.S. into a seamless raster format. NED is designed to provide the U.S. with elevation data in a seamless form, with a consistent datum, elevation unit, and projection. Data corrections were made in the NED assembly process to minimize artifacts, perform edge matching, and fill sliver areas of missing data. NED is the result of the maturation of the USGS effort to provide 1:24,000-scale DEM data for the conterminous U.S. and 1:63,360-scale DEM data for Alaska. NED has a resolution of 1 arc-sec (approximately 30 m) for the conterminous U.S., Hawaii, and Puerto Rico and a resolution of 2 arc-sec for Alaska. Using a hill-shade technique, USGS has also derived a shaded relief coverage that can be used as a base map for vector themes. Other themes, such as land use or land cover, can be draped on the NED-shaded relief maps to enhance the topographic display of themes. The NED store offers seamless data for sale, by user-defined area, in a variety of formats.

DEM DATA AVAILABILITY

USGS DEMs can be downloaded for free from the USGS geographic data download Web site. DEM data on CD-ROM can also be purchased from the USGS EarthExplorer Web site for an entire county or state for a small fee to cover the shipping and handling cost. DEM data for other parts of the world are also available.

The 30 arc-sec DEMs (approximately 1 km^2 square cells) for the entire world have been developed by the USGS Earth Resources Observation Systems (EROS) Data Center and can be downloaded from the USGS Web site. More information can be found on the Web site of the USGS node of the National Geospatial Data Clearinghouse. State or regional mapping and spatial data clearinghouse Web sites are the most valuable source of free local spatial data. For example, the Pennsylvania Spatial Data Access system (PASDA), Pennsylvania's official geospatial information clearinghouse and its node on the National Spatial Data Infrastructure (NSDI), provides free downloads of DEM and other spatial data.

DEM DATA CREATION FROM REMOTE SENSING

In February 2000, NASA flew one of its most ambitious missions, using the space shuttle *Endeavor* to map the entire Earth from 60° north to 55° south of the equator. Mapping at a speed of 1747 km^2 every second, the equivalent of mapping the state of Florida in 97.5 sec, the Shuttle Radar Topography Mission (SRTM) provided 3D data of more than 80% of Earth's surface in about 10 days. The SRTM data will provide a 30-m DEM coverage for the entire world (Chien, 2000).

Topographic elevation information can be automatically extracted from remote sensing imagery to create highly accurate DEMs. There are two ways in which DEM data can be created using remote sensing methods: image processing and data collection.

Image Processing Method

The first method uses artificial intelligence techniques to automatically extract elevation information from the existing imagery. Digital image-matching methods commonly used for machine vision automatically identify and match image point locations of a ground point appearing on overlapping areas of a stereo pair (i.e., left- and right-overlapping images). Once the correct image positions are identified and matched, the ground point elevation is computed automatically. For example, the French satellite SPOT's stereographic capability can generate topographic data. USGS Earth Observing System's (EOS) Terra satellite can provide DEMs from stereo images.

Off-the-shelf image processing software products are available for automatic extraction of DEM data from remote sensing imagery. For instance, Leica Geosystems' IMAGINE OrthoBASE Pro software can be used to automatically extract DEMs from aerial photography, satellite imagery (IKONOS, SPOT, IRS-1C), and digital video and 35-mm camera imagery. It can also subset and mosaic 500 or more individual DEMs. The extracted DEM data can be saved as raster DEMs, TINs, ESRI 3D Shapefiles, or ASCII output (ERDAS, 2001b).

Data Collection Method

In this method, actual elevation data are collected directly using lasers. This method uses laser-based LIDAR and radar-based IFSAR systems described in the following text.

LIDAR

Unlike photogrammetric techniques, which can be time consuming and expensive for large areas, this method is a cost-effective alternative to conventional technologies. It can create DEMs with accuracy levels ranging from 20 to 100 cm, which are suitable for many engineering applications. This remote-sensing technology does not even involve an image. Laser imaging detection and ranging (LIDAR) is a new system for measuring ground surface elevation from an airplane. LIDAR can collect 3D digital data on the fly. LIDAR sensors provide some of the most accurate elevation data in the shortest time ever by bouncing laser beams off the ground. LIDAR technology, developed in the mid-1990s, combines global positioning system (GPS), precision aircraft guidance, laser range finding, and high-speed computer processing to collect ground elevation data. Mounted on an aircraft, a high-accuracy scanner sweeps the laser pulses across the flight path and collects reflected light. A laser range-finder measures the time between sending and receiving each laser pulse to determine the ground elevation below. The LIDAR system can survey up to 10,000 acres per day and provide horizontal and vertical accuracies up to 12 and 6 in., respectively. Chatham County, home of Savannah, Georgia, used the LIDAR approach to collect 1-ft interval contour data for the entire 250,000 acre county in less than a year. The cost of conventional topographic survey for this data would be over $20 million. The County saved $7 million in construction cost by using data from Airborne Laser Terrain Mapping (ALTM) technology, a LIDAR system manufactured by Optech, Canada. The new ALTM data were used to develop an accurate hydraulic model of the Hardin basin (Stones, 1999).

Chatham County, Georgia, saved $7 million in construction cost by using LIDAR data.

Boise-based Idaho Power Company spent $273,000 on LIDAR data for a 290 km stretch of the rugged Hell's Canyon, through which the Snake River runs. The cost of LIDAR data was found to be less than aerial data and expensive ground-surveying. The company used LIDAR data to define the channel geometry, combined it with bathymetry data, and created digital terrain files containing ten cross sections of the canyon per mile. The cross-section data were input to a hydraulic model that determined the effect of power plants' releases on vegetation and wildlife habitats (Miotto, 2000).

IFSAR

Interferometric Synthetic Aperture Radar (IFSAR) is an aircraft-mounted radar system for quick and accurate mapping of large areas in most weather conditions without ground control. Because it is an airborne radar, IFSAR collects elevation data on the first try in any weather (regardless of fog, clouds, or rain), day or night, significantly below the cost of satellite-derived DEM. The IFSAR process measures elevation data at a much denser grid than photogrammetric techniques, using overlapping stereo images. A denser DEM provides a more detailed terrain surface in

an image. IFSAR is efficient because it derives the DEM data by digital processing of a single radar image. This allows elevation product delivery within days of data collection. A DEM with a minimum vertical accuracy of 2 m is necessary to achieve the precision level orthorectification for IKONOS imagery. DEMs generated from the IFSAR data have been found to have the adequate vertical accuracy to orthorectify IKONOS imagery to the precision level (Corbley, 2001).

Intermap Technologies' (Englewood, Colorado, www.intermaptechnologies.com) Lear jet-mounted STAR-3i system, an airborne mapping system, has been reported to provide simultaneous high-accuracy DEMs and high-resolution orthorectified imagery without ground control. STAR-3i IFSAR system typically acquires elevation points at 5-m intervals, whereas photogrammetric sources use a spacing of 30 to 50 m. STAR-3i can provide DEMs with a vertical accuracy of 30 cm to 3 m and an orthoimage resolution of 2.5 m.

DEM ANALYSIS

Cell Threshold for Defining Streams

Before starting DEM analysis, users must define the minimum number of upstream cells contributing flow into a cell to classify that cell as the origin of a stream. This number, referred to as the cell "threshold," defines the minimum upstream drainage area necessary to start and maintain a stream. For example, if a stream definition value of ten cells is specified, then for a single grid location of the DEM to be in a stream, it must drain at least ten cells. It is assumed that there is flow in a stream if its upstream area exceeds the critical threshold value. In this case, the cell is considered to be a part of the stream. The threshold value can be estimated from existing topographic maps or from the hydrographic layer of the real stream network. Selection of an appropriate cell threshold size requires some user judgment. Users may start the analysis with an assumed or estimated value and adjust the initial value by comparing the delineation results with existing topographic maps or hydrographic layers. The cell threshold value directly affects the number of subbasins (subwatersheds or subareas). A smaller threshold results in smaller subbasin size, larger number of subbasins, and slower computation speed for the DEM analysis.

The D-8 Model

The 8-direction pour point model, also known as the D-8 model, is a commonly used algorithm for delineating a stream network from DEMs. As shown in Figure 4.4, it identifies the steepest downslope flow path between each cell and its eight neighboring cells. This path is the only flow path leaving the cell. Watershed area is accumulated downslope along the flow paths connecting adjacent cells. The drainage network is identified from the user-specified threshold area at the bottom of which a source channel originates and classifies all cells with a greater watershed area as part of the drainage network. Figure 4.4 shows stream delineation steps using the D-8 model with a cell threshold value of ten cells. Grid A shows the cell elevation

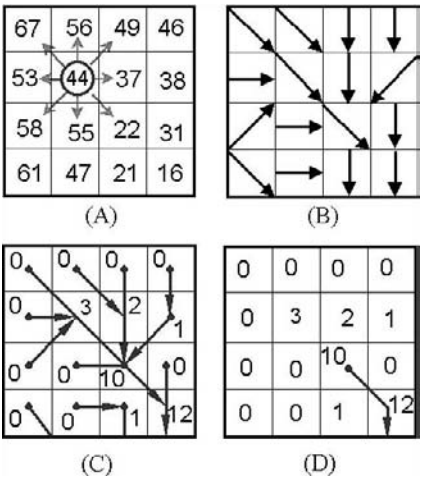

Figure 4.4 Figure 11-4. D-8 Model for DEM-based stream delineation (A) DEM elevation grid, (B) flow direction grid, (C) flow accumulation grid, and (D) delineated streams for cell threshold of ten.

values. Grid B shows flow direction arrows based on calculated cell slopes. Grid C shows the number of accumulated upstream cells draining to each cell. Grid D shows the delineated stream segment based on the cells with flow accumulation values greater than or equal to ten.

DEM Sinks

The D-8 and many other models do not work well in the presence of depressions, sinks, and flat areas. Some sinks are caused by the actual conditions, such as the Great Salt Lake in Utah where no watershed precipitation travels through a river network toward the ocean. The sinks are most often caused by data noise and errors in elevation data. The computation problems arise because cells in depressions, sinks, and flat areas do not have any neighboring cells at a lower elevation. Under these conditions, the flow might accumulate in a cell and the resulting flow network may not necessarily extend to the edge of the grid. Unwanted sinks must be removed prior to starting the stream or watershed delineation process by raising the elevation of the cells within the sink to the elevation of its lowest outlet. Most raster GIS software programs provide a FILL function for this purpose. For example, ArcInfo's GRID extension provides a FILL function that raises the elevation of the sink cells until the water is able to flow out of it.

The FILL approach assumes that all sinks are caused by underestimated elevation values. However, the sinks can also be created by overestimated elevation values, in which case breaching of the obstruction is more appropriate than filling the sink created by the obstruction. Obstruction breaching is particularly effective in flat or low-relief areas (ASCE, 1999).

Stream Burning

DEM-based stream or watershed delineations may not be accurate in flat areas or if the DEM resolution failed to capture important topographic information. This problem can be solved by "burning in" the streams using known stream locations from the existing stream layers. This process modifies the DEM grid so that the flow of water is forced into the known stream locations. The cell elevations are artificially lowered along the known stream locations or the entire DEM is raised except along known stream paths. The phrase *burning in* indicates that the streams have been forced, or "burned" into the DEM topography (Maidment, 2000). This method must be used with caution because it may produce flow paths that are not consistent with the digital topography (ASCE, 1999).

DEM Aggregation

Distributed hydrologic models based on high-resolution DEMs may require extensive computational and memory resources that may not be available. In this case, high-resolution DEMs can be aggregated into low-resolution DEMs. For example, it was found that the 30-m USGS DEM would create 80,000 cells for the 72.6 km^2 Goodwater Creek watershed located in central Missouri. Distributed modeling of 80,000 cells was considered time consuming and impractical (Wang et al., 2000). The 30 m $\times$ 30 m cells were, therefore, aggregated into 150 m x 150 m (2.25 ha) cells. In other words, 25 smaller cells were aggregated into one large cell, which reduced the number of cells from 80,000 to approximately 3,000. Best of all, the aggregated DEM produced the same drainage network as the original DEM. The aggregation method computes the flow directions of the coarse-resolution cells based on the flow paths defined by the fine-resolution cells. It uses three steps: (1) determine the flow direction of the fine-resolution DEM, (2) determine outlets of coarse-resolution DEM, and (3) approximate the flow direction of coarse-resolution DEM, based on the flow direction of the fine-resolution DEM.

Slope Calculations

Subbasin slope is an input parameter in many hydrologic models. Most raster GIS packages provide a SLOPE function for estimating slope from a DEM. For example, ERDAS IMAGINE software uses its SLOPE function to compute percent slope by fitting a plane to a pixel elevation and its eight neighboring pixel elevations. The difference in elevation between the low and the high points is divided by the horizontal distance and multiplied by 100 to compute percent slope for the pixel. Pixel slope values are averaged to compute the mean percent slope of each subbasin.

SOFTWARE TOOLS

The DEM analysis functions described in the preceding subsections require appropriate software. Representative DEM analysis software tools and utilities are listed in Table 4.3.

Table 4.3 Sample DEM Analysis Software Tools

Software	Vendor and Web site	Notes
Spatial Analyst and Hydro extension	ESRI, Redlands, California www.esri.com	ArcGIS 8.x and ArcView 3.x extension
ARC GRID extension		ArcInfo 7.x extension
Analyst		ArcGIS 8.x and ArcView 3.x extension
IDRISI	Clark University Worcester, Massachusetts www.clarklabs.org	
ERDAS IMAGINE	Leica Geosystems, Atlanta, Georgia gis.leica-geosystems.com www.erdas.com	Formerly, Earth Resource Data Analysis System (ERDAS) software
TOPAZ	U.S. Department of Agriculture, Agricultural Research Service, El Reno, Oklahoma grl.ars.usda.gov/topaz/TOPAZ1.HTM	
MicroDEM	U.S. Naval Academy www.usna.edu/Users/oceano/pguth/website/microdem.htm	Software developed by Peter Guth of the Oceanography Department
DEM3D viewer	USGS, Western Mapping Center, Menlo Park, California craterlake.wr.usgs.gov/dem3d.html	Free download, allows viewing of DEM files through a 3D perspective

Some programs such as Spatial Analyst provide both the DEM analysis and hydrologic modeling capabilities. ASCE (1999) has compiled a review of hydrologic modeling systems that use DEMs. Major DEM software programs are discussed in the following text.

Spatial Analyst and Hydro Extension

Spatial Analyst is an optional extension (separately purchased add-on program) for ESRI's ArcView 3.x and ArcGIS 8.x software packages. The Spatial Analyst Extension adds raster GIS capability to the ArcView and ArcGIS vector GIS software. Spatial Analyst allows for use of raster and vector data in an integrated environment and enables desktop GIS users to create, query, and analyze cell-based raster maps; derive new information from existing data; query information across multiple data layers; and integrate cell-based raster data with the traditional vector data sources. It can be used for slope and aspect mapping and for several other hydrologic analyses, such as delineating watershed boundaries, modeling stream flow, and investigating accumulation. Spatial Analyst for ArcView 3.x has most, but not all, of the functionality of the ARC GRID extension for ArcInfo 7.x software package described below.

Spatial Analyst for ArcView 3.x is supplied with a Hydro (or hydrology) extension that further extends the Spatial Analyst user interface for creating input data for hydrologic models. This extension provides functionality to create watersheds and stream networks from a DEM, calculate physical and geometric properties of the watersheds, and aggregate these properties into a single-attribute table that can be attached to a grid or Shapefile. Hydro extension requires that Spatial Analyst be already installed. Hydro automatically loads the Spatial Analyst if it is not loaded.

Depending upon the user needs, there are two approaches to using the Hydro extension:

1. Hydro pull-down menu options: If users only want to create watershed subbasins or the stream network, they should work directly with the Hydro pull-down menu options (Figure 4.5). Table 4.4 provides a brief description of each of these menu options. "Fill Sinks" works off an active elevation grid theme. "Flow Direction" works off an active elevation grid theme that has been filled. "Flow Accumulation" works off an active flow direction grid theme. "Flow Length" works off an active flow direction grid theme. "Watershed" works off an active flow accumulation grid theme and finds all basins in the data set based on a minimum number of cells in each basin. The following steps should be performed to create watersheds using the Hydro pull-down menu options, with the output grid from each step serving as the input grid for the next step:
   - Import the raw USGS DEM.
   - Fill the sinks using the "Fill Sinks" menu option (input = raw USGS DEM). This is a very important intermediate step. Though some sinks are valid, most are data errors and should be filled.
   - Compute flow directions using the "Flow Direction" menu option (input = filled DEM grid).
   - Compute flow accumulation using the "Flow Accumulation" menu option (input = flow directions grid).

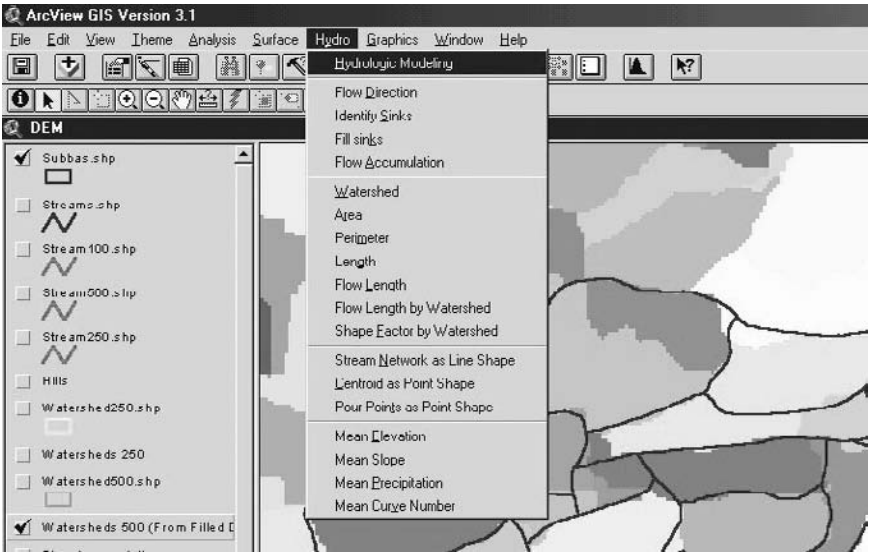

Figure 4.5 Hydro extension pull-down menu.

- Delineate streams using the "Stream Network" menu option (input = flow accumulation grid).
- Delineate watersheds using the "Watershed" menu option.

2. Hydrologic Modeling Dialogue: If users want to create subbasins and calculate many additional attributes for them, they should use the Hydrologic Modeling Dialogue (Figure 4.6), which is the first choice under the Hydro pull-down menu. The Hydrologic Modeling Dialogue is designed to be a quick one-step method for calculating and then aggregating a set of watershed attributes to a single file. This file can then be used in a hydrologic model, such as the Watershed Modeling System (WMS) (discussed in Chapter 11 [Modeling Applications]), or it can be reformatted for input into HEC's HMS model, or others. The following steps should be performed to create watersheds using the Hydrologic Modeling Dialogue:
   - Choose "Delineate" from DEM and select an elevation surface.
   - Fill the sinks when prompted.
   - Specify the cell threshold value when prompted. This will create watersheds based on the number of cells or up-slope area defined by the user as the smallest watershed wanted.

Additional DEM analysis resources (tutorials, exercises, sample data, software utilities, reports, papers, etc.) are provided at the following Web sites:

- ESRI Web site at www.esri.com/arcuser/ (do a search for "Terrain Modeling")
- University of Texas at Austin (Center for Research in Water Resources) Web site at www.crwr.utexas.edu/archive.shtml

The last four Hydro options (Table 4.4) work with existing data layers. They do not create elevation, slope, precipitation, and runoff curve number layers. They

Table 4.4 Hydro Extension Menu Options

Hydro Menu Option	Function
Hydrologic modeling	Creates watersheds and calculates their attributes
Flow direction	Computes the direction of flow for each cell in a DEM
Identify sinks	Creates a grid showing the location of sinks or areas of internal drainage in a DEM
Fill sinks	Fills the sinks in a DEM, creating a new DEM
Flow accumulation	Calculates the accumulated flow or number of up-slope cells, based on a flow direction grid
Watershed	Creates watersheds based upon a user-specified flow accumulation threshold
Area	Calculates the area of each watershed in a watershed grid
Perimeter	Calculates the perimeter of each watershed in a watershed grid
Length	Calculates the straight-line distance from the pour point to the furthest perimeter point for each watershed
Flow length	Calculates the length of flow path for each cell to the pour point for each watershed
Flow length by watershed	Calculates the maximum distance along the flow path within each watershed
Shape factor by watershed	Calculates a shape factor (watershed length squared and then divided by watershed area) for each watershed
Stream network as line shape	Creates a vector stream network from a flow accumulation grid, based on a user-specified threshold
Centroid as point shape	Creates a point shape file of watershed centroids
Pour points as point shape	Creates a point shape file of watershed pour points
Mean elevation	Calculates the mean elevation within each watershed
Mean slope	Calculates the mean slope within each watershed
Mean precipitation	Calculates the mean precipitation in each watershed
Mean curve number	Calculates the mean curve number for each watershed

simply compute mean areal values of these four parameters for the subbasins, using the existing GIS layers of these parameters. Thus, the GIS layers of elevation, slope, precipitation, and runoff curve number must be available to use the mean functions of the Hydro extension.

Figure 4.7 shows Hydro's raindrop or pour point feature. Using this capability, the user can trace the flow path from a specified point to the watershed outlet. Hydro also calculates a flow length as the maximum distance along the flow path within each watershed. The flow path can be divided by the measured or estimated velocity to estimate the time of concentration or travel time that are used to estimate runoff hydrographs. Travel time can also be used to estimate the time taken by a hazardous waste spill to reach a sensitive area or water body of the watershed. Laurent et al. (1998) used this approach to estimate travel time between any point of a watershed and a water resource (river or well). This information was further used to create a map of water resources vulnerability to dissolved pollution in an area in Massif Central, France. Subbasin area can be divided by flow length to estimate the overland flow width for input to a rainfall-runoff model such as EPA's Storm Water Management Model (SWMM).

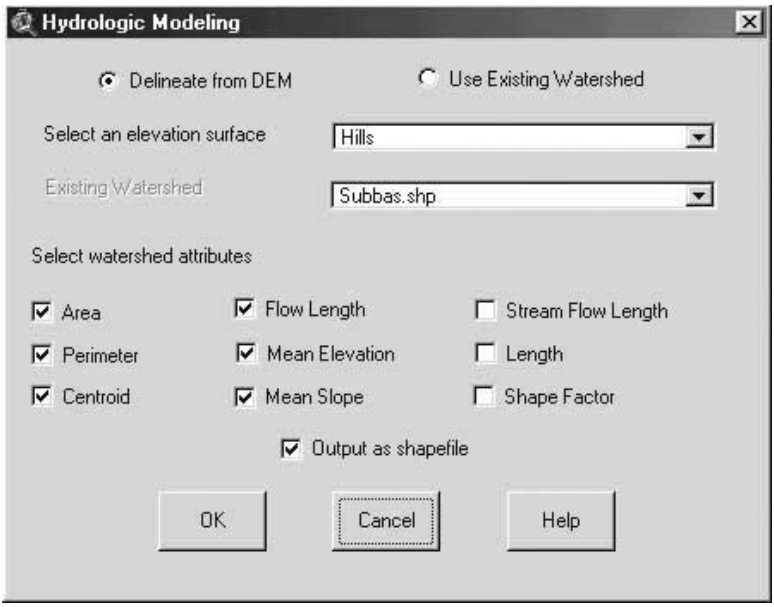

Figure 4.6 Hydro extension Hydrologic Modeling Dialogue.

ARC GRID Extension

ARC GRID is an optional extension for ESRI's ArcInfo® 7.x GIS software package. GRID adds raster geoprocessing and hydrologic modeling capability to the vector-based ArcInfo GIS. For hydrologic modeling, the extension offers a Hydrologic Tool System and several hydrologically relevant functions for watershed and stream network delineation.

The FLOWDIRECTION function creates a grid of flow directions from each cell to the steepest downslope neighbor. The results of FLOWDIRECTION are used in many subsequent functions such as stream delineation. The FLOWACCUMULATION function calculates upstream area or cell-weighted flow draining into each cell. The WATERSHED function delineates upstream tributary area at any user-specified point, channel junction, or basin outlet cell. This function requires step-by-step calculations. Arc Macro Language (AML) programs can be written to automate this function for delineating subbasins at all the stream nodes.

GRID can find upstream or downstream flow paths from any cell and determine their lengths. GRID can perform stream ordering and assign unique identifiers to the links of a stream network delineated by GRID. Spatial intersection between streams and subbasins can define the links between the subbasins and streams. This method relates areal attributes such as subbasin nutrient load to linear objects such as streams. The NETWORK function can then compute the upstream accumulated nutrient load for each stream reach (Payraudeau et al., 2000). This approach is also useful in DEM-based runoff quality modeling.

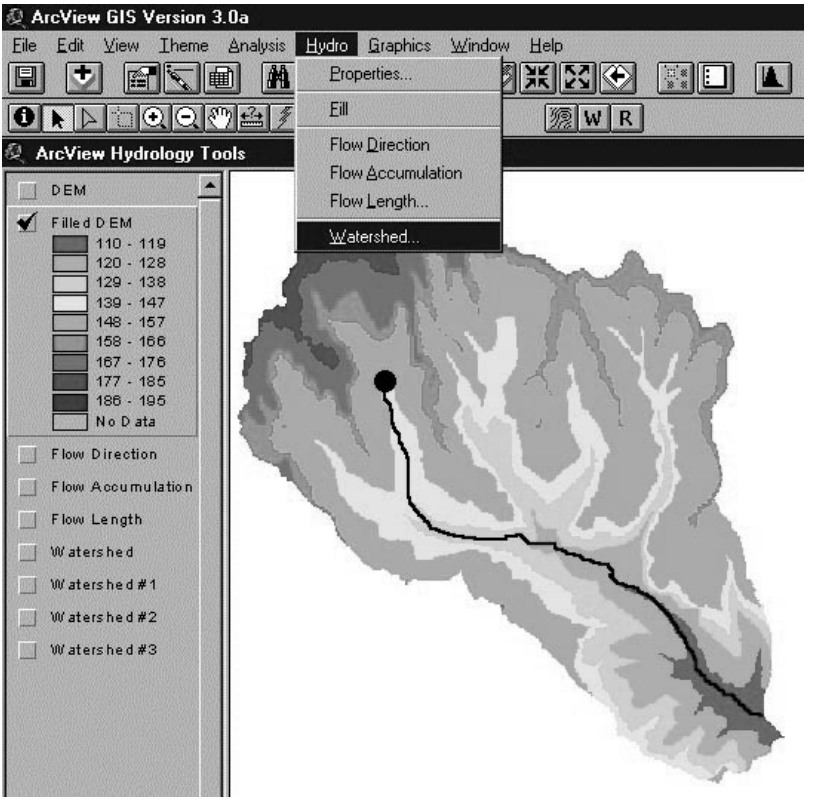

Figure 4.7 Hydro extension's pour point feature.

IDRISI

IDRISI is not an acronym; it is named after a cartographer born in 1099 A.D. in Morocco, North Africa. IDRISI was developed by the Graduate School of Geography at Clark University. IDRISI provides GIS and remote sensing software functions, from database query through spatial modeling to image enhancement and classification. Special facilities are included for environmental monitoring and natural resource management, including change and time-series analysis, multicriteria and multiobjective decision support, uncertainty analysis (including Bayesian and Fuzzy Set analysis), and simulation modeling (including force modeling and anisotropic friction analysis). TIN interpolation, Kriging, and conditional simulation are also offered.

IDRISI is basically a raster GIS. IDRISI includes tools for manipulating DEM data to extract streams and watershed boundaries. IDRISI GIS data has an open format and can be manipulated by external computer programs written by users. This capability makes IDRISI a suitable tool for developing hydrologic modeling applications. For example, Quimpo and Al-Medeij (1998) developed a FORTRAN

program to model surface runoff using IDRISI. Their approach consisted of delineating watershed subbasins from DEM data and estimating subbasin runoff curve numbers from soils and land-use data.

Figure 4.8 shows IDRISI's DEM analysis capabilities. The upper-left window shows a TIN model created from digital contour data. The upper-right window shows a DEM created from the TIN with original contours overlayed. The lower-right window shows an illuminated DEM emphasizing relief. The lower-left window shows a false color composite image (Landsat TM bands 2, 3, and 4) draped over the DEM (IDRISI, 2000).

TOPAZ

TOPAZ is a software system for automated analysis of landscape topography from DEMs (Topaz, 2000). The primary objective of TOPAZ is the systematic identification and quantification of topographic features in support of investigations related to land-surface processes, H&H modeling, assessment of land resources, and management of watersheds and ecosystems. Typical examples of topographic features that are evaluated by TOPAZ include terrain slope and aspect, drainage patterns and divides, channel network, watershed segmentation, subcatchment identification, geometric and topologic properties of channel links, drainage distances, representative subcatchment properties, and channel network analysis (Garbrecht and Martz, 2000). The FILL Function of TOPAZ recognizes depressions created by embankments and provides outlets for these without filling, a better approach than the fill-only approach in other programs (e.g., IDRISI or Spatial Analyst).

CASE STUDIES AND EXAMPLES

Representative applications of using DEM data in GIS are described in this section.

Watershed Delineation

A concern with streams extracted from DEMs is the precise location of streams. Comparisons with actual maps or aerial photos often show discrepancies, especially in low-relief landscapes (ASCE, 1999). A drainage network obtained from a DEM must be comparable to the actual hydrologic network. Thus, it is worthwhile to check the accuracy of DEM-based delineations. This can be done by comparing the DEM delineations with manual delineations. Jenson (1991) found approximately 97% similarity between automatic and manual delineations from 1:50,000-scale topographic maps.

The objective of this case study was to test the efficacy of DEM-based automatic delineation of watershed subbasins and streams. It was assumed that manual delineations are more accurate than DEM delineations. Thus, a comparison of manual and DEM delineations was made to test the accuracy of DEM delineations.

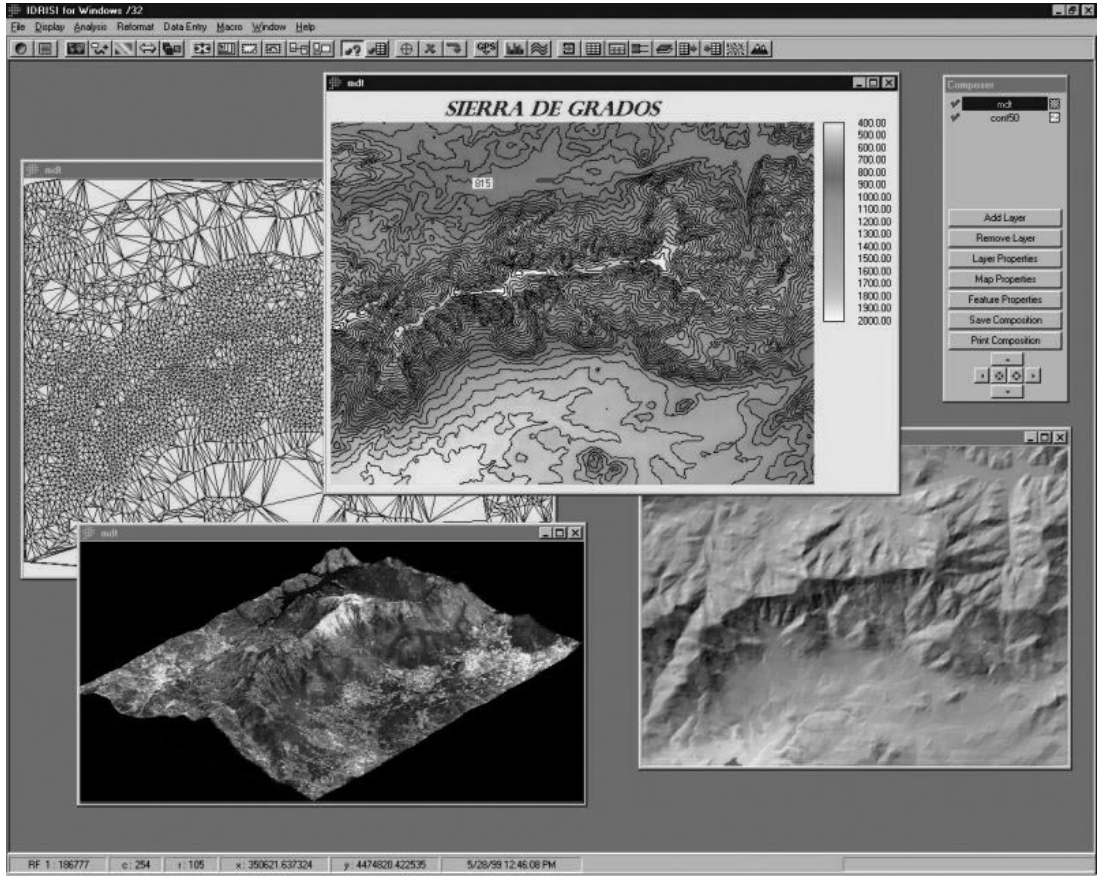

Figure 4.8 IDRISI's DEM analysis features.

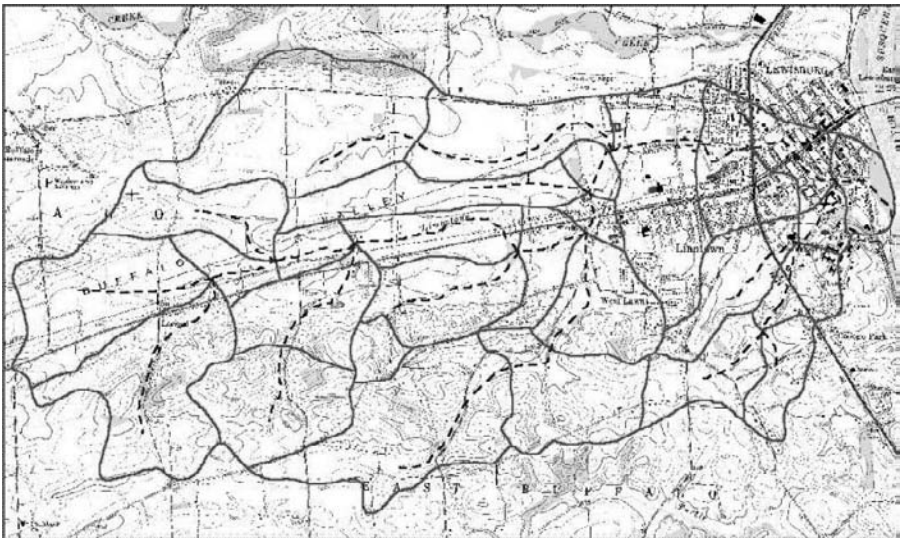

Figure 4.9 Bull Run Watershed showing manual subbasins and streams.

The case study watershed is the Bull Run Watershed located in Union County in north-central Pennsylvania (Shamsi, 1996). This watershed was selected because of its small size so that readable report-size GIS maps can be printed. The proposed technique has also been successfully applied to large watersheds with areas of several hundred square miles. Bull Run Watershed's 8.4 mi^2 (21.8 km^2) drainage area is tributary to the West Branch Susquehanna River at the eastern boundary of Lewisburg Borough. The 7.5-min USGS topographic map of the watershed is shown in Figure 4.9. The predominant land use in the watershed is open space and agricultural. Only 20% of the watershed has residential, commercial, and industrial land uses.

Manual watershed subdivision was the first step of the case study. The 7.5-min USGS topographic map of the study area was used for manual subbasin delineation, which resulted in the 28 subbasins shown in Figure 4.9. This figure also shows the manually delineated streams (dashed lines).

Next, ArcView Spatial Analyst and Hydro extension were used to delineate subbasins and streams using the 7.5-min USGS DEM data. Many cell threshold values (50, 100, 150, …, 1000) were used repeatedly to determine which DEM delineations agreed with manual delineations. Figure 4.10, Figure 4.11, and Figure 4.12 show the DEM subbasins for cell thresholds of 100, 250, and 500. These figures also show the manual subbasins for comparison. It can be seen that the 100 threshold creates too many subbasins. The 500 threshold provides the best agreement between manual and DEM delineations.

Figure 4.13, Figure 4.14, and Figure 4.15 show the DEM streams for cell threshold values of 100, 250, and 500. These figures also show the manually delineated streams for comparison purposes. It can be seen that the 100 threshold creates too many streams (Figure 4.13); the 500 threshold looks best (Figure 4.15) and

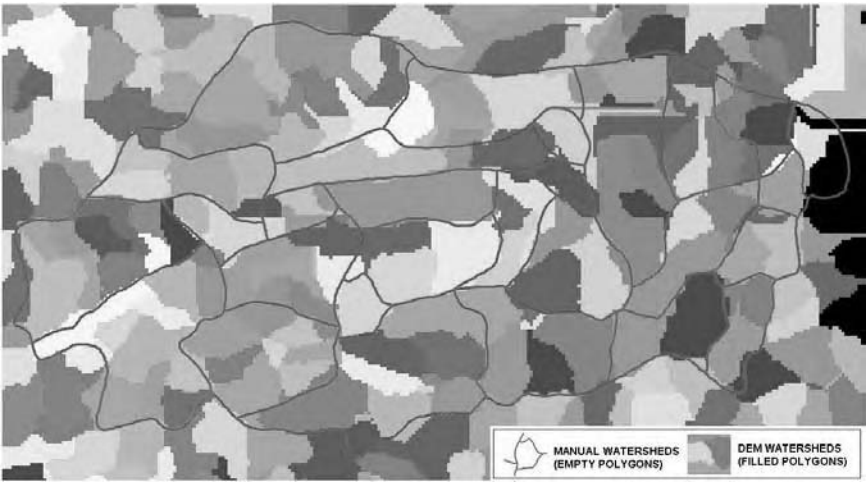

Figure 4.10 Manual vs. DEM subbasins for cell threshold of 100 (too many subbasins).

provides the best agreement between the manual and DEM streams. The upper-right boundary of the watershed in Figure 4.15 shows that one of the DEM streams crosses the watershed boundary. This problem is referred to as the boundary "cross-over" problem, which is not resolved by altering threshold values. It must be corrected by manual editing of DEM subbasins or using DEM preprocessing methods such as the stream burning method described earlier.

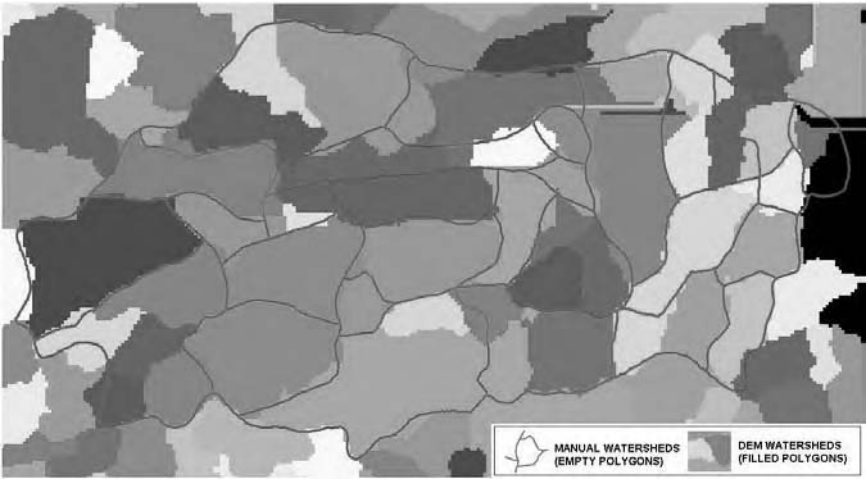

Figure 4.11 Manual vs. DEM subbasins for cell threshold of 250 (better).

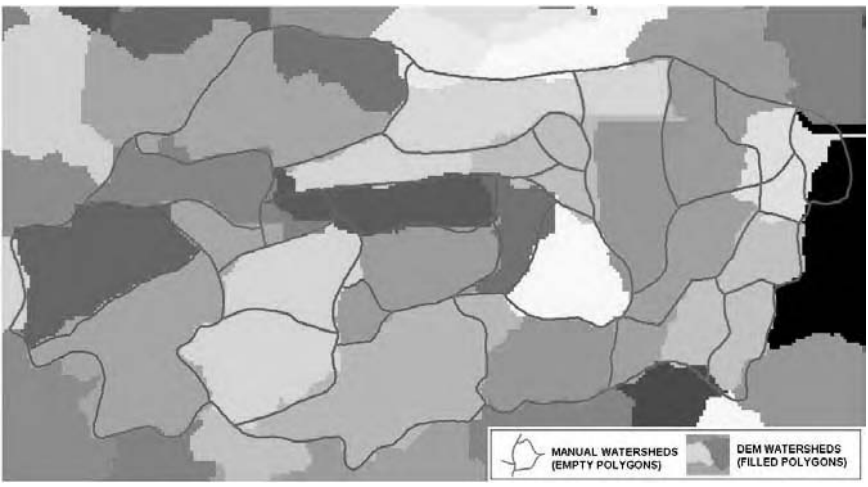

Figure 4.12 Manual vs. DEM subbasins for cell threshold of 500 (best).

Figure 4.16 shows DEM-derived subbasin and stream maps for a portion of the very large Monongahela River Basin located in south western Pennsylvania, using the 30-m USGS DEM data and a cell threshold value of 500 cells.

From the Bull Run watershed case study, it can be concluded that for rural and moderately hilly watersheds, 30-m resolution DEMs are appropriate for automatic delineation of watershed subbasins and streams. The 30-m DEMs work well for the mountainous watersheds like those located in Pennsylvania where subbasin boundaries

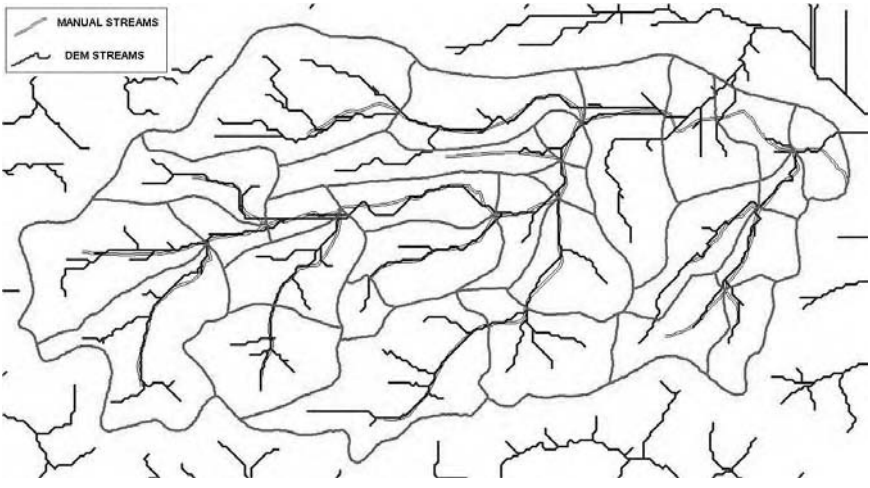

Figure 4.13 Manual vs. DEM streams for cell threshold of 100 (too many streams).

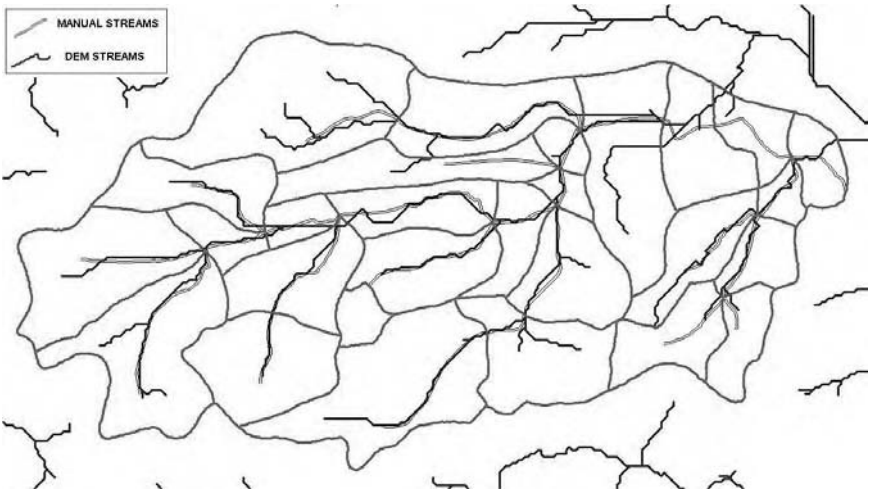

Figure 4.14 Manual vs. DEM streams for cell threshold of 250 (better).

are well defined and distinct due to highly variable topography. For 30-m USGS DEMs, a cell threshold of 500 is appropriate. Stream networks generated from the 30-m USGS DEMs at a cell threshold value of 500 were satisfactory, with a minor watershed boundary crossover problem. Correction of boundary crossover problems might require some manual intervention to ensure the efficacy of the DEM-based automatic

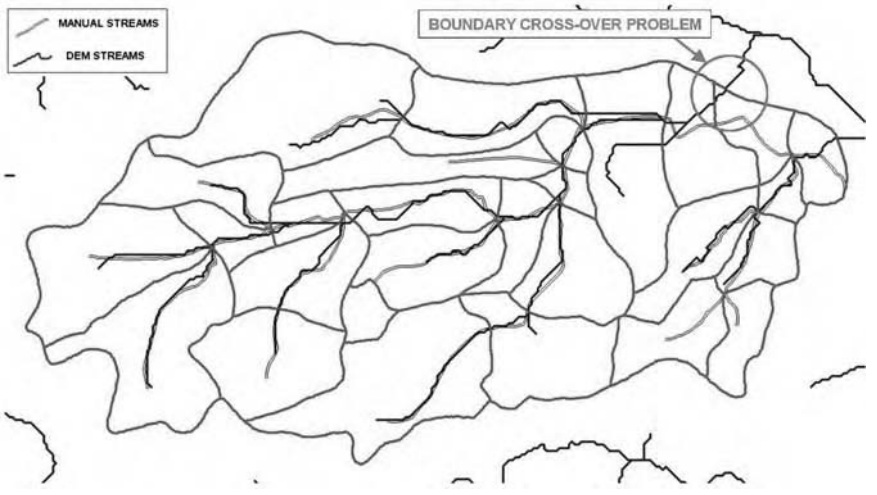

Figure 4.15 Manual vs. DEM streams for cell threshold of 500 (best).

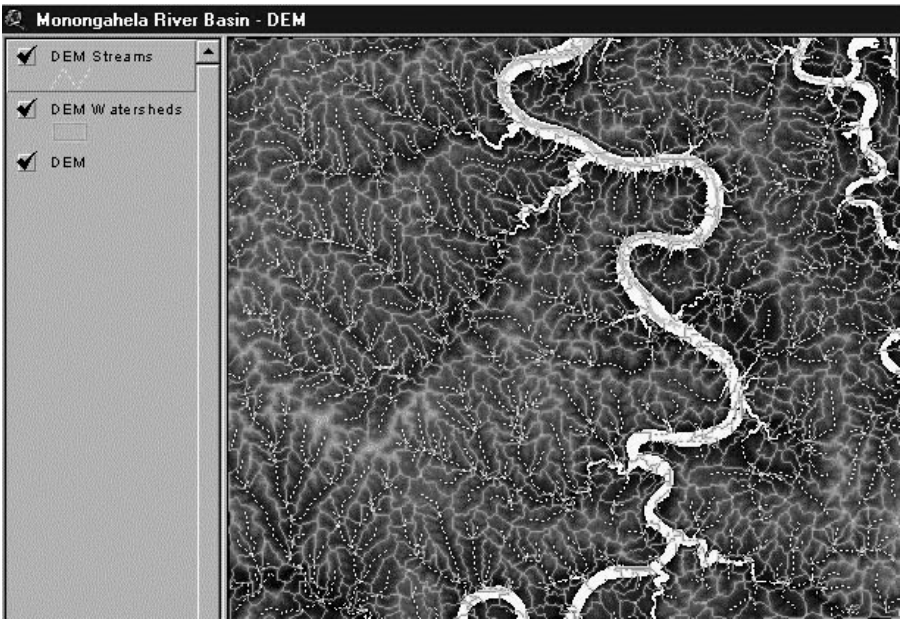

Figure 4.16 DEM-derived watersheds and streams for a large watershed.

watershed delineation approach. Compared with the manual watershed delineation approach, the DEM approach offers significant time savings, eliminates user subjectivity, and produces consistent results.

Sewershed Delineation

Watersheds define the drainage areas of natural streams and rivers. Sewersheds define the drainage areas of man-made sewers and storm drains. The conventional manual method of sewershed delineation is cumbersome, and an automated method is desirable. Can we use DEMs for automatic delineation of sewersheds? Unfortunately, the current research indicates that DEMs are generally applicable to natural landscapes and may not apply to urbanized settings (ASCE, 1999). This limitation is expected to be more pronounced in low-relief or flat areas. DEM delineations are based on the premise that water flows in the downslope direction, i.e., that all the sewers are gravity pipes. Therefore, DEM-based sewershed delineations will not be accurate for a pumped system with force mains and will require manual editing of the sewershed boundaries.

Figure 4.17 shows a comparison of DEM watersheds (filled polygons) and manually delineated sewersheds for the gravity sewers area of the Borough of Charleroi located near Pittsburgh, Pennsylvania. The watersheds were created from the 30-m resolution USGS DEM of the study area using a cell threshold of 100. The mean land slope of the study area is approximately 15%. The comparison shows that some sewersheds (for example, Sewershed Nos. 3, 4, 5, and 6) are reasonably

Figure 4.17 Comparison of DEM watersheds (filled polygons) and manually drawn sewersheds.

close to the watershed boundaries and some sewersheds (for example, Sewershed No. 2) are quite different from the watershed boundaries.

The Massachusetts Water Resources Authority (MWRA) recently determined that DEMs were not too helpful in delineating sewershed boundaries (Herrlin, 2000). MWRA, instead, used a "Euclidean Distance" approach consisting of the following steps:

1. All the sewers tributary to a pour point (point where a trunk sewer connects an interceptor) are identified using a custom network-tracing utility (upstream trace). The group of pipes identified like this defines a tributary area.
2. A new attribute with the name of the tributary area is manually added to all the sewers. This step is quite laborious but needs to be done only once.
3. Vector sewer layers are converted to a grid format. This is necessary because the Euclidean distance approach works only on raster layers.
4. The Euclidean distance allocation function is applied to all the sewer cells. The Euclidean distance is calculated in the same manner as finding the hypotenuse of a triangle. This generates a sewershed boundary around sewers.
5. The raster Euclidean distance boundaries are converted back to vector (polygon) format.

Some techniques that may be used for improving the accuracy of DEM-based sewershed delineations are listed below:

1. Use large-scale, high-resolution DEMs derived from digital orthophotos. These relatively dense DEMs have break lines at breaks in grades, which may provide valuable information for delineating sewersheds in flat urban areas. LIDAR technology can also provide highly accurate and cost-effective DEMs and 3D break lines that can be used for delineating sewersheds.
2. Burning in the DEMs with streams improves the accuracy of delineated watersheds in flat areas. Burning in the DEMs with sewers may improve the delineated sewersheds.
3. Adding manhole rim elevations to DEMs may be helpful in delineating sewersheds. Alternatively, DEMs may be burned in with manhole rim elevations.

Water Distribution System Modeling

The performance of a water distribution system depends on variations in ground surface elevation. For example, high-elevation areas may experience inadequate pressure if appropriate pumping is not provided. Thus, all distribution system models require input data for the elevation of each model node. DEMs can be used for 3D representation of water systems and estimating elevation at the nodes of a water distribution network model.

Shamsi (1991) showed applications of personal computer-based 3D graphics in network and reliability modeling of water distribution systems. Optional 3D extensions of GIS software, such as ESRI's 3D Analyst, can create 3D maps of terrain, water demand, and modeled pressures. Figure 4.18 shows three stacked surfaces: ground surface elevations, demands, and modeled average daily pressures for the Borough of White Haven, Pennsylvania. The land area of the borough is 773 acres, the population is 1,091 persons, and the average daily demand is 197,000 gal/d. The distribution system consists of water mains ranging in size from 2 to 8 in. It is interesting to note the high-pressure areas coinciding with the low-elevation areas, and vice versa. It also quickly becomes apparent that the high-demand areas predominate in the lower elevations. A display such as Figure 4.18 is an effective visual aid to displaying the hydraulic model results. Most importantly, such graphics can be easily understood by system operators without the extensive training that is usually required to understand the model output in tabular format.

Node elevation is a critical input parameter for all water distribution system models. Traditionally, the node elevations have been determined manually by overlaying the water distribution network over a topographic map of the study area. Unfortunately, due to its tedious nature, this approach is cumbersome. GIS is now being used to automatically extract the node elevations from a DEM of the study area. This approach requires a vector layer of the network nodes, a DEM grid, and a user script. The script appends a new "Elevation" field to the "Node" layer table, queries the DEM grid at node locations, and writes the elevation values in the Elevation field.

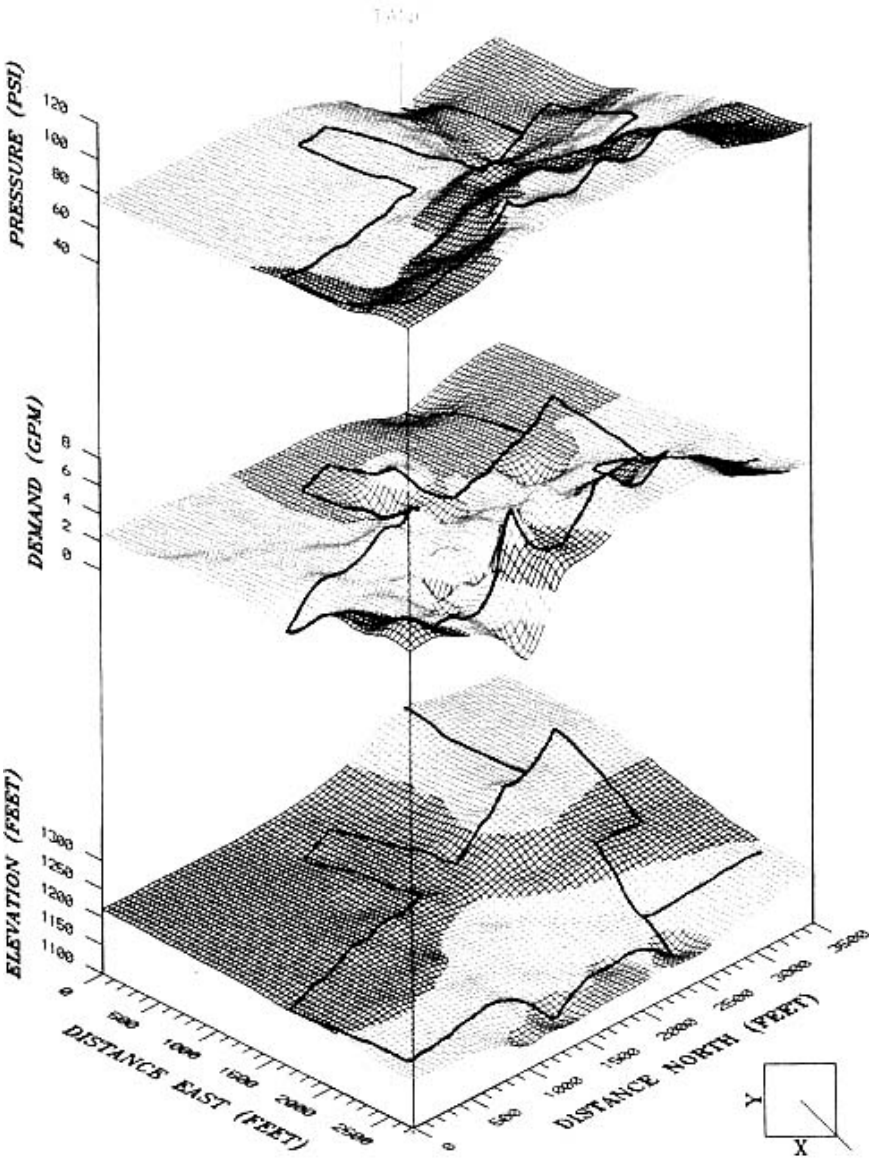

Figure 4.18 Hydraulic modeling results as 3D surfaces.

WaterCAD Example

If node locations are available in an ArcView Shapefile, ArcView 3D Analyst extension (Version 3.x) can be used to calculate node elevation from a DEM grid. This extension uses bilinear interpolation to calculate the node elevation from the

grid cell elevation data. The elevation data are pulled from the DEM overlay, and the node file is converted to a 3D file. The steps for this procedure for Haestad Method's WaterCAD modeling software are listed below (Walski et al., 2001):

1. Start ArcView and load the 3D Analyst extension.
2. Add both the DEM grid and the node point themes to the same view.
3. Select "Theme\Convert to 3D Shapefile." Select "Surface" for the elevation file type and enter the name of the DEM grid (input). Also provide a name for the 3D Shapefile (output).
4. Use an Avenue script to extract elevation data from the 3D Shapefile and place them in the node theme table. A sample script called addxyz.ave (Hsu, 1999; Shamsi, 2002) can be downloaded from the ESRI ArcScripts Web site (www.esri.com/arcscripts/scripts.cfm).
5. Select "File\Export" from the ArcView pull-down menus and enter the export filename for a dBase IV (DBF) or delimited text (TXT) file.
6. Select "File\Synchronize\database Connections" from the WaterCAD's pull-down menus and set up a link between the export file (created in the previous step) and WaterCAD.
7. Select "Elevation" as the WaterCAD field into which the elevation data should be imported and the name of the corresponding field in the export file (e.g., "Z-coord").
8. Select the link in the Database Connection Manager and click the "Synchronize In" button.
9. Finally, validate the success of elevation data import process by checking the elevations at a number of nodes against known elevations.

CHAPTER SUMMARY

GIS provides an integrated platform for using DEMs. DEM data can be used for automatic watershed and stream delineation and computation of watershed hydrologic parameters. DEMs can be used as source data for digital orthophotos and as base maps in a GIS. DEM data can be created from topographic maps and remote

sensing data. DEMs are not intended to replace elevation data obtained from surveys, high-accuracy GPS, or even well-calibrated altimeters. Rather, DEMs should be used as a labor-saving process to relieve the user of the tedium and human error involved in the conventional manual interpolation method from paper maps. Public-domain DEMs generally do not have adequate resolution and accuracy for engineering design. They are suitable for applications where a high degree of accuracy is not required, such as H&H modeling.

CHAPTER QUESTIONS

1. What are DEMs and how are they used in GIS?
2. List at least ten applications of DEMs?
3. What are the limitations of DEM data? How are they overcome?
4. How are DEMs used for delineating (1) streams, (2) watersheds, and (3) sewersheds?
5. How are DEMs created using the remote sensing technology?

CHAPTER 5

GPS Applications

GPS technology is no longer limited to determining coordinates. It has become an efficient and increasingly popular way for collecting GIS attribute data for water and wastewater infrastructure.

GIS data collection for sewer system manholes using GPS.

LEARNING OBJECTIVE

The learning objective of this chapter is to discover the applications of global positioning system (GPS) technology in water industry GIS projects.

MAJOR TOPICS

- GPS basics
- GPS applications in water industry
- GPS applications in GIS
- GPS survey steps
- GPS equipment
- GPS software

LIST OF CHAPTER ACRONYMS

DGPS Differential Global Positioning System
GPS Global Positioning System

STREAM MAPPING IN IOWA

Application	Stream traversing and mapping channel features using GPS
GPS software	Trimble's Pathfinder Office
GPS equipment	Trimble Pathfinder Pro XR
GPS accuracy	1 m for discrete data and 5 m for continuous data
GPS data	Streambank conditions, bottom sediment material and thickness, channel cross sections, debris dams, tile lines, tributary creeks, and cattle access points
Study area	Neal Smith National Wildlife Refuge, Jesper County, Iowa
Organization	Iowa Department of Natural Resources

In 2000, GIS and GPS were used together to map a 12-km portion of Walnut Creek located near Prairie City in Jesper County, Iowa (Schilling and Wolter, 2000). The objective of the mapping project was to locate channel features and identify spatial trends among alluvial system variables that could be used to identify and prioritize portions of the stream channel and watershed in need of further investigation or restoration. Using Trimble Pathfinder Pro XR GPS equipment, discrete locations (channel cross sections, debris dams, tile lines, tributary creeks, and cattle access points) were mapped to an accuracy of 1 m, whereas the continuous data (bank erosion rates, streambed materials, and thickness) were recorded to an accuracy of

5 m. To record continuous conditions, the GPS equipment was operated in continuous line mode with location recorded every 5 sec. GPS data were exported into a GIS format (ESRI Shapefile), using Pathfinder Office software. Field descriptions of the continuous line segments and discrete features were added to the GPS location information to create various GIS layers. Segment lengths varied from 10 to 50 m. Discrete channel features were located by pausing the continuous line mode of the GPS and taking points at feature locations. Stream survey data were used to model watershed conditions, identify water sampling points, and evaluate and select appropriate channel-rehabilitation measures.

This chapter is intended for professionals in the geographic "positioning" field. It presents applications of GIS and GPS for water industry infrastructure management. The use of GPS in collecting attributes data is discussed, and methods of data attribution are described. A review of GPS equipment and software is presented. GPS accuracy issues are also discussed.

GPS BASICS

GPS, also referred to as Navigation System by Timing and Ranging (NAVSTAR), is a satellite-based radio navigation system developed and operated by the U.S. Department of Defense. The Russian government operates a similar system called Global Navigation Satellite System (GLONASS). At the present time, GPS includes 29 active satellites located in 6 orbital planes.

GPS systems utilize a constellation of satellites orbiting the earth twice daily (i.e., passing over approximately the same world location every 12 hours) and transmitting precise time and position signals. GPS receivers read signals from orbiting satellites to calculate the exact spot of the receiver on Earth as geographic coordinates (latitude and longitude) referenced to the World Geodetic System of 1984 (WGS84) datum. The signals from at least four satellites should be available to determine the coordinates of a position. Physical obstructions such as mountains, trees, and buildings, and other factors such as satellite malfunction and rephasing operations can restrict GPS signals and degrade GPS accuracy. Ideal GPS operating conditions that provide the best accuracy are listed below (Lyman, 2001):

- Low positional dilution of precision (PDOP), a measure of best geometrical configuration of satellites
- Good signal strength
- Little or no multipath (reflection of GPS signals off distant reflective environment such as mountains and buildings)
- Little or no signal degradation because of geomagnetic storms and ionospheric or atmospheric effects

The accuracy of GPS coordinates can be increased by applying differential corrections. Differential corrections move user points closer to their "actual" location. This is done by comparing the user's new data on unknown locations with the data collected at the same time on a point with known coordinate values (Zimmer, 2001b). The GPS receivers that can receive and apply the corrections in real time

are called real time kinematic (RTK) receivers. Non-RTK receivers require postprocessing of raw GPS data in the office. In the U.S., federal and state agencies are cooperating to make differential GPS readily available to all users.

GPS precision can vary from a few millimeters to hundreds of meters. The required precision depends on the project-specific requirements. The available precision varies with GPS mode (static, RTK, or kinematic), GPS equipment, time of occupation, and location (vegetation, reflection, and buildings). GPS survey cost increases with the accuracy requirements. The typical utility precision standard is 3 to 5 cm.

To prevent misuse by hostile forces, the U.S. Department of Defense had introduced an intentional error called the Selective Availability (SA) error in their GPS signals. The recent advances in GPS technology had reduced the effectiveness of the SA error. On midnight May 2, 2000, the SA error was removed 6 years ahead of schedule by a presidential order. This event marked an important day in the history of GPS because it increased the GPS accuracy up to ten times. The SA removal has improved the accuracy of inexpensive GPS receivers. SA removal has also increased the accuracy of GPS receivers operating in an autonomous (unassisted) mode without a base station. No significant impact has been noted in the performance of survey grade receivers (Murphy, 2001).

GPS technology is making major progress in improving the speed, reliability, and accuracy of the mathematical processes by which coordinates are calculated from the satellite beams (ASCE, 2001).

GPS APPLICATIONS IN THE WATER INDUSTRY

At the present time, the GPS revolution is well under way. For example, a Mercedes-Benz driver equipped with TeleAid system can press an SOS button to summon a tow truck, police, or ambulance. This button uses GPS technology to transmit the specific location, model, and color of the vehicle. The GPS applications for the water, wastewater, and stormwater systems, though not as dramatic as TeleAid, are revolutionizing the way these systems are designed, constructed, operated, and maintained. Representative GPS applications for the management of water, wastewater, and stormwater systems are:

1. GPS can be used to increase the accuracy of existing system maps by verifying and correcting locations of the system components. Frequent field changes often mean utility lines can be several feet off horizontally and/or vertically from where they appear on the plans. Thus, unless updated frequently, most utility plans, especially in growing cities, are outdated frequently. GPS data collection is no longer limited to collecting coordinates of point features. Now users can bike along a channel to map line features, or walk around a detention pond to map polygon features.
2. New water system or sewer system maps can be created if they do not exist.
3. Water system or sewer system attributes can be collected for populating the GIS database.

Surveying

Traditionally, people have used geodetic surveying to locate and map utility infrastructure components. Such transit survey required traversing between a known point to the point of interest, which often took several hours per point. GPS has been found to be up to 50% faster than the traditional methods (Anderson, 1998). GPS survey takes only a few minutes or seconds per point. For example, up to 300 points can be surveyed in 1 day, using a GPS survey. A two-man crew with bicycle-mounted equipment can survey up to 500 points per day.

The familiar total station is still the backbone of engineering survey work. Although GPS is not a replacement for optical surveying, interoperability between optical equipment and GPS is growing, and GPS is gaining ground slowly among engineers. GPS is an ideal addition to the surveying toolbox for a variety of applications, such as locating the starting point for a new stakeout. The conventional total station survey will require traversing a large distance for this work. GPS can do this work much faster by navigating a person right to the point where the stake should be placed (ASCE, 2001).

Fleet Management

An efficient fleet management system is essential to improving customer service. A wireless system that uses GIS and GPS technologies can substantially and economically improve the efficiency of fleet management. An integrated GIS/GPS procedure can be used to track multiple moving vehicles from a command center. It can show the location, speed, and movement of each vehicle on the tracking display. Off-the-shelf mobile devices such as Web-enabled cell phones and personal digital assistants (PDAs) can be used in conjunction with a GIS/GPS to provide the information needed for fleet management, such as dispatching and tracking the maintenance vehicles, generating driving directions, and trip routing. For example, Gearworks customized MapInfo's MapMarker J Server and Routing J Server to calculate driving directions and travel statistics. A client-side custom mapping application was created, which communicates with a MapXtreme server to create the data requested by the dispatcher and to deliver the information to the drivers mobile device. This application allows the dispatcher to view a map of the entire fleet to better assign work orders and deliveries, perform real time tracking, and deliver accurate status updates through the Web interface (GEOWorld, 2001).

GIS/GPS applications have consistently lowered the cost of fleet management by 10 to 15%.

GPS APPLICATIONS IN GIS

GPS technology represents a space-age revolution in GIS data collection. It is providing an efficient and increasingly popular way for collecting both the location (coordinates) and the attributes data in the field. The new line of GPS receivers brings

technology to water- and wastewater system operators and managers, who can populate their existing maps with precise location of features such as manhole covers, catch basins, overflow points, hydrants, valves, pumps, flow meters, and rain gauges.

The most basic application of GPS is collection of (x,y) coordinates for the GIS features. Initially, these coordinates were manually entered into the GIS database. Most GPS receivers record their data in an American Standard Code for International Interchange (ASCII) format that can be imported into a GIS without having to type the coordinates' values. Recent GPS equipment can provide data in a GIS-compatible format, such as the ESRI Shapefile format.

Attributes are usually collected in two phases:

1. Initial attribution phase (Phase I) or first pass: Limited attributes can be collected by the GPS survey crew when a structure is visited or surveyed for the first time. These attributes — such as manhole cover type, catch basin condition (clean, debris, etc.), or outfall condition (submerged, flowing, dry, etc.) — should be visible from outside and should not require confined space entry or opening of structures. This phase may also include ID-marking of structures for the second phase or future visits. In this phase, typically 250 to 300 points can be surveyed per day.
2. Final attribution phase (Phase II) or second pass: Additional attributes can be collected when a structure is revisited by the attribute crew. These attributes may require field measurements, detailed inspections, confined space entry, or opening of structures. Examples include manhole depth, pipe size, and structural or hydraulic deficiencies. The final attributes depend on the mapping application. For example, if the maps will be used to develop an H&H model, weir height in an overflow structure might be measured. If the GIS will be used for NPDES permit reporting, the condition of the sanitary outlet (clean, clogged, surcharged, etc.) in the overflow structure might be a critical attribute. In this phase, final attributes for 50 to 75 structures can be surveyed per day. New real time differential GPS (DGPS) receivers can navigate the attribute crew back to the structures visited in Phase 1.

GPS SURVEY STEPS

The data conversion process for municipal utilities often begins with GPS data. Features such as manholes and hydrants are collected using a GPS unit. These point features are combined into a GIS layer and then attributed. At the conclusion of each day, GPS corrections are applied if necessary. The data set is massaged to ensure its stability including calculating the IDs and building the data set. The data set is then exported and saved as a backup file. After the process is completed for an entire area, check plots are created. These check plots show the lines and points along with their attributes. The flow direction of the lines is also displayed to ensure that proper connectivity has been established for the system. The plots are then delivered to the municipal engineer for review.

Generally, the following steps are required to collect GIS data, using GPS (Zimmer, 2001b):

1. Prepare a project plan to define the scope, resource inventory (paper maps, databases, etc.), and data dictionary. The data dictionary is a template for field data

collection. It specifies the features to be surveyed and their attributes. A simple data dictionary for Phase-1 GPS survey of a sewer system is given below:

- Sanitary features
  - San_mh
    - Lid_size
    - Lid_type
    - Condition
    - ID
- Storm features
  - Catchbasin
    - Size
    - Type
    - Condition
    - ID
- Endwall
  - Condition
    - ID

2. Conduct field work.
3. Download data from GPS receiver to computer.
4. Perform quality assurance/quality control (QA/QC) for completeness and attribute information.
5. Apply differential corrections if not using RTK equipment.
6. Calculate the spatial error.
7. Export GPS data and attributes to GIS.
8. Create a metadata file to document GPS survey information, such as survey date, equipment used, horizontal and vertical accuracy, etc.

GPS EQUIPMENT

GPS equipment selection depends on the purpose or application of GPS data. For example, for utility mapping projects, mapping-grade GPS equipment equipped with code-based receivers is suitable. For engineering design and projects that require highly accurate survey data, survey grade GPS equipment equipped with carrier-phase receivers is needed. Table 5.1 provides a summary of GPS receiver types. Accuracy specifications are based on the ideal operating conditions described earlier.

Table 5.1 GPS Receivers

Receiver Type	Horizontal Accuracy (m)	Price (US$)
Recreation	5–10	100–300
Basic	1–5	3,000–5,000
Advance	<1	8,000–10,000
Survey and geodetic	<0.2	25,000 and upward

Recreational GPS Equipment

These types of receivers are intended to support recreational activities such as hiking and camping. Commonly referred to as the "*$200 receivers*," they provide

low accuracy and are, therefore, not suitable for most engineering, mapping, or surveying work. They can be used as basic navigation and reconnaissance tools.

Basic GPS Equipment

These lightweight and handheld systems are about the size of a calculator. They are less expensive ($4000) and less accurate (1 to 5 m; least accurate in woods). Differential corrections are applied in a postprocessing step after the collected field data have been downloaded to a computer running a GPS-processing software package. Because of their low accuracy, they are not suitable for utility surveys. They are more suitable for educational use. Trimble's Geoexplorer III handheld GIS data collection system shown in Figure 5.1 is an example of this category. Geoexplorer

Figure 5.1 Basic GPS equipment example (Trimble Geoexplorer III).

provides support for popular GIS and CAD software packages such as ArcInfo, Intergraph, MGE, MapInfo, ERDAS, and AutoCAD. Geoexplorer provides for GIS export of GPS data, using Trimble's Pathfinder Office software. The steps for using Geoexplorer III GPS data in GIS are given below:

- Install Pathfinder Office software on your PC
- Create a data dictionary, i.e., define attributes for each feature type
- Transfer data dictionary from PC to receiver
- Enter attributes during GPS survey
- After the GPS survey, transfer the location and attribute data from receiver back to Pathfinder Office on your PC
- From Pathfinder Office, export data to your GIS in ArcView Shapefile or MapInfo format

Advanced GPS Equipment

Advanced-grade GPS receiver types include the so-called professional, mapping-grade, and resource-grade products. These systems are more expensive ($10,000) but provide the submeter horizontal accuracy generally required in utility mapping. Differential corrections, which are especially applicable for accurate navigation, can be applied in real time if the GPS receiver is linked to a radio receiver designed to receive broadcast corrections; Trimble's GPS Pathfinder Pro XR/XRS GIS data collection system is an example. In Pathfinder, attributes can be entered using Trimble's handheld Asset Surveyor, or a pen-based notebook or Tablet PC running Trimble's ASPEN software. As with Geoexplorer, GIS export is accomplished using Pathfinder Office software. The XRS models have an integrated differential correction receiver and can provide real time submeter accuracy. Reportedly, Pathfinder also features patented Everest multipath rejection technology to reduce or eliminate multipath signals in reflective environments. Figure 5.2 shows Trimble's Pathfinder Pro XR system, which is also referred to as the "Backpack" because it stores the system components in a convenient backpack. Figure 5.3 shows the components stored inside the Backpack.

Leica Geosystems (Heerbrugg, Switzerland) is a surveying and geomatics company that provides systems for accurate 3D data capturing, visualization, and modeling of space-related data to customers in surveying, engineering, construction, GIS, and mapping. In the GIS community, Leica Geosystems is known for its GPS and field data collection related equipment. ERDAS, Inc. (Atlanta, GA), is the world's leading provider of geographic-imaging solutions. The company's products and related services help organizations visualize, manipulate, analyze, measure, and integrate geographic imagery and geospatial information into 2D and 3D environments. In July 2001, ERDAS's geographic-imaging software company was acquired by Leica Geosystems to form a new GIS and Mapping Division for growth in the GIS and remote sensing markets. Congestion builds up as too many users crowd the same radio frequencies. Leica's new GPS equipment, Leica System 500 (GS50), provides uninterrupted RTK data link through cell phones. Also referred to as the *GIS Receiver*, GS50 is Shapefile-compatible and boasts a new "maximum tracking technology" that allows users to work under trees and in deep urban or natural canyons.

Figure 5.2 Advanced GPS equipment example (Trimble Pathfinder Pro XR Backpack).

Mapping-grade GPS equipment vertical accuracy of ± m is not adequate if accurate elevation data (e.g., manhole rim elevations) are required to support specific applications, such as H&H modeling and engineering design that require precise elevation data.

SURVEY GRADE GPS EQUIPMENT

Survey grade equipment features RTK technology, which can deliver ±1 cm horizontal and vertical accuracy in real time, using dual frequency receivers. Due to their high accuracy, they are expensive ($25,000). Trimble's GPS Total Station 4800 integrated real time kinematic survey system is an example of this category. Due to their more-than-needed accuracy and high cost, they are not essential for wastewater system mapping applications. However, survey grade GPS can save substantial amount of time compared with the conventional ground survey method when high accuracy is required. For example, the RTK survey for a sewer construction project in Fitchburg (Massachusetts) was completed in a quarter of the time that a ground survey would have taken (Mische, 2003). Survey grade GPS equipment's centimeter-level vertical accuracy is adequate for collecting accurate elevation data.

CHAPTER SUMMARY

Today's GPS equipment is like a GIS mapping device. GPS receivers are being referred to as the GIS receivers because they can collect both the geographic data (coordinates) and the attribute data for the water industry infrastructure. The water system and sewer system feature attributes can be captured from a GPS survey by using field computers, handheld computers, and field data collectors. The GPS equipment should be selected carefully to meet both the horizontal and vertical accuracy requirements of the utility mapping projects. The so-called $200 receivers designed for recreation activities that cannot provide accuracy of 5 m or better are not suitable for GPS mapping of water and sewer systems. A differential GPS that can provide real time submeter horizontal accuracy is suitable if accurate elevations are not necessary. Survey sgrade RTK GPS equipment that provides centimeter-level horizontal and vertical accuracy is suitable if accurate elevations are important.

CHAPTER QUESTIONS

1. What is GPS accuracy, and what factors can affect it?
2. List the typical applications of GPS technology in the water industry.
3. How are GIS and GPS related? How are they helping each other?
4. Describe the typical steps for conducting a GPS survey.
5. List the various types of GPS equipment and their suitability for different applications.

CHAPTER 6

Internet Applications

Internet-based mapping applications are changing the way people use and manage geographic information for their water, wastewater, and stormwater systems.

Johnson County (Kansas) Web-based wastewater mapping application.

LEARNING OBJECTIVE

The learning objective of this chapter is to familiarize ourselves with the applications of Internet technology in GIS for the water industry.

MAJOR TOPICS

- Internet GIS applications
- Internet GIS software
- Internet GIS case studies

DUBLIN'S WEB MAP

Application	Web-based mapping
GIS software	AutoCAD, AutoCAD Map, and MapGuide
GIS data	1-m, natural color, orthorectified, precision pan-sharpened imagery of the entire city from Space Imaging (Thornton, Colorado) and vector layers for school districts, corporate limits, county boundaries, subdivisions, streets, parcels, and water (mains and hydrants), stormwater (sewers, structures, and streams), and sanitary sewer (sewers and manholes) systems
Study area	Dublin, Ohio

One of the fastest growing communities in the Midwest, Dublin's 22 mi^2 area is home to about 30,000 people and 2,500 businesses. The city received the year 2000 Best Practices Award from the Ohio Geographically Referenced Information Program, a state agency responsible for educating local government about GIS technology. The city is constantly enhancing its GIS capabilities and serves as a model medium-sized municipal GIS for the state. This application was developed after City personnel started to realize that retrieving data from hard-copy records was inefficient because it reduced staff time to perform engineering review and analysis. The city needed an automated system that could recall, evaluate, and reproduce data more quickly. The City implemented a Web-based GIS data server using Autodesk's (San Rafael, California) Web-based MapGuide technology

Figure 6.1 Screenshot of Dublin (Ohio) Internet GIS Web Site.

(Cerasini and Herskowitz, 2001). Figure 6.1 shows a screenshot of Dublin's Internet GIS Web site.

In addition to serving the development department, Dublin's GIS serves all other city departments and divisions, with data distributed to more than 200 users. Dublin's GIS Web site (gis.dublin.oh.us) provides quick access to utility data for maintenance, planning, and emergency response activities. The users range from planning and engineering professionals to grounds maintenance staff. A major challenge for any GIS is deciding who will maintain the data and how. Dublin's management structure encourages departments and divisions to exchange information freely, allowing departments to maintain their own data within the enterprise framework while feeding the GIS. Such an approach benefits everyone.

In 2001, the City started to implement GIS based asset management systems for the water, wastewater, and stormwater systems. Dublin also moved much of the GIS mapping and city assets to a mobile environment with wireless technology and GPS to allow data products to be distributed to a mobile workforce with personal digital assistants (PDAs) and wireless notebooks. The future is expected to bring even more integration between traditional municipal applications and GIS because the City also plans to integrate other applications, including work orders, asset management, crime analysis, public safety, and emergency dispatch.

Determining how much money Internet GIS technology is saving the City of Dublin is difficult to assess. However, the City feels that in most cases the time and effort required to respond to utility data requests have decreased from several hours to minutes, which translates to increased staff productivity and enhanced responsiveness to customers.

This chapter provides information on the GIS applications for serving water, wastewater, and stormwater system maps on the Internet.

INTERNET GIS

The Internet is the place where an increasing number of people are going for their mapping needs. In fact, the word *map* is one of the most commonly searched keywords on the Web (ESRI, 2002).

Imagine going to a GIS Web site, zooming to a piece of property, defining the building footprint, and displaying various cut and fill configurations. You could then simulate a 10-year, 24-hour design storm to model where the runoff will go and how you would control it to meet the local stormwater management ordinance.

The Internet is the fastest growing and most efficient technology for distributing GIS data to the public. The Internet and the World Wide Web (WWW or Web) are simplifying how the maps are created and maintained. The Internet is facilitating GIS data sharing between different organizations. Intranets are making it easy to share GIS data between coworkers of the same organization. Until the mid-1990s spatial information was generally distributed via the Internet as static map images. In the late 1990s dynamic GIS Web pages started allowing the public to interactively display and query GIS databases, using what is now referred to as Internet GIS technology (Wild and Holm, 1998).

Web browsers now provide both experts and novices with a common, powerful, inexpensive, and intuitive interface for accessing a GIS. Because casual public users can now access GISs through Web browsers, the water industry GIS staff is free to spend more time on improving the database for providing better customer service (Irrinki, 2000). Many large utilities are now using the Internet and GIS to improve the operation and management of their water and sewer systems. They are using Internet and GIS-based work order management and customer service software to accomplish this.

Figure 6.2 shows a screenshot of an Internet GIS Web site for the municipality of Penn Hills, Pennsylvania, created using ESRI's ArcIMS software. The tools shown at the top of the screen can be used to navigate (pan, zoom, etc.) and query the maps. Users can also apply the measure tool to determine distance and area from the map. The right side of the screen helps the users select the active layer for analysis (e.g., query) and turn it on (visible) or off (invisible). The bottom of the screen shows the query results.

Cincinnati Water Works reported a $2-million cost savings in the first year of using Internet GIS (Anderson, 2000).

GIS and enterprise database management systems can be combined to create geospatial data warehouses. For example, using the power of Oracle's spatial extensions, a data mining software (e.g., KnowledgeMiner from SpatialAge Solutions, Atlanta, Georgia, www.byers.com) can mine a network inventory model from an automated mapping/facilities management/geographic information system (AM/FM/GIS) and make it readily available to the enterprise using the Web. The object

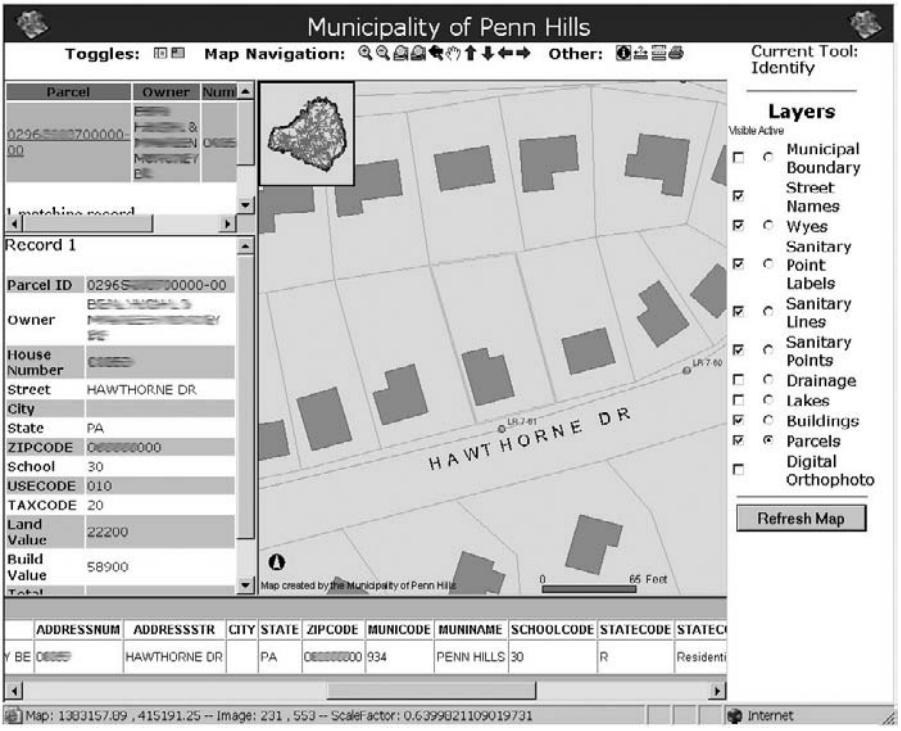

Figure 6.2 Screenshot of Penn Hills, Pennsylvania ArcIMS Web site.

relational database management system (RDBMS) spatial extensions, such as Oracle Spatial, facilitate linking data warehouses with GIS software packages. RDBMS is especially well suited for Internet and intranet data sharing. A data mining application can translate Internet requests into RDBMS queries and send RDBMS responses back to the Internet as Web pages. Utilities that rely on large and complex spatial data sets could greatly benefit from the recent fusion of object RDBMS and Internet technologies (Lowe, 2000a).

Internet Security

Security issues and concerns should be evaluated when posting GIS maps on the Internet. Precautions need to be taken to assure application security and data integrity (Miller et al., 2004). Appropriate security measures such as firewalls, data backups, user authentication, and password access can be used to reduce the chances of security breaches by hackers to harm the GIS data or corrupt the application software. Sensitive information that could help terrorists should not be posted or should be restricted to authorized users only. According to a Rand Corporation (www.rand.org) study released in April 2004, less than 1% of publicly available federal Web sites and databases in the U.S. contain geospatial information that could

help terrorists and other hostile forces mount attacks in the U.S. (Geospatial Solutions, 2004). In the wake of the September 11, 2001, terrorist attacks in the U.S., many Internet GIS sites were removed. Others began restricting public access to some of their sensitive information through the Internet.

INTERNET GIS SOFTWARE

Internet GIS uses a client/server architecture. Therefore two types of software are required to Web-enable a GIS: client-side and server-side (Shamsi, 2003). Client-side software is very easy to use but does not provide data creation or editing capability. It is usually available for free. Examples include:

- ArcExplorer, ESRI
- GeoMedia Viewer, Intergraph
- MapGuide Viewer, Autodesk

Server-side software, accessible through browsers, makes GIS usable over the Web. Based on the capabilities, the cost ranges from $5,000 to $25,000. Examples include:

- ArcIMS, ESRI
- GeoMedia Web Map, Intergraph
- MapGuide, Autodesk
- MapXtreme, MapInfo

INTERNET GIS APPLICATIONS

Representative applications of Internet GIS technology are described in the following subsections.

Data Integration

Imagine an organization with watershed data in ESRI Shapefiles, parcel data in an Oracle Universal Data Server with Spatial Cartridge, and water main data in an AutoCAD file. Imagine further that different data are stored on different network drives in different projections. Software is now available to integrate different data formats and convert them into a common projection system on the fly. Intergraph's GeoMedia Web Map is an example of such a software (Lowe, 2000).

Project Management

A project Web site promotes collaboration and efficient completion of utility construction or rehabilitation projects by providing all involved parties instant access to current information and allowing them to disseminate information automatically and immediately. A Web site also eliminates software and hardware compatibility problems among project team organizations. Redline (edit) capability can be added to a project Web site to expedite the design review process (Irrinki, 2000).

These possibilities are the result of a new generation of software from the leading GIS and CAD software companies. For example, in addition to the traditional CAD work, Autodesk's AutoCAD 2000i enables users to collaborate with design professionals anywhere in the world and move the designs and processes to their companies' intranets and the Web. Similarly, Intergraph's GeoMedia, in conjunction with Oracle Spatial, enables all the users to see the latest engineering project information against the base-map images. The various projects are represented as polygons overlayed on the base-map image. A user can simply click on one of the project polygons to obtain the most recent information about that project. After a project has been completed, the engineering information (including redlines) is used to update the spatial data stored in Oracle Spatial. This approach was successfully implemented by the Public Works Department of the City of Minneapolis. The City used GeoMedia and an Oracle Spatial data warehouse to provide future users the most current information about the city's infrastructure (Murphy, 2000). Figure 6.3 shows a project portal designed using this approach for a wastewater improvement project for the Borough of California (Pennsylvania), created by Chester Engineers, Pittsburgh, Pennsylvania.

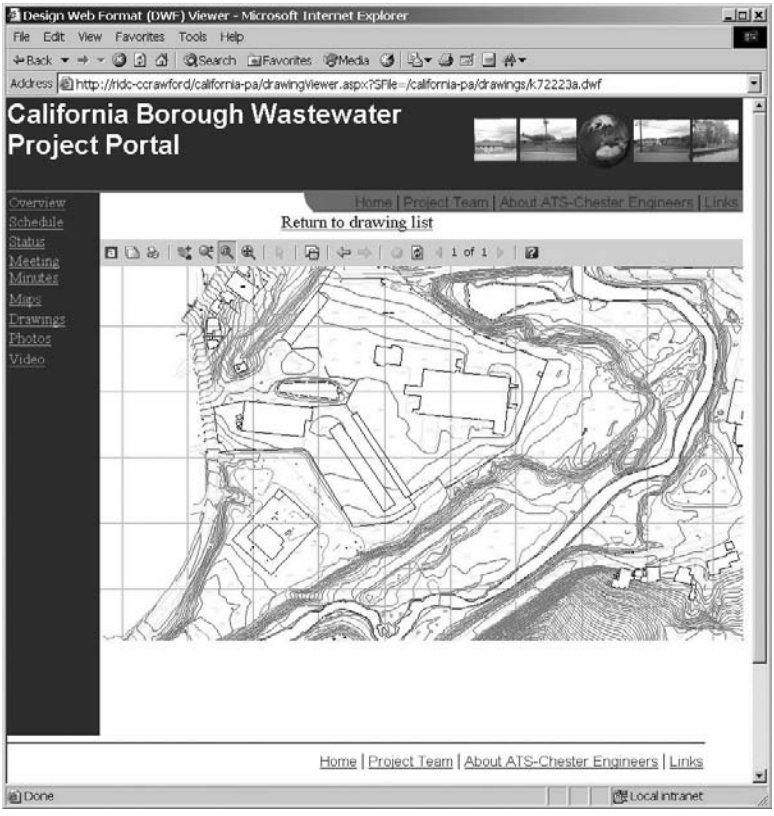

Figure 6.3 Screenshot of the Borough of California (Pennsylvania) project portal.

3D Visualization Applications

Internet GIS applications can also provide 3D visualization capability that converts 2D aerial photographs and satellite images into 3D terrain. The 3D terrain can be used as a base map for draping other information such as realistically textured buildings. For example, Skyline Software Systems' (www.skylinesoft.com) TerraExplorer provides realistic, interactive, photo-based, 3D maps of many locations and cities of the world on the Internet. Skyline's Internet technology enables creation, delivery, and interaction with content-rich, 3D geographic environments. Skyline enhances the Web experience for a variety of location-specific applications such as travel and tourism, real estate, entertainment, mapping, tracking, planning, and engineering. Standard CAD or GIS data layers such as DXF or Shapefiles can be easily incorporated to create dramatic 3D movies. Such Internet-based mapping applications are designed for a layperson and do not require GIS expertise.

CASE STUDIES

Two case studies illustrating the application of Internet GIS technology are described in the following subsections.

Tacoma's Intranet and Mobile GIS

Application	Intranet and Wireless GIS
GIS software	AutoCAD, AutoCAD Map, MapGuide, and GE Smallworld
Other software	Microsoft Access and SQL Server databases
Hardware	Laptop computers from Dell Computer Corp. and Gateway, Inc., 14.4K CDPD wireless PC card modems from Sierra Wireless
GIS data	Black and white orthophotos and planimetric base map layers from Bentley ADR, 3-ft and 6-ft color digital orthophotos from Triathlon, Inc.
Study area	Tacoma, Washington
Organization	Tacoma Public Utilities and Tacoma Water

Tacoma Water, a division of Tacoma Public Utilities (TPU) located in the state of Washington, serves 146,000 customers in the city of Tacoma's 52 mi^2 area and surrounding parts of Pierce and King counties. Tired of flipping through outdated map books and clumsy blueprints to locate water and sewer lines, Tacoma Water implemented intranet and wireless GIS applications.

Because of their familiarity with CAD, which was used in their engineering projects, Tacoma Water began a $750,000 multiyear project in 1990 to create CAD-based digital base maps and facility layers. The base map consisted of digital orthophotos and planimetric layers, such as building footprints, pavement edges, rights-of-way, lots and blocks, and easements, in a CAD format. Data conversion was completed in 1997 producing 6.5 GB of data with a horizontal accuracy of 6 in. Initially these data were distributed on CD-ROMs. In 1998, Tacoma Water

implemented an intranet GIS using Autodesk's intranet and Internet software suite consisting of AutoCAD, AutoCAD Map, and MapGuide for an initial investment of $12,000. Using these packages, they integrated their CAD data in a GIS and hosted it on a central server from where it was accessible to any computer using a standard Internet browser. The intranet GIS enabled the users to query the map features by simply placing the mouse cursor over that feature. By putting the cursor over a valve, for instance, the user will see a pop-up window showing the size, type, and number of turns required to open or close the valve.

According to Tacoma Public Utilities, "Having multiple layers of information available on mobile computing devices is like a holy grail to the water field crews."

In order to provide the available intranet GIS data to crews in the field, Tacoma Water implemented a wireless GIS in 1999. Consisting of off-the-shelf laptop computers and wireless modems, the truck-mounted wireless GIS was initially used by 18 field crews. The cost of unlimited wireless airtime was $50 per month. The mobility allowed by such a system puts field crews light years ahead of the time when finding a water main meant rummaging through a map book or reading microfiche (Teo, 2001).

Montana's Watershed Data Information Management System

Application	GIS-based watershed data management system
GIS software	ArcView
Organization	Montana Department of Environmental Quality

Montana Department of Environmental Quality (DEQ) is responsible for developing integrated water, air, waste management, and energy plans to protect Montana's environmental resources. To comply with the Montana Water Quality Act and the Federal Clean Water Act, an ArcView-based watershed data management system called MontanaView was developed in 2000. The system was designed to meet the specific information management needs of the state of Montana, focusing on water resource management issues. The project goals were: (1) integrating extensive and diverse data into one system, covering demographic, land-use and land-cover, infrastructure environmental, and natural resource information and (2) orienting programs and organizations around watersheds as the primary unit for assessing and managing resources.

These goals were accomplished by developing MontanaView, a PC-based application that runs under Windows operating systems, and linked to distributed databases over the Internet. The system provided online access to U.S. EPA mainframe databases and United States Geological Survey (USGS) real time and historical stream-flow data. For example, it provided access to EPA's national water quality database, STORET, to identify water quality monitoring stations that met user-defined requirements for selected parameters. It could then go to the Montana USGS Internet site (montana.usgs.gov) and import stream-flow data for the user-specified

station. The maps generated by MontanaView proved to be excellent visual aids during public meetings (Samuels et al., 2000).

CHAPTER SUMMARY

This chapter provided information on the GIS applications for serving water, wastewater, and stormwater system maps on the Internet. The Internet is the fastest growing and most efficient technology for distributing GIS data. Internet-based mapping applications are changing the way people use and manage geographic information in the water industry. The Internet can be used to both obtain and distribute GIS data. Two types of software are required for creating Internet GIS Web sites: client-side software and server-side software. Many cities and counties in the U.S. have developed Internet GIS sites for sharing their GIS data and maps.

CHAPTER QUESTIONS

1. What is Internet GIS?
2. What are the applications of Internet GIS technology?
3. What kind of software is required for developing Internet GIS applications?
4. Search the Internet to describe three Internet GIS Web sites that provide water, wastewater, and stormwater system maps on the Internet.

CHAPTER 7

Mobile GIS

Mobile GIS is helping the field workers by providing them with GIS maps on their hand-held computing devices. Field workers equipped with mobile GIS can update their enterprise GIS database from the field.

Mobile GIS brings GIS maps to field workers using mobile computers and PDAs.

LEARNING OBJECTIVE

The learning objective of this chapter is to determine the applications of mobile GIS technology in water industry.

MAJOR TOPICS

- Mobile GIS basics
- Mobile GIS applications

- GPS integration

LIST OF CHAPTER ACRONYMS

LBS Location Based Services
PDA Personal Digital Assistant
RTK Real Time Kinematic

MOBILE GIS BASICS

Integration of GIS with consumer electronics such as cell phones and automobile navigation systems has spawned a whole new industry called location-based services (LBS). LBS services are used for managing dispatch and routing, fleets, work orders, and field crews — all of which improve customer service. Telegeoinformatics is also a new discipline resulting from the integration of mobile computing with wired and wireless communications, GIS, GPS, and remote sensing technologies (Karimi and Hammad, 2004). GIS lies at the heart of most mobile information resource systems. For example, it is now possible to wirelessly transmit a GPS location from the field, which can then be viewed on a GIS map via the Internet.

Using GIS directly in the field for data collection into a GIS database is referred to as mobile or field GIS. According to a recent study, about 40% of all mobile data applications in utilities are using a GIS (Wilson, 2001). With mobile GIS, feature location and attribute data can be verified, augmented, and immediately updated. New features can be added, existing features moved to their correct location, and nonexisting features deleted in the field. The ultimate goal of a mobile GIS is to link mobile workers with data to make their jobs easier and more efficient.

Mobile computers are the field devices used by mobile workers and field personnel to run GIS software (or its field version) and to collect location and attribute data in the field. Examples include notebooks, laptops, and pocket computers; tablet PCs and slate tablets; pen and touch-screen computers; handheld devices and PDAs; and smart phones (a combination of a PDA and a cell phone). Due to their small screen; limited memory, storage, processing speed, and battery life; and lack of a keyboard for field data entry, PDAs may not be suitable for large inspection projects. Currently, in the U.S., most PDAs use three operating systems: Linux, Palm OS, and Windows

Figure 7.1 Tablet PC being used for GPS and field data collection.

CE (Lowe, 2002). Basically a hybrid between a laptop and a PDA, the tablet PC combines the mobility and handwriting recognition of PDAs with the larger screen size and full-featured operating systems provided by laptops. Tablet PC screens can rotate 180° to create digital writing pads that lie flat against the keyboard. This feature allows field workers to sketch notes and diagrams or redline existing maps using a digital pen. Figure 7.1 shows a tablet PC connected to a mapping-grade GPS being used for field inspections. Figure 7.2 is a tablet PC screenshot showing notes and sketches taken in the field.

This field editing feature requires taking appropriate GIS layers and base maps in the field on a mobile computer. Custom forms can be created to mimic the paper forms that field crews are accustomed to using. The main advantage of a mobile GIS is that it eliminates postprocessing of paper data in the office.

Mobile GIS is the result of advances in four key areas: (1) field GIS software (e.g., ESRI's ArcPad); (2) lightweight, reliable, and affordable field computing devices; (3) more accurate and affordable GPS receivers; and (4) wireless communications (ESRI, 2004).

MOBILE GIS APPLICATIONS

Mobile GIS is helping cities in their field data collection and asset inventory activities. For example, many local governments are using ESRI's ArcPad field GIS software to improve speed and accuracy and lower the costs associated with the field inventory of their infrastructure assets (ESRI, 2004a). ArcPad, now a mobile client

Figure 7.2 Tablet PC screenshot showing field notes and sketches.

for ArcGIS, allows data collectors to collect asset locations and attributes in the field as ESRI-compatible GIS files. ArcPad Application Builder allows creation of custom field inspection forms using Visual Basic Scripting (VBScript). OnSite from Autodesk, InService from Intergraph, and MapXtreme from MapInfo are other examples of mobile GIS software.

Mobile GIS applications can benefit from wireless and Internet technologies for live import or export to office or enterprise data. Wireless connections allow real time access to office GIS data in the field and real time updates to office data. When a persistent network connection is not feasible, mobile GIS can transport the field data back to the parent software in an office for automatic validation and delivery to the target system at the end of each inspection day. Intergraph's IntelliWhere OnDemand vector-based mapping product for PDAs also runs on some smart phones. Among other features, this product allows workers to red-line maps on their mobile

devices and then wirelessly send the edits back to GIS servers in the office for immediate inclusion into the system. It also has an "occasionally connected" mode that allows field workers to extract data from the office GIS, view it, and disconnect until it is time to synchronize updates back to the office GIS (Lowe, 2002a).

WIRELESS INTERNET TECHNOLOGY

Wireless Internet solutions consist of four key technology components: (1) applications software running on the Internet and mobile devices; (2) mobile middleware software that resides on a server and a mobile device; (3) wireless data network to deliver data to and from mobile devices; and (4) mobile devices. In 2000, one of Southern California's largest wholesale water providers, the Calleguas Municipal Water District began a program to improve its infrastructure and operations management. It used Fieldport™ mobile operations management solution from Spacient Technologies, Inc. (Los Angeles, California). The system provides both Web-based and wireless asset management as either a traditional on-site software installation or as an Internet-hosted service. Fieldport allows GIS integration using its GIS/Mapping Module with an industry-standard database design powered by ESRI's ArcIMS software (Stern and Kendall, 2001).

GPS INTEGRATION

Mobile GIS applications typically use a GPS receiver; however, using a GPS is optional. Tiny GPS receivers are now available from various vendors that clip into most mobile devices and enable real time positioning on the map display. Without GPS integration, mobile GIS collects only attribute data; with a GPS receiver, data such as coordinates, elevation, and attributes can be collected. Inexpensive recreation-grade GPS receivers that provide typical 10-m horizontal accuracies can be used for navigation purpose. This arrangement would eliminate the need to pan and zoom around the map file to find the inspection location; the GPS connection can automatically center the map on the inspection location. Note that recreation-grade GPS receivers cannot and should not be used for collecting accurate horizontal and vertical positions. Figure 7.3 shows a sample GPS integration with a mobile device. The top part of the figure shows Hewlett Packard's iPAQ Pocket PC and Navman's recreation-grade GPS receiver for iPAQ. The GPS unit comes in the form of a sleeve that the iPAQ can slide into, as shown in the bottom part of the figure. According to the manufacturer, this GPS receiver typically provides better than 5 m (16 ft) horizontal accuracy for 95% of the time under optimal conditions.

Another technology that is helping mobile GIS is the Bluetooth wireless technology. Bluetooth is an international specification for a compact, low-cost radio solution that links mobile devices without using cables. Bluetooth devices can find each other when they are within their working range, which is typically 10 m (33 ft). For example, an RTK GPS rover on a pole can be wirelessly connected to the GPS receiver mounted inside a vehicle, or RTK GPS corrections can be received via a Bluetooth-enabled cell phone.

CHAPTER SUMMARY

Mobile GIS plays an important role in simplifying the jobs of field workers and reducing the cost of field inspections and maintenance. For example, GIS allows users to identify valves to be closed for repairing or replacing broken water mains by simply clicking on a mobile field device such as a tablet PC.

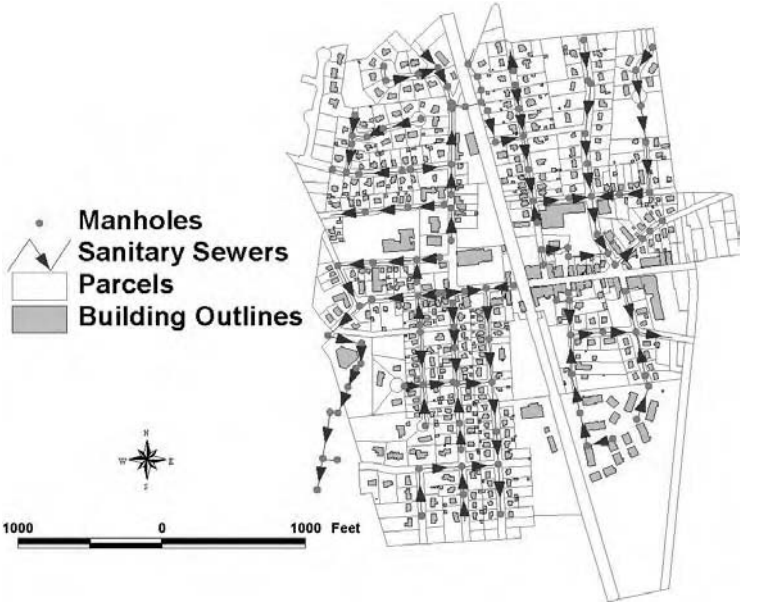
CHAPTER QUESTIONS

1. What is mobile GIS?
2. What is the main application of mobile GIS in the water industry?
3. How is mobile GIS related to Internet, GPS, and wireless technologies?

CHAPTER 8

Mapping

GIS provides powerful and cost-effective tools for creating intelligent maps for water, wastewater, and stormwater systems.



A sewer system map created by GIS (Borough of Ramsey, New Jersey).

LEARNING OBJECTIVE

The learning objective of this chapter is to understand how to create GIS maps for water, wastewater, and stormwater systems.

MAJOR TOPICS

- Mapping basics
- Map types
- Advantages of GIS maps
- GIS mapping steps
- Mapping case studies

This book focuses on the four main applications of GIS, which are mapping, monitoring, maintenance, and modeling and are referred to as the "4M applications." In this chapter we will learn how to implement the first *m* (mapping).

LOS ANGELES COUNTY'S SEWER MAPPING PROGRAM

In the 1980s, the Sanitation Districts of Los Angeles County, California, envisioned a computerized maintenance management system that would provide decision makers with essential information about the condition of the collection system. A sewer and manhole database was subsequently developed, but investments in GIS technology were deferred until the early 1990s when desktop PCs became powerful enough to run sophisticated GIS applications. In 1993, a GIS needs analysis study was performed, which recommended implementation of a large-scale enterprise-wide GIS. An in-house effort was started to implement the recommendations of the study. Several sections in the Districts formed a project committee to pilot test GIS technology that could be duplicated in all 25 districts. The pilot project developed a mapping application for a small district that acted as a front-end to the large database of sewerage

facilities developed in the 1980s and 1990s. At this point, much of the information was nonspatial, including multiple databases in a variety of formats and paper maps. Converting this information into GIS proved to be the most time consuming and costly operation. Creation of the layers for sewers and manholes was the most laborious of all the layers that had to be created. Manhole data were represented by approximately 24,000 points or nodes digitized from the paper maps, using a base map. The GIS layers were created in CAD software and linked to the legacy databases. Once linked, detailed data such as sewer pipe and manhole construction material, size, condition, flow, capacity, and inspection data were available for query and analysis through an intuitive map-driven interface. By 2003, the pilot project had grown to become the first enterprise-wide solution deployed by the Districts. Called "Sewerage Facilities GIS," the system allowed users to access and view data from the legacy databases by selecting sewers and manholes on a map or using standard queries. The mapping application also provided sewer tracing functionality that proved helpful in delineating study area boundaries for design projects, annotating sewers with flow direction, and tracking potential discharge violations (Christian and Yoshida, 2003).

MAPPING BASICS

The basic concepts essential for understanding GIS mapping are summarized in the following subsections.

Map Types

There are two major types of GIS maps: vector and raster. In *vector* format, objects are represented as points, lines, and polygons. Examples of the vector format are maps of water mains, hydrants, and valves. Scanned maps, images, or aerial photographs are examples of *raster* format. Raster data are also referred to as grid, cell, or grid–cell data. In raster format, objects are represented as an image consisting of a regular grid of uniform size cells called *pixels*, each with an associated data value. Many complex spatial analyses, such as automatic land-use change detection, require raster maps. Raster maps are also commonly used as base maps (described later in this chapter). Existing paper maps that are used to create GIS maps are called *source maps.*

Topology

Topology is defined as a mathematical procedure for explicitly defining spatial relationships between features. Spatial relationships between connecting or adjacent features, such as a sewer tributary to an outfall or the pipes connected to a valve, which are so obvious to the human eye, must be explicitly defined to make the maps "intelligent." A topological GIS can determine conditions of adjacency (what is next to what), containment (what is enclosed by what), and proximity (how near something is to something else). Topological relationships allow spatial analysis functions, such as network tracing, that can be used to facilitate development of hydraulic models for water and sewer systems.

Map Projections and Coordinate Systems

Because the Earth is round and maps are flat, transferring locations from a curved surface to a flat surface requires some coordinate conversion. A *map projection* is a mathematical model that transforms (or projects) locations from the curved surface of the Earth onto a flat sheet or 2D surface in accordance with certain rules. Mercator, Robinson, and Azimuthal are some commonly used projection systems. Small-scale (1:24,000 to 1:250,000) GIS data intended for use at the state or national level are projected using a projection system appropriate for large areas, such as the Universal Transverse Mercator (UTM) projection. The UTM system divides the globe into 60 zones, each spanning 6° of longitude. The origin of each zone is the equator and its central meridian. X and Y coordinates are stored in meters. Large-scale local GIS data are usually projected using a State Plane Coordinate (SPC) projection in the United States.

A *datum* is a set of parameters defining a coordinate system and a set of control points with geometric properties known either through measurement or calculation. Every datum is based on a spheroid that approximates the shape of Earth. The North American Datum of 1927 (NAD27) uses the Clarke spheroid of 1866 to represent the shape of the Earth. Many technological advances, such as the global positioning system (GPS), revealed problems in NAD27, and the North American Datum of 1983 (NAD83) was created to correct those deficiencies. NAD83 is based on the GRS80 spheroid, whose origin is located at the Earth's center of mass. The NAD27 and NAD83 datum control points can be up to 500 ft apart.

Coordinates are used to represent locations on the Earth's surface relative to other locations. A *coordinate system* is a reference system used to measure horizontal and vertical distances on a map. A coordinate system is usually defined by a map projection. The GIS and mapping industries use either latitude/longitude- or geodetic-based coordinate grid projections. Because much of the information in a GIS comes from existing maps, a GIS must transform the information gathered from sources with different projections to produce a common projection.

Map Scale

Map design addresses two fundamental map characteristics: accuracy and depicted feature types. Both characteristics vary with map scale. Generally, larger scale maps are more accurate and depict more detailed feature types. Smaller scale maps, such as U.S. Geographical Survey (USGS) quadrangle maps, generally show only selected or generalized features. Table 8.1 summarizes the relationships among map scale, accuracy, and feature detail.

Data Quality

The famous computer industry proverb "garbage in, garbage out" conveys very well the importance of GIS data quality. A GIS map is only as good as the data used to create it. Data quality roughly means how good the data are for a given application. Data quality is important because it determines the maximum potential reliability of the GIS application results. Use of inappropriate data in a GIS map may lead to

Table 8.1 Relationships among Map Scale, Accuracy, and Feature Detail

Map Scale	Minimum Horizontal Accuracy, per National Map Accuracy Standards	Examples of Smallest Features Depicted
1 in. = 50 ft	±1.25 ft	Manholes, catch basins
1 in. = 100 ft	±2.50 ft	Utility poles, fence lines
1 in. = 200 ft	±5.00 ft	Buildings, edge of pavement
1 in. = 2000 ft	±40.00 ft	Transportation, developed areas, watersheds

misleading results and erroneous decisions, which may erode public confidence or create liability.

Data Errors

There are two types of data errors: inherent errors embedded in the source of data and operational errors introduced by users during data input, storage, analysis, and output. Inherent errors can be avoided by using the right kind of data. Operational errors can be prevented by quality control and training.

A data conversion team should be aware of sources and magnitudes of data error. For example, spatial information in USGS 1:24,000-scale (7.5-min) topographic maps is certified to have 90% of its features within 50 ft (15 m) of their correct location. 50 ft is large enough to underestimate the runoff from a new development and undersize a detention pond for adequate stormwater management.

Map Accuracy

A primary factor in the cost of data conversion is the level of positional accuracy. Required map accuracy and resolution depend on the application in which the maps will be used. A 2000 survey conducted by the Geospatial Information and Technology Association (GITA) indicated that the water utilities were seeking more landbase accuracy of 5-ft compared with other utilities, such as the 50-ft accuracy sought by the gas companies (Engelhardt, 2001; GITA, 2001). The same survey for 2002 indicated that the water industry required the highest accuracy in their GIS projects. Among the water organizations, 27% were using a 6-in. landbase accuracy compared to electric (12%), gas (17%), pipeline (17%), and telecom (0%) organizations (GITA, 2003). These data reveal that a trend toward increasing accuracy may be emerging in the water industry.

Engineering applications usually require ±1 to 2 ft accuracy. For planning and regional analysis applications, ±5 to 10 ft accuracy is generally appropriate (Cannistra, 1999). Sometimes relative accuracy (e.g., ±1 ft from the right-of-way line) is more important than an absolute level of accuracy (e.g., ±1 ft from the correct location). For the applications where positional accuracy is less important, supposedly low-resolution data, such as USGS digital orthophoto quadrangles (DOQs), may be acceptable. In other applications where features must be positioned within a foot of their actual position, even the presumably high-resolution data, such as 1-m IKONOS imagery,

may not be accurate enough. As a rule of thumb, a database built from a map will have positional inaccuracies of about 0.5 mm at the scale of the map because this is the typical line width of the drawing instrument. This can cause inaccuracies of up to 12 m in a database built from 1:24,000 mapping, such as USGS DRGs (Goodchild, 1998).

Precision and accuracy are two entirely different measures of data quality and should not be confused. A GIS can determine the location of a point feature precisely as coordinates with several significant decimal places. However, many decimal places in coordinates do not necessarily mean that the feature location is accurate to a 100th or 1000th of a distance unit. Once map data are converted into a GIS environment, the data are no longer scaled, as the data can be scaled as desired to create any output map scale. However, the spatial data can never be any more accurate than the original source from which the data were acquired. GIS data are typically less accurate than the source, depending on the method of data conversion. Therefore, if data were captured from a source map scale of 1 in. = 2000 ft, and a map was created at 1 in. = 100 ft, the map accuracy of features shown would still be 1 in. = 2000 ft (PaMAGIC, 2001).

MAP TYPES

Various map types used in GIS are discussed in the following subsections.

Base Map

The map layers are registered to a coordinate system geodetic control framework and a set of base information, often referred to as a base map. The foundation for a successful GIS mapping project is an appropriately designed base map. The base map is the underlying common geographic reference for all other map layers. The common reference provides registration between various layers and allows them to be overlayed, analyzed, and plotted together. Because the base map serves as the reference layer for other layers, its accuracy can affect the accuracy of other layers. This is especially true if the base map is used to create other layers by on-screen (heads-up) digitization.

Selection of an appropriate base-map scale is largely determined by the earlier choice of GIS applications. Each application inherently requires a certain minimum base-map accuracy and certain map features. For engineering and public-works applications, the required map accuracy is in the range of ±1 ft, as dictated by the need to accurately locate specific physical features, such as manholes and catch basins. Planning applications, which most often deal with areawide themes, do not generally require precise positioning. Accuracies of ±5 ft, or perhaps as much as ±40 ft, are often acceptable. Less detailed maps, showing nothing smaller than roads and buildings, for example, may be adequate for many planning applications.

Whatever the range of mapping requirements, the base map must be accurate and detailed enough to support applications with the most demanding map accuracies of better than ± 2 ft. Utility asset location also requires mapping that depicts specific small features such as manholes and catch basins. As shown in Table 8.1, these requirements are met by a map scale of 1 in. = 50 ft.

There are three common types of base maps: digital orthophotos, planimetric maps, and small-scale maps.

Digital Orthophotos

For laypersons, digital orthophotos (or orthophotographs) are scanned aerial photos. For GIS professionals, they are orthorectified raster images of diapositive transparencies of aerial photographs. Creation of a digital orthophoto requires more than a photo and a scanner, and includes surveyed ground control points, stereo plotters, and a digital elevation model. In fact, the digital orthophoto creation process involves many steps, which are listed below:

- Establish ground control
- Conduct aerial photography
- Perform analytical aerotriangulation
- Set stereo models in stereo plotters
- Capture digital elevation models
- Scan aerial photographs
- Digitally rectify the scanned photographs to an orthographic projection
- Produce digital orthophotos

Digital orthophotos are popularly used as base maps that lie beneath other GIS layers and provide real-life perspectives of terrain and surroundings that are not available in the vector GIS layers. Typical vector data do not show vegetation. The vector layers can show the manhole location but may not include the vegetation hiding the manhole. High-resolution orthophotos with submeter accuracy can guide the public-works crews directly to a manhole hidden behind bushes. Knowing the land-cover characteristics before leaving for an emergency repair of a broken water main will allow the crews to bring the appropriate tools and equipment. Knowing whether the job will be on a busy intersection or in somebody's backyard will determine the kind of equipment, material, and personnel required for the job. Figure 8.1 shows a water system map overlayed on a digital orthophoto base map with an accuracy of ±1.25 ft. Typical digital orthophotos cost $800 to $1600 per mi^2.

Planimetric Maps

Like digital orthophotos, planimetric base maps are also created from aerial photographs. However, instead of scanning the aerial photos, the features are digitized from them. Thus, whereas digital orthophotographs are raster files, planimetric maps are vector files. Planimetric maps generally show building footprints, pavement edges, railroads, and hydrography. Parcels digitized from existing maps are often added to the mix. Figure 8.2 shows a sample planimetric map for the Borough of Munhall, Pennsylvania, extracted from the Allegheny County land base. The borough's sewer lines and manholes are overlayed on the planimetric base map. The cost of planimetric maps depends on the level of detail and, therefore, varies significantly from project to project. The typical cost range is $2,500 to $10,000 per mi^2.

Figure 8.1 A water distribution system overlayed on a digital orthophoto base map.

Small-Scale Maps

Small or rural systems often use small-scale street maps or topographic maps as base maps. Street maps can be created by digitizing the existing maps, obtained from a government agency (e.g., U.S. Census Bureau, USGS, or state department of transportation) or purchased from commercial data vendors. In the U.S., 1:24,000-scale raster topographic map layers called digital raster graphics (DRG) are provided by USGS. Shamsi (2002) provides detailed information about the sources of small-scale maps. Users should be aware of the scale, resolution, accuracy, quality, and intended use of small-scale base maps before using them. Most maps at scales of 1:100,000 and smaller are not detailed enough to be used as site maps or engineering drawings, but they can be used for preliminary studies and planning projects. Figure 8.3 shows interceptor sewers and pumping stations for the Kiski Valley Water Pollution Control Authority in Pennsylvania, on a base map

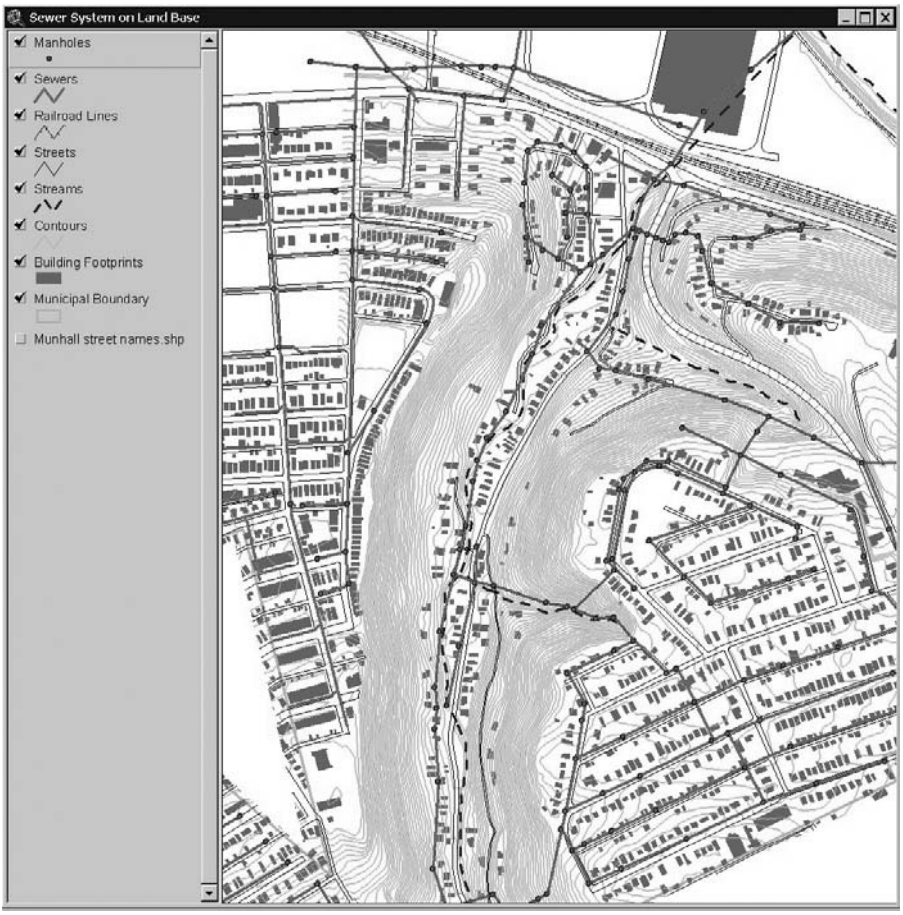

Figure 8.2 A sewer system overlayed on a planimetric base map.

of streets. The 1:100,000-scale solid roads are from the U.S. Census Bureau's 1990 Topologically Integrated Geographic Encoding and Referencing System (TIGER) data. The 1:24,000-scale dashed roads are from the Pennsylvania Department of Transportation. Unlike double-line pavement edges shown on the planimetric maps, these road layers show the single-line street center lines. The difference in the position of the roads in the two layers can be attributed to the resolution, scale, and accuracy of the two layers.

ADVANTAGES OF GIS MAPS

The most challenging part of a GIS application project is to obtain the right kind of maps in the right format at the right time. Therefore, maps are the most important component of a GIS. Without maps, you simply have a computer program, not a GIS.

Figure 8.3 A sewer system overlayed on a streets base map.

In many water and wastewater systems, there is a backlog of revisions that are not shown on the maps and the critical information is recorded only in the memories of employees. However, there is no longer any excuse to procrastinate because GIS-based mapping is easy and affordable.

In the past, users have selected computer-aided drafting (CAD) and automated mapping and facilities management (AM/FM) systems to map their water and sewer systems, CAD being the most common method. Although a map printed from CAD or AM/FM might look like a GIS map on paper, it does not have the intelligence of a GIS map. GIS maps are intelligent because they have attributes and topology. Most conventional CAD maps do not have attributes; they simply print data as labels or annotations. For example, the mapmaker must manually write the pipe diameter next to a pipe or must manually change the pipe color or line type to create a legend for pipe size. This is a very cumbersome process. On the other hand, GIS stores the attributes in a database and links them to each feature on the map. This capability allows automatic creation of labels and legends at the click of a mouse button. In GIS, map labels and legends are changed automatically if an attribute changes. In CAD, the mapmaker must manually delete the old label and retype the new label. Only a GIS map knows the spatial relationships among its features. Called *topology*, this capability makes the GIS maps intelligent. For example, a GIS map is intelligent enough to know which watershed is adjacent to which. Although both the CAD and AM/FM offer map layers to store different types of objects, only a GIS map has the capability to relate data across layers. The spatial relations among layers allow spatial

analysis operations such as identifying the gate valves that must be closed to isolate a broken water main for repair.

A commercial map atlas company may use a CAD system because its applications are primarily for cartographic products. A telephone company will use an AM/FM system to support its telephone system operations and maintenance, because it must be able to quickly trace a cable network and retrieve its attributes (Korte, 1994). For a water or sewer system, a GIS map is most suitable because the system must conduct many types of spatial analyses, asking questions such as how many customers by type (residential, commercial, industrial) are located within 1000 ft of a proposed water or sewer line.

In addition to water and sewer system management, GIS-based maps can also support other needs of the municipality. For example, a planning department can generate 200-ft notification lists as part of its plan review process. A public works department can conduct maintenance tracking and scheduling. A public-safety department can perform crime location analysis. GIS-based mapping is therefore the most appropriate mapping technology to meet all the mapping needs of a municipality.

GIS MAPPING STEPS

GIS mapping consists of five typical steps:

1. Needs analysis
2. Data collection
3. Data conversion
4. Data processing
5. Map production

These steps are intended for GIS technicians who work in a GIS lab (or production shop) equipped with map-making equipment such as digitizers, scanners, and plotters. Some professionals, such as civil and environmental engineers who are users rather than creators of GIS maps, generally do not perform all of these steps.

Needs Analysis

Mapping work should begin with needs analysis as described in Chapter 2. The needs analysis study describes the features that should be captured during the data conversion step, mapping specifications (accuracy, resolution, scale, etc.), and source documents. For example, the needs analysis determines whether or not the customer meters should be mapped. If the answer is yes, then how and to what accuracy should they be mapped. Are precise coordinates needed or can they be drawn at the end of service line? For large systems (populations greater than 50,000), a pilot project should be conducted as described in Chapter 2 (Needs Analysis). The pilot project allows potential fine-tuning of mapping specifications in a two- to four-sheet area before starting the map production phase.

Data Collection

When existing maps do not exist or are inadequate, mapping data should be collected using a field survey with or without GPS. Required data are usually scattered among a multitude of different organizations and agencies. For instance, it is claimed that 800 worker-years would be needed to convert England's sewer system to digital format, including field verification work (Bernhardsen, 1999). Field data collection using mobile GIS and GPS technology that employs handheld devices and tablet PCs is becoming common for collecting attributes (Chapter 7, Mobile GIS). The question of quantity should be evaluated carefully before the data conversion is started. Too little data limits the mapping applications. Too much data typical of a "data-driven" approach might be wasteful.

Data Conversion

Also referred to as the production work, this step converts hard-copy maps into digital files using digitization with or without scanning. The data conversion process is typically the most expensive and time-consuming part of a GIS mapping project. Depending on the level of detail, data conversion can cost $500 to $5000 per map sheet. Approximately 75% of typical GIS costs are related to data conversion and creation. The data conversion work, therefore, should be structured to ensure consistency, integrity, and accuracy.

Captured data are stored in *layers* also referred to as coverages or themes. For example, manholes are captured as a point layer, sewer pipes are captured as a line layer, and sewersheds are captured as a polygon layer. The layers that support development of other layers should be given a higher development priority. For example, geodetic control and base-map layers should be developed first because most other layers depend on them.

Data conversion includes capturing both the graphic (geometry and coordinates of features) and nongraphic (attributes) data. Graphic and nongraphic data may be entered simultaneously or separately.

Capturing Attributes

The annotations (labels) shown on the source map are the most common source of attributes. The source document ID (e.g., drawing number) is one of the most important attributes that should always be captured during data conversion. Features such as valves and hydrants have unique IDs, which can be easily captured from labels (annotations) on source maps. The features without IDs should be assigned new IDs during data conversion. Some data conversion application software allow automatic ID creation during data conversion.

Most source maps show pipe sizes as labels or legends, which can also be easily captured during data conversion. Geometric properties like length, area, and perimeter of features can be internally calculated by GIS and entered as an attribute. For example, if pipe length is labeled, it can be entered as a Length_Map (source map)

attribute. If pipe length is not shown, it can be automatically calculated by GIS and entered as Length_GIS (GIS-calculated) attribute.

Additional attributes are collected from other sources such as legacy databases, tables, and field and GPS surveys. Some existing databases and tables can be linked to GIS databases to avoid manual entry of attributes. Once the linkage has been established, attributes from the linked documents are available in the GIS database for query, analysis, and thematic mapping. For example, unique hydrant IDs captured during data conversion can be used to link to a hydrant-testing database. Applications that require locating the facilities by customer address such as work orders and customer complaints should also capture the address attribute in at least one layer (buildings, parcels, or meters). GIS attributes can also be found in some unexpected places, such as customer billing records. With a technique called address geocoding, GIS can convert the billing records or any postal address to a point on a map. Alternatively, facilities can be located by customer address using a geocoded streets layer.

Capturing Graphics

The data conversion methodology for capturing graphics depends on database design, source materials, and project budget. Digitization and scanning are the two most common data conversion methods.

Digitization

Digitization is a process of converting a paper map into a vector file by a computer using a digitizer or digitizing table (or tablet). The source map is placed on the usually backlit surface of the digitizer, and map features are traced using the digitizer puck that looks like a computer mouse with a crosshair. The source map should be registered (or calibrated) to control points. Figure 8.4 shows map conversion work using a digitizer. Digitizers cost approximately $10,000. Digitized files, when properly prepared, are ready for immediate use in a GIS.

Conventional table digitization is a laborious process. New "heads-up" or "on-screen" digitization is a less cumbersome alternative in which the visible features from scanned maps, digital aerial photos, or satellite imagery can be traced with a standard computer mouse on the computer monitor. If a digitizer is not available but a scanner is, data conversion can be done by scanning the source maps followed by heads-up digitization. The use of this process for certain specialized mapping projects, such as land-use/land-cover mapping, requires familiarity with photo interpretation techniques. For easy identification, certain utility assets that are difficult to see on the aerial photographs (e.g., valves, hydrants, manholes) can be premarked. Premarking is done by placing (or painting) targets with special symbols and colors over or adjacent to the asset to be captured. Premarking cost is usually $2 to $10 per target.

As-built or construction drawings usually have dimensional or offset information on utility assets (e.g., a sewer pipe 10 ft from the street right-of-way). This information can be used to position the utility assets using the automated drafting capabilities of modern GIS packages. This method is more accurate than digitization (Cannistra, 1999).

Figure 8.4 Data conversion using digitization.

Scanning

Scanning is a process of converting a paper map into a raster file (or image) by a computer using a map-size scanner. Black-and-white scanners are most common because they cost about the same as a digitizer. Color scanners cost twice as much. Figure 8.5 shows map-conversion work using a scanner. Scanning is generally most efficient when converting maps for archival purposes. Sometimes, as-built drawings are scanned and linked to vector features. Because many applications (e.g., hydraulic modeling and field inspections) require the utility features in vector format, scanned images must be converted to a vector format. This can be done by heads-up digitization of the scanned maps or by using a process called *vectorization* that automatically converts the raster data to vector format. Vectorization is a cost-effective data conversion method but it is based on new technology that is still improving. Vectorization may not always produce reliable results, especially in the unsupervised (unmanned) mode. Linework and symbols vectorize better than annotations. Complex, faded, or unclear maps may require extensive postprocessing and manual touch-up.

Data Conversion Software

Data conversion requires GIS development software that draws objects as points, lines, or polygons or represents them as pixels. ESRI's ArcGIS® and Intergraph's GeoMedia Pro® are examples of GIS development software (Shamsi, 2002). For large projects, data conversion application programs are very useful. These programs

Figure 8.5 Data conversion using scanning.

are usually developed as extensions to standard GIS packages to supplement specific mapping needs. For example, ESRI's ArcFM water data model supports water and sewer system mapping in a geodatabase. Chester Engineers' (Pittsburgh, Pennsylvania) water editing tool is an application that allows user-friendly mapping of water and sewer systems for ESRI software users. It eliminates attribute entry and editing via command prompts or database tables, which require data conversion skills. Users without prior data conversion experience can enter attributes from sources documents (e.g., as-built drawings) in a menu environment simply by clicking on points (e.g., manholes) and lines (e.g., sewers). The water editing tool was developed in several

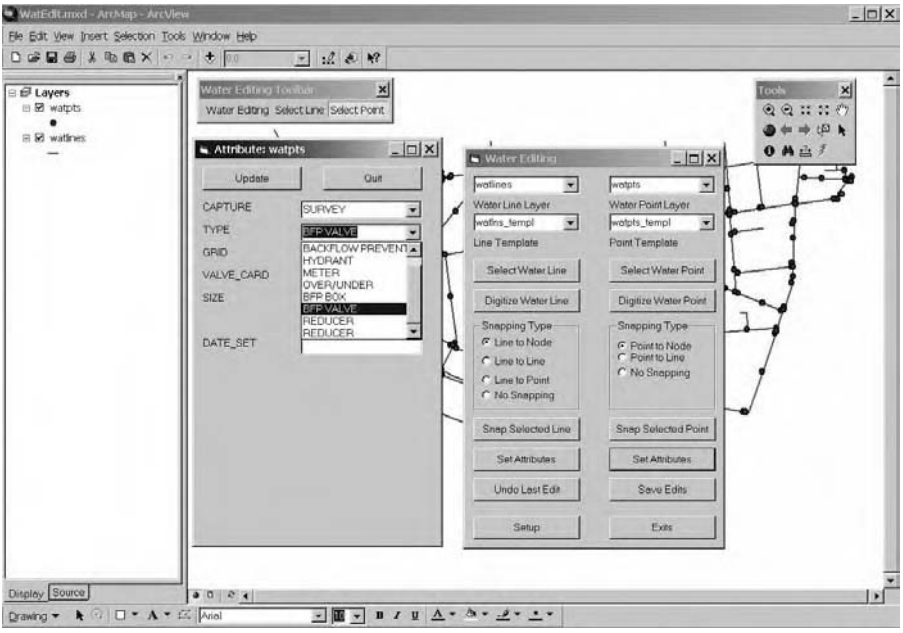

Figure 8.6 Sample water system data conversion application for ArcMap.

versions for different users. The ArcView version was developed using Avenue and ESRI's Dialog Designer Extension to support water system and sewer system mapping needs of the ArcView 3.x users. The ArcInfo 7.x version was written in Arc Macro Language (AML) to support water system and sewer system mapping in an Arcedit session. The latest ArcMap version that adds a new water editing toolbar in ArcMap was developed using Visual Basic for Applications (VBA) for ArcGIS users. Figure 8.6 shows a screenshot of the ArcMap version of the water editing tool. The right window shows the form for adding and editing point and line features. The left window shows the form for editing point attributes.

Data conversion is started by drawing and attributing the points. After the points are attributed, the connecting lines are added from point to point. The application prompts the user to select the upstream and the downstream points. After both are selected, the line is added to the data set. By selecting upstream and downstream manholes to add the lines, the flow direction of a gravity sewer is incorporated into the data set, ensuring the proper connectivity of the system. Additionally, the lines are snapped to the point features, ensuring that the points of connection correspond to manholes.

Data conversion applications like the water editing tool increase the speed, efficiency, and accuracy of data conversion for water, wastewater, and stormwater systems. They reduce data-entry errors and can even be used to validate the input data. If desired, the applications can be modified to meet the project-specific mapping requirements.

Data Processing

Data processing includes some or all of the following tasks:

1. Data preparation
2. Topological structuring
3. Data management
4. Quality control

Data Preparation

This task makes the raw data from source maps or field/GPS surveys available for GIS use or GIS-ready. Typical activities include postprocessing of capture data, changing data formats (e.g., from DXF to Shapefile), applying map projections, georeferencing the image data, and/or clipping or mosaicking the aerial photos.

Postprocessing of captured data is warranted if the source maps and the base map have different accuracy, and captured data do not align with the base map. In this case, captured data is edited (moved, stretched, or resized) to fit the base map.

GIS data are stored in various file formats. The number of data formats has increased exponentially with the growth in the GIS industry (Goodchild, 2002). According to some estimates, there might be more than 80 proprietary geographic data formats (Lowe, 2002b). Why are there so many geographic data formats? One reason is that a single format is not appropriate for all applications. For example, a single format cannot support both fast rendering in a command and control system and sophisticated hydraulic analysis in a water distribution system. Different data formats have evolved in response to diverse user requirements.

GIS software cannot read all the data formats simply because there are so many formats. Disparate data formats should be converted to one of the formats compatible with a particular GIS software. Although many GIS packages provide data conversion for the most common data formats, no GIS can support all possible conversions. Many government agencies and data and software companies provide data translators for this purpose (Shamsi, 2002).

Data translation from one format to another can potentially lead to the loss or alteration of data. For instance some platforms can support better numeric precision than others. Depending on the mapping scale and the coordinate system, this could seriously affect data quality. In one system, curves representing a water main might be defined mathematically, but in another described as a series of straight line segments.

Topological Structuring

How much topology should be captured in a GIS map depends on the intended applications of the map. For example, in a sewer system modeling application, correct topology (e.g., flow direction) is generally more important than the correct pipe location on the street (e.g., left, right or center of the street). As much topology as possible should be captured during data conversion. For example, flow direction

Figure 8.7 Common digitizing errors: undershoot (left) and overshoot (right).

should be captured if flow direction arrows are shown on source maps. Flow direction can be automatically captured if sewer pipes are digitized from upstream to downstream direction. In ArcInfo 7.x "coverage" model, the topology of an arc includes its upstream and downstream nodes (fnode, tnode). ArcInfo 7.x performs computationally intensive topological relationship calculations up front and stores that information as attributes (fnode, tnode). These attributes are used to determine flow direction of arcs. If source maps do not have topological relationships or if the data conversion technicians are not adequately skilled to understand them, topology can be added after the data conversion by knowledgeable staff. For example, in a water distribution system mapping project, valves and hydrants are logically linked to their appropriate pipe segments by the people who are knowledgeable about system characteristics (Cannistra, 1999).

Conventional GIS packages, such as ArcInfo 7.x and ArcCAD, provide the legacy *BUILD* and *CLEAN* commands to build topology and eliminate topological digitizing errors such as undershoots and overshoots. As shown in Figure 8.7, an undershoot occurs when a line stops short of an intended intersection point and an overshoot occurs when a line extends past an intended intersection point. Traditionally, these "cleaning" operations were done after the data conversion step. Today's modern GIS packages allow enforcing the topological rules (spatial constraints) during data conversion and editing. Thus, when a manhole is moved, the topological rules ensure that the sewers connected to that manhole move simultaneously. For example, ArcInfo 8.3 provides new tools to define, validate, and maintain topology in a geodatabase. Users define which layers participate in a topology and which rules are appropriate. Topology is stored in a commercial off-the-shelf DBMS.

Data Management

This step organizes attribute data in a database management system (DBMS) format. A GIS database, though not as visible as a GIS map, is an equally critical GIS component. The most difficult job in creating a GIS is the enormous effort required to enter the large amount of data and to ensure both its accuracy and proper maintenance (Walski and Male, 2000). Conventional file-based GIS databases (e.g., ArcInfo 7.x) store geographic data in vendor-specific proprietary format files. Attribute

data are stored in a separate file, which generally has a common nonproprietary format (e.g., a .dbf file). The two separate files are linked using pointers. Modern spatial or object-oriented databases do not require links between features and attributes because they store both the features and attributes in the same file. Incorporating spatial data with attribute data in a relational database provides a platform for efficient management of huge data resources, as well as fast and sophisticated spatial query and retrieval methods (Dalton, 2001).

Quality Control

A comprehensive and well-defined quality assurance/quality control (QA/QC) program should be implemented for large data conversion projects. Data conversion QA/QC can be ensured by checking data completeness, content, symbology, format, structure, and compliance with database specifications during data production. Positional accuracy can be checked using field trips, survey, GPS, photographs, and video tapes (Cannistra, 1999).

QA/AC can employ both manual checks and automatic methods. For example, the water editing application shown in Figure 8.6 provides an automatic QA/QC capability. It displays the points that are completely defined using a white box. Points that have missing attributes are displayed as a box with an X through it. Points that are added from source drawings are shown as a green box with an X through it. After each point is defined, the list of attributes for each point is displayed on the screen, allowing the user to double-check the attributes entered for each point.

Data-entry QA/QC can be accomplished by restricting the user input to valid data ranges and rejecting the data entries outside the valid ranges. This capability generally requires development of custom data-entry forms using computer programming.

Map Production

The previous steps enable display of GIS layers on the computer screen. The map production step allows plotting of GIS data on paper and other print media. It includes creation of thematic maps using appropriate symbols, colors, patterns, and legends. For example, water main sizes are shown by different line widths, pressure zones by different colors, and valve types by different symbols. Map production also involves printing the scale bar, north arrow, and organization logo. Sometimes tables, charts, and photographs are also inserted. Every map should have a title. Other information such as filename, map number, project name and number, plot date, mapmaker, and map source should also be printed on each important map.

This last step is important because it shows the final result of all the previous steps. Plotting of GIS maps in the correct style, orientation, scale, size, and format is a time-consuming process. Plotter speed and network speed are often the main bottlenecks. Templates for symbology, legends, and layouts should be developed in-house or obtained from other organizations to expedite map production. Some vendors package templates and symbol libraries specific to water, wastewater, and stormwater system with their software products.

Maps are needed for map books, wall mounting, archives, presentations, reports, etc. The purpose of the map and the target audience should be considered to design an appropriate map layout. For example, a map for an engineering application should be plotted differently from a map for a water utility newsletter. This step also includes distribution of the maps to the staff of an organization and optionally to the general public using the Internet, intranet, or wireless technology.

CASE STUDIES

Borough of Ramsey, New Jersey

The Ramsey Board of Public Works is responsible for the operation and maintenance of water distribution and sanitary sewer collection systems throughout the Borough of Ramsey, New Jersey. In an effort to more efficiently manage its geographically referenced data, the board started to explore the benefits and applications of GIS technology and computer mapping in early 1993. As a first step, with the assistance of Chester Engineers, Inc. (Pittsburgh, Pennsylvania), the board completed a needs analysis and a GIS pilot project described in Chapter 2 (Shamsi et al., 1995; Shamsi et al., 1996). The Borough did not have any complete large-scale mapping resources suitable for utility asset location. System design recommended the following mapping specifications:

- A new digital orthophoto base map should be developed accurate to the tolerances normally associated with mapping at a scale of 1 in. = 50 ft.
- Orthophoto base mapping should be established on the New Jersey State Plane Coordinate System. Survey monuments should be established to enable subsequent mapping efforts to be tied to the basemap coordinate system.
- Lot and block boundaries should be included as a unique layer in the base map.
- Additional map layers for the water distribution system, the sanitary sewer collection system, the stormwater collection system, and census geography should be developed to support other needs of the Borough.
- Use GPS to verify the locations of valves, hydrants, and manholes.

Table 8.2 summarizes the required map layers and the features depicted in each layer. Table 8.3 presents the data dictionary for Ramsey's pilot project.

Table 8.2 Map Layers and Depicted Features

Layer	Features
New Jersey State Plane Grid System	Grid tics, survey monuments
Photogrammetric base map	Building outlines, street outlines and centerlines, vegetation, water courses, topography
Parcels	Lot and block boundaries
Water distribution system	Mains, valves, hydrants
Sanitary sewer collection system	Sanitary sewers, manholes, cleanouts
Stormwater collection system	Storm sewers, manholes, catch basins
Census geography	Blocks, block groups, tracts

Table 8.3 Data Dictionary

Feature Type	Required Attributes
Water mains	Segment ID Pipe material Pipe size Repair date(s) Repair type(s)
Water valves	Valve ID Installation date Type Date last cycled Normal position
Fire hydrants	Hydrant ID Associated valves Type Installation date Flow data Preferred status
Sewers	Sewer ID Pipe material Pipe size From manhole ID To manhole ID
Manholes	Manhole ID Manhole type Lid type Depth Inflow problem status
Catch basins	Catch basin ID

All of the borough's sewer system data were stored in a nondigital form. This information was manually entered into the GIS database. Map features and attribute information were gleaned from a variety of sources. Table 8.4 lists recommended sources for specific map features and attributes. After reviewing the Borough's available maps and considering the mapping requirements of the priority applications, the use of digitization was recommended for data conversion.

ESRI's ArcInfo (Version 6) and ArcView (Version 2) software products were the two main software programs used in this project. Because the Borough did not have the technical staff to maintain an ArcInfo GIS, data conversion work was done by the consultant using ArcInfo. Due to its low cost, ease of use, and compatibility

Table 8.4 Source Documents for Map Features and Attributes

	Source Documents			
Types of Features	Base Map	Utility Markouts	Water System as Built, 1970, 1:50-Scale	Sewer System as Built, 1970, 1:100-Scale
Water mains		☑	☑

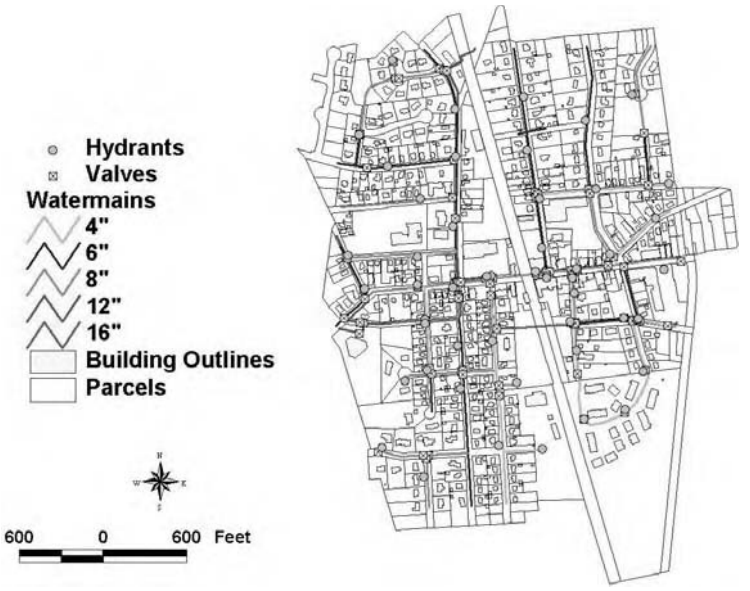

Figure 8.8 Water distribution system map showing pipes classified by diameter.

with the ArcInfo file format, ArcView was installed in the Borough for routine display and plotting of maps and querying the GIS database.

Figure 8.1 shows the Ramsey digital orthophoto base map with an accuracy of ± 1.25 ft. The figure on the first page of this chapter shows a map of sanitary sewers and manholes overlayed on the parcel and buildings layers. The sewer features were taken from as-built drawings and adjusted to locations of surface features that were field verified. Figure 8.8 shows a water system map with water mains, hydrants, and valves overlayed on the parcel and buildings layers. Water mains have been classified by the diameter attribute of the water main layer.

City of Lake Elsinore, California

Elsinore Valley Municipal Water District located in the city of Lake Elsinore, CA, provides water, wastewater, and agricultural services to approximately 25,000 customers. It maintains an infrastructure consisting of 305 mi of water mains, 290 mi of sewer pipes, and 246 mi of irrigation pipelines. An ESRI software user since 1992, the District migrated to ESRI's new ArcGIS geodatabase platform in 2000. The migration data conversion work, which included 5000 as-built drawings and 300 atlas pages, was completed in 8 months. The source documents were scanned and linked to GIS features. The system has 35 users and employs SQL Server 7 relational database management system software, Gateway 7400 and XI NetRAIDer dual 800 MHz servers, and Pentium III workstations. The system maintains approximately 75,000 maps in an enterprise GIS environment. GIS allows operations

personnel to create atlas maps and perform asset maintenance, a customer service department to analyze meter-reading routes and identify illegal connections, and an engineering department to generate as-built construction drawings (ESRI, 2002a).

Allegheny County, Pennsylvania

Each year, sewage overflows affect Pittsburgh's rivers up to 70 days during the boating season, making water unacceptable for recreational contact. In addition, the overflows affect Allegheny County's primary source of drinking water. Municipalities in the region could face a potential $2-billion investment in order to correct the problem. In 2003, the U.S. Environmental Protection Agency (USEPA) issued administrative consent orders to 83 municipalities of Allegheny County for controlling the sewage overflows. The orders required communities to address the sewage overflow issue through mapping, cleaning, and televising the system, and flow monitoring. This information will help communities develop a long-term wet-weather control plan. The orders required the following GIS mapping requirements:

- Create an ESRI-compatible base map that includes streets, street names, municipal boundaries, and streams.
- Create an updated ESRI-compatible comprehensive sewer map of the sanitary sewers with the following content:
  - Location of the sewer lines
  - Direction of flow
  - Size of the sewer lines
  - Sewer line material
  - Locations of interconnections with other municipal sewer systems
  - Field-verified location of manholes and catch basins (identified by a comprehensive numbering or lettering system)
  - Location of pump stations, force mains, and siphons
  - Location of streams or drainage ways tributary to the sewers
  - Location of overflow (combined sewer overflow [CSO] and sanitary sewer overflow [SSO]) structures
- Locate all significant structures to a minimum horizontal accuracy of 3 ft.
- Use as-built drawings, GPS, or traditional land surveying methods to determine structure locations.
- Use State Plane Pennsylvania South NAD83 projection system for coordinates and NAVD88 datum for elevations.
- Manhole inverts and rim elevations to a minimum vertical accuracy of 0.10 ft for overflow structures, sewers with greater than 10-in. diameters, and other critical sewers.
- Incorporate field inspection data into comprehensive sewer maps.

CHAPTER SUMMARY

GIS provides powerful capabilities for creating cost-effective and intelligent maps for water, wastewater, and stormwater systems. The quality of maps depends on data quality, errors, accuracy, scale, and resolution. GIS maps can be developed in many different ways. A mapping approach that best meets the application needs of an organization should be selected. GIS mapping requires five steps: needs analysis, data collection, data conversion, data processing, and map production. Needs analysis and pilot project testing is highly recommended, as explained in Chapter 2 (Needs Analysis). Data conversion is the most time-consuming and costly part of mapping projects and should be performed carefully. Data conversion application software can be used to reduce data conversion cost. Digitization and scanning are the two popular methods of data conversion but users can benefit from innovative variations of these methods. GIS maps should always be constructed in reference to a base map that has the required accuracy and resolution to support the intended applications of GIS maps.

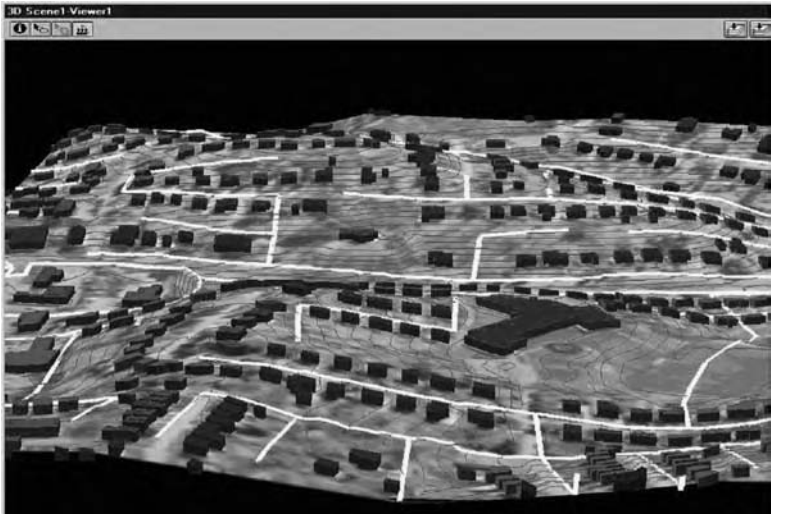
CHAPTER QUESTIONS

1. What are the different types of maps?
2. What are the different types of base maps and their characteristics?
3. How is a GIS map different from a CAD drawing?
4. What is the relationship between map accuracy, scale, and resolution?
5. What are the various steps for making GIS maps? Which step is most critical and why?
6. What is data conversion and how is it done?
7. What is topology, and how does it affect GIS maps?
8. Identify a GIS application in your organization and recommend the appropriate mapping layers and source documents to implement that application.

CHAPTER 9

Mapping Applications

A map is worth a thousand numbers but you must go beyond mapping to sustain your GIS program. This requires putting your GIS maps to beneficial use.



3D display of sewer system for the Municipality of Bethel Park, Pennsylvania.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand the applications of GIS maps in the water industry.

MAJOR TOPICS

- Common mapping functions
- Mapping application examples for water systems
- Mapping application examples for wastewater systems
- Mapping application examples for stormwater systems

---

This book focuses on the four main applications of GIS, which are mapping, monitoring, modeling, and maintenance and are referred to as the "4M applications." In this chapter we will learn the applications of the first *M* (mapping).

CUSTOMER SERVICE APPLICATION IN GURNEE

The Village of Gurnee, located near Chicago (Illinois), has seen explosive growth since the 1970s. Population more than doubled from 13,701 in 1990 to 28,834 in 2000. This growth bogged down Gurnee personnel with public meetings, rezoning hearings, code violations, road construction, and water line and sewer line repairs. Several departments were legally required to notify property owners of meetings, pending changes, or future disruptions. The Village used GeoMedia GIS software from Intergraph to automate the resident notification process (Venden and Horbinski, 2003). The automated system — known as Notifast™ — allows staff members to enter a street address or select a parcel, specify a distance radius, and identify all property owners within that distance. Notifast then generates a list of mailing labels

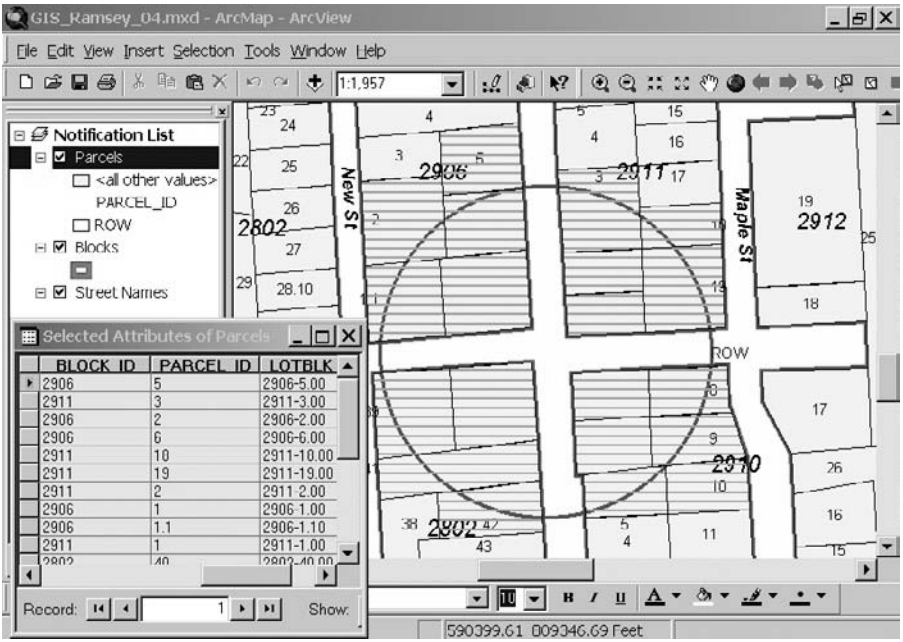

Figure 9.1 Selecting notification parcels in ArcGIS.

and mail-merged form letters. Each letter includes an embedded map that clearly shows the area in question. This application of existing GIS maps has improved efficiency and customer service. What used to take hours is now completed in minutes.

Figure 9.1 shows a screenshot of how parcels can be selected in ESRI's ArcGIS software by drawing a circle. The 200-ft radius circle is drawn with its center at the project site. All the parcels that are intersected by the circle are selected as shown in the hatched pattern. The attribute data for the selected parcels are shown in the table to the left of the circle. These data can be copied in a word processor's mail-merge feature to generate notification letters.

As explained in Chapter 8 (Mapping), creation of GIS maps is a huge undertaking. Unfortunately, in today's competitive world, despite the enormous effort required to create them, colorful maps alone can no longer justify the existence of a GIS program. This is because, after spending large sums of money on a mapping project, many water and sewerage agencies are wondering what else to do with their GIS maps. To garner continued financial support for a GIS program, GIS programs must go beyond conventional map printing activities and demonstrate the usefulness (applications) of GIS maps. This chapter shows how to do that.

It does not occur to most people that a good map raises more questions than it answers — that the question of why things are located where they are raises important intellectual issues, with immediate serious implications. (Lewis, 1985).

A paper map provides the power of place but a map in GIS can automate "the why of where." Most GIS applications originate from GIS maps. This chapter describes simple mapping applications. Advanced applications like hydrologic and hydraulic modeling, facilities management, inspection and maintenance, and planning are described in other chapters.

COMMON MAPPING FUNCTIONS

Most GIS packages provide simple data analysis capabilities that can be used to create basic mapping applications without custom programming. Typical examples of these GIS functions are given in the following subsections.

Thematic Mapping

Thematic mapping is one of the easiest ways to develop mapping applications. Map components can be logically organized into sets of layers called *themes*. A theme is a group of similar geographic features, such as hydrants (points), water mains (lines), or pressure zones (polygons). These themes can be manipulated using classification and legend (symbology) to create different thematic maps. Classification places attribute values into groups. For example, water mains for a city can be classified by diameter to create groups such as pipes smaller than 6 in., pipes 8 to 12 in., and pipes greater than 12 in. These groups can then be displayed using different legends reflecting different colors, line thicknesses, and symbols (e.g., solid, dashed, or dotted lines). Each combination of a classification method and legend will produce a different thematic map. Figure 9.2 shows the difference between an unclassified and nonsymbolized sewer map (top) and the same map classified and symbolized by pipe diameters (bottom). Obviously, the bottom map will be more useful in applications that require pipe diameters, such as flow monitoring and hydraulic modeling.

Spatial Analysis

Many GIS packages also allow users to select the features of one or more themes using the features of another theme. Referred to as spatial or overlay analyses, these *theme-on-theme* selection functions identify whether one feature lies within another, whether it completely contains another, or whether it is within a specified distance of another, and so on. For example, these mapping operations can identify the manholes in a given drainage basin, or census blocks within a watershed, or the properties within a certain distance of a water main.

Buffers

A buffer can be created around one or many features by using the buffer function typically found in most GIS packages. Creating a buffer provides a visual representation on a map of the area within a certain distance of one or more features. Buffer can also be used to select features in other layers that fall within the buffered area.

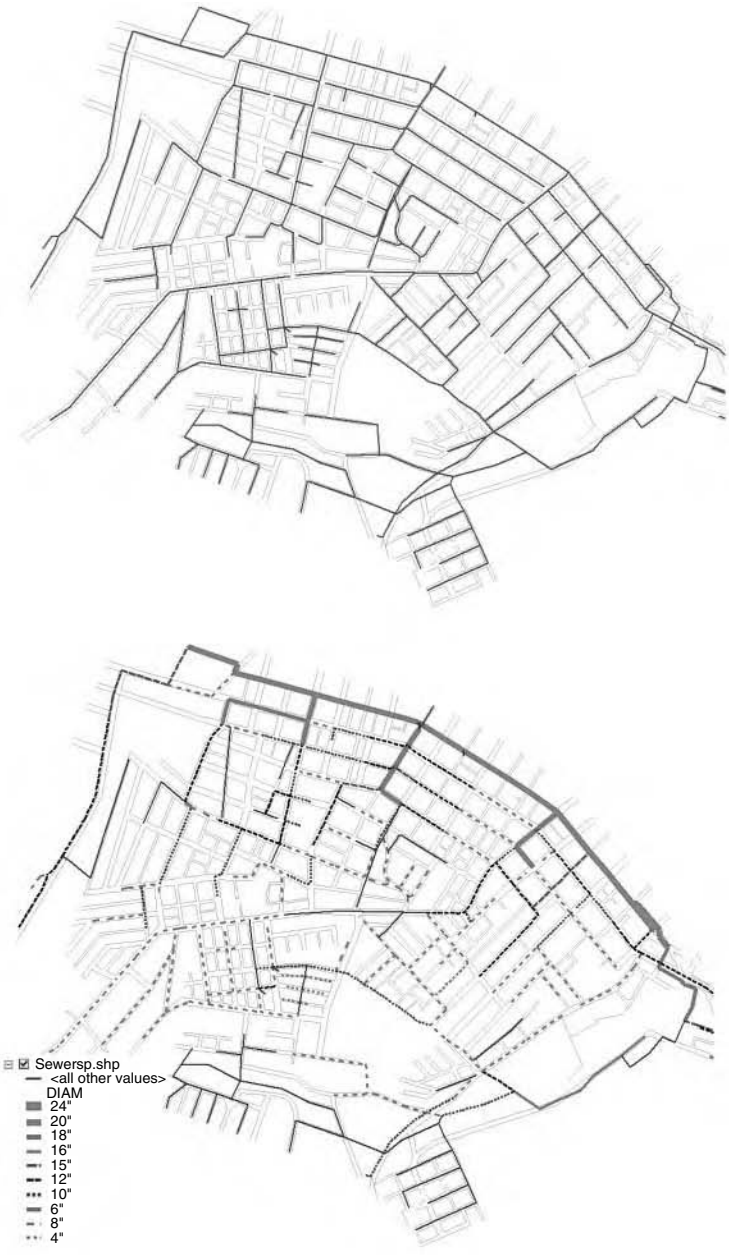

Figure 9.2 A sewer system map. Above: without attribute classification and symbology; below: with attribute classification and symbology for pipe diameter.

Figure 9.3 Buffer for a sewer separation project.

For instance, a buffer can be drawn to show the area around a well that is contaminated or to represent a floodplain around a river. Figure 9.3 shows a buffer created around existing combined sewers in the Borough of Kittanning, Pennsylvania. It identifies the area targeted for sewer separation in the Borough's combined sewer overflow (CSO) control plan.

Hyperlinks

Some GIS packages such as ArcView and ArcGIS have Hotlink or Hyperlink functions respectively to provide additional information about the features. For example, when a feature is clicked with the Hyperlink tool, a document or file is launched using the application associated with that file type. This function can be used as a document management system from within a GIS. For example, users can click on a valve to display the valve card, on a sewer pipe to launch a televised video file, or on a water main to display its as-built drawing. Figure 9.4 shows a display of a scanned image of a water distribution system valve parts list using ArcView's Hotlink function. Additional information on hyperlinks is provided in Chapter 15 (Maintenance Applications).

WATER SYSTEM MAPPING APPLICATIONS

Representative mapping applications for water distribution systems are given in the following subsections.

MWRA Water System Mapping Project

In the late 1990s the Massachusetts Water Resources Authority (MWRA) conducted a major in-house effort to develop a linked system schematic set. These overview maps did not have a scale or base, but showed how the elements of the system connected hydraulically. In addition to developing the digital version of these maps, the GIS staff created links to a number of real time databases and the location plans for each valve. Thus, the schematic showed the status of all mainline valves for emergency response planning. If a valve was inoperable or had been opened or closed, the GIS updated the color of the pipe line on the schematic, alerting the users to its condition.

MWRA then consolidated their water distribution facility data and source document references into a manageable set of data tables and digital maps that were easily accessible to MWRA staff. They also linked the records of every pipe, valve, meter, and fitting in the distribution system to existing databases of record plans, land takings, hydraulic conditions, leaks, maintenance activities, and schematic representations in the GIS. This effort allowed MWRA users to click on a pipe drawing, and instead of being able to access just the record drawing, choose from a menu of options regarding the land records and model scenarios, as well as the physical condition and maintenance history of the pipe. This provided access to a variety of maintenance and data development activities throughout the water division (Estes-Smargiassi, 1998).

Service Shutoff Application

To strengthen enforcement activities on delinquent accounts, the Philadelphia Water Department (PWD) developed an ArcView GIS tool to support its shutoff program. The shutoff tool identifies priority sites and automates crew assignments

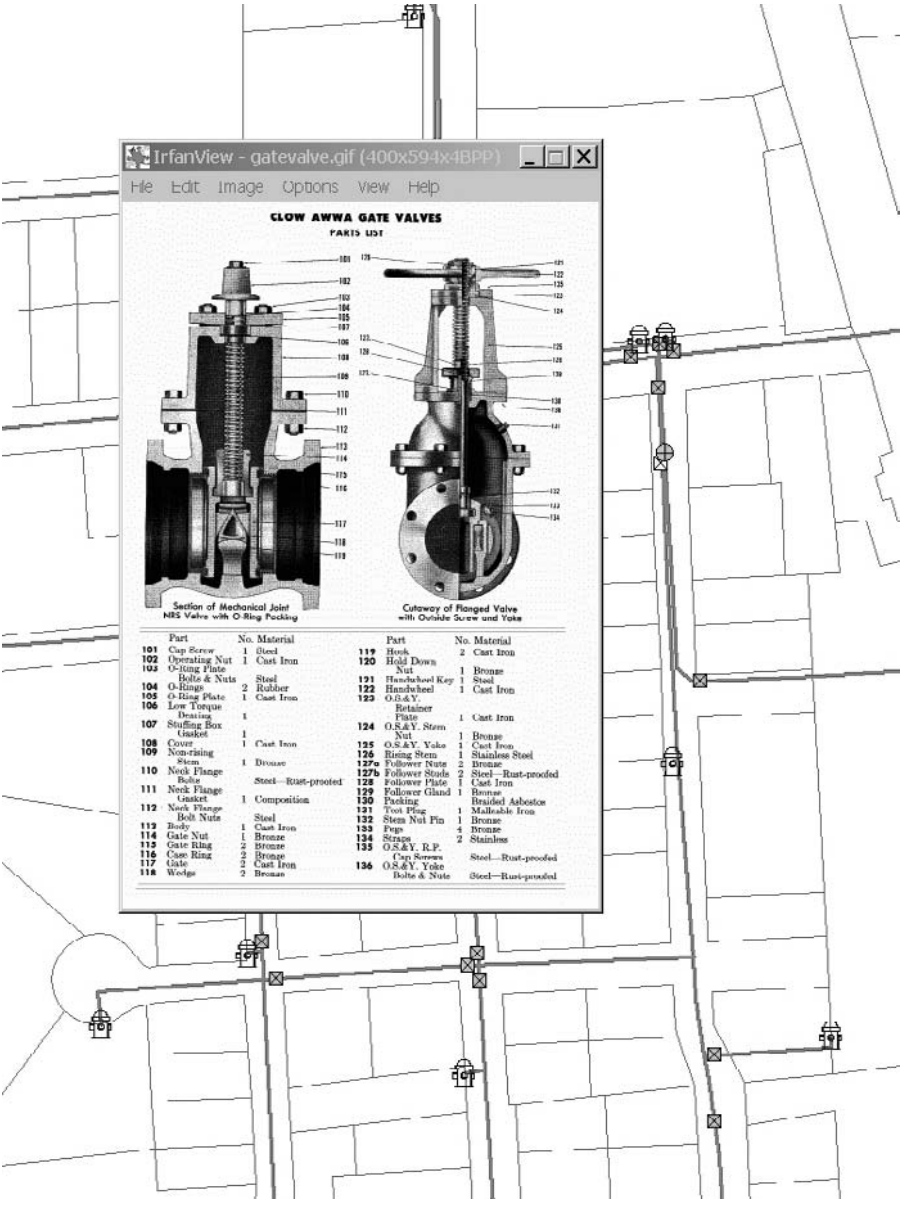

Figure 9.4 Hotlink function displaying valve information for a water distribution system.

to increase crew productivity. A prioritizing algorithm identifies delinquent customers based on age and amount in arrears. These priority accounts identify clusters of shutoff sites. Clusters are formed using ArcView Network Analyst extension to locate nearby sites reachable by the street network. The application generates maps and tables for each crew's daily schedule. With the help of this

application and other measures, PWD improved enforcement efficiency by 60% (Lior et al., 1998).

Generating Meter-Reading Routes

Seattle Public Utilities (SPU) has more than 174,000 customers. In an effort to save meter-reading cost and improve customer service, GIS was used to create more efficient meter-reading routes. In 1995, SPU's Metering and GIS departments joined forces to explore the feasibility of rerouting meter-reading routes. In 1997, a pilot project was completed using software from ESRI and RouteSmart Technologies, which convinced the SPU management to implement a citywide rerouting project. The project implementation resulted in cost savings for the ratepayer, especially because of SPU's prior investments in GIS data conversion (Lee, 1998).

Map Maintenance Application

In Ohio, Cincinnati Water Works (CWW) developed a GIS application for water distribution system maintenance, hydraulic modeling, and customer service. A major component of this application was the development of a Map Maintenance Application (MMA), which is an update developed using ArcInfo and Oracle. It allows simultaneous maintenance of water system layers and related RDBMS tables. The MMA features COGO data entry, scroll lists for table inserts, and feature abandonment. It also utilizes the integrity constraint checking capability of the RDBMS (Guetti, 1998).

WASTEWATER SYSTEM MAPPING APPLICATIONS

Representative mapping applications for wastewater systems are given in the following subsections.

Public Participation with 3D GIS

At the present time many cities in the U.S. are planning to spend billions of dollars to meet the regulatory requirements for correcting their wastewater problems, such as wet-weather overflows from the sewer systems. Given the potential for significant expenditures of public funds, a key to the future success of capital projects is public participation. The regulatory agencies are mandating public participation as a required element of these projects. Therefore, establishing early communication with both the public and the regulatory agencies should be an important first step in a long-term planning approach, and crucial to the success of a wastewater capital improvement program. By informing the public early on in the planning process about the scope and goals of the program, and continuing this public involvement during development, evaluation, and selection of alternatives, issues and potential conflicts can be identified and addressed more expeditiously, minimizing the potential for prolonged delay or additional cost.

Three-dimensional (3D) maps are an effective means of public education, notification, and communication. They provide impressive "real-life" visions of proposed

projects. GIS, CAD, and multimedia technologies can be combined to produce 3D models and 3D animations.

3D maps can be created by adding elevation data to existing 2D vector layers. Elevation data can be obtained from contour maps, digital elevation models (DEM), digital terrain models (DTM), aerial surveys, engineering drawings, or GPS surveys. The quality of 3D analysis largely depends on the accuracy and resolution of elevation data. For engineering design, highly accurate data are required. For presentation mapping, less accurate data can be used. For example, in-lieu of accurate heights, buildings can be elevated in proportion to the number of floors.

GIS fly-through scenes allow the public to experience a 3D walk-through of a proposed project. Animation can animate objects within a model, e.g., cars moving down the road or people walking on the curbs. Realistic materials and textures can be added to depict the actual field conditions, e.g., wet streets. Climatic conditions, e.g., snow cover or sunlight can be added to portray the specific design conditions.

3D capability is usually added to standard GIS packages by installing additional 3D extensions or modules. For example, 3D Analyst Extension enables ESRI's ArcGIS users to visualize and analyze surface data. Using 3D Analyst, one can view a surface from multiple viewpoints, query a surface, determine what is visible from a selected location on a surface, and create a realistic perspective image draping raster and vector data over a surface.

The figure on the first page of this chapter shows a 3D map of a sewer system for the Municipality of Bethel Park, Pennsylvania. Created using 3D Analyst Extension, the map shows buildings, contours, and sewer lines overlaid on an aerial photograph. Because wastewater must flow down the hill, design of gravity sewers depends on topography. GIS can help create 3D maps to facilitate efficient engineering of a new sewer system, quick assessment of an existing sewer system, or presentation of the project layout to the general public.

Figure 9.5 shows a 3D fly-through animation of an Allegheny County Sanitary Authority (ALCOSAN) sewer construction project in the City of Pittsburgh, Pennsylvania. Completed in 1999, this $24-million project involved construction of a 5.2-mi-long parallel relief interceptor to relieve sewer overflows and basement flooding in the Saw Mill Run Watershed of the city. The pipe sizes for the relief interceptor ranged from 36 to 54 in. in diameter. The parallel interceptor was designed to follow the alignment of the Saw Mill Run Creek because the right-of-way corridor along the main street (Route 51) was not conducive to a major interceptor construction project. Animation was used to present the project design in a general public meeting. Figure 9.5 shows the sewers and manholes exposed above the ground surface to help the general public envision the proposed interceptor layout. The animation clearly indicated that the new sewers will mostly avoid backyards, parking lots, and roads — an issue that was very important to the residents of the community. This approach helped ALCOSAN to win the public support for the project.

Mapping the Service Laterals

Recent inflow and infiltration (I/I) studies have shown that service laterals are one of the most significant I/I contributors, generating as much as 60% of the total

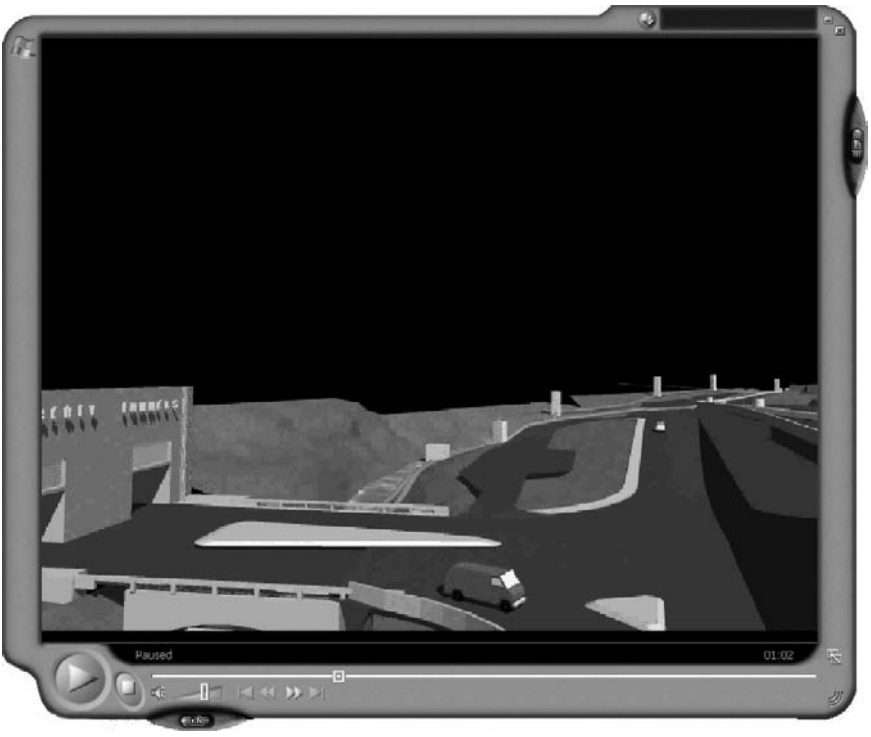

Figure 9.5 3D fly-through animation of a sewer construction project.

I/I quantity. Unfortunately, most collection systems do not have maps of their service laterals. TV inspection logs provide accurate lateral location information, which can be used to prepare service lateral GIS maps. For example, Chester Engineers (Pittsburgh, Pennsylvania) developed a Wyemaker ArcView extension to add service wyes (Ys) to sewer lines. Developed using ArcView Dialog Designer extension, this utility is a good example of GIS customization.

Figure 9.6 shows a typical two-page TV inspection log. The first page provides general information about a sewer pipe. The second page details the specific pipe defects and their location. This page also includes the location of service laterals measured in feet from one manhole to the next. The Wyemaker extension will first create a database containing the wye information for each sewer main. The wye information is entered in a wye input form shown in Figure 9.7 that basically replicates the data fields on the log sheets. The upstream and downstream manhole identification numbers are entered. In this case, the sewer segment ID is created by concatenating the upstream and downstream manholes. The sewer length from the inspection log is entered as well as the beginning distance (usually zero). The user then indicates the direction of the measurements, the wye measurement and the side of the line in which the wye is located. The direction of the measurements is the direction in which the line was inspected. The direction is either "against the flow" (from the downstream manhole to the upstream manhole) or "with the flow" (from

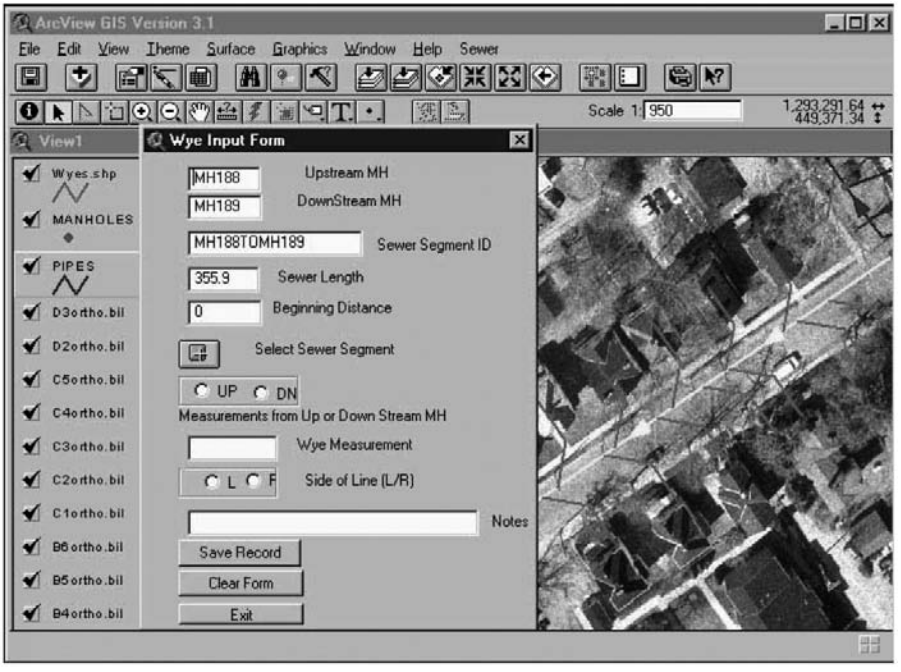

Figure 9.7 Service laterals view in ArcView.

the upstream manhole to the downstream manhole). Entering the direction of measurement and the side of the line eliminates the need for the user to recalculate distances if the line was measured against the flow. The calculations are automatically done by the extension and the position of the wye (right or left) is automatically switched if necessary. Once the form is completed, the user simply clicks on "Save Record" and the wye record is automatically saved to the wye table.

When all records are entered, the database table is used to create a Shapefile of the wyes. All the wyes in the Shapefile are exactly the same length and at the exact same angle from the sewer line, creating an aesthetically appealing data set. The wyes are kept in a separate Shapefile rather than being added to the existing sewer theme in order to maintain the connectivity of the main lines. A sample lateral map created using this method is shown in Figure 9.7.

Additional examples of wastewater system mapping applications are included in Chapter 15 (Maintenance Applications).

STORMWATER SYSTEM MAPPING APPLICATIONS

A representative mapping application for stormwater systems is presented below.

Stormwater Permits

In the U.S., many cities with storm sewers and outfalls must comply with a National Pollution Discharge Elimination System (NPDES) Stormwater Permit under the U.S. Environmental Protection Agency's Municipal Separate Storm Sewer System (MS4) permit program. These permits require U.S. municipalities to develop stormwater pollution prevention programs, track the compliance schedules, and monitor stormwater system maintenance and water quality sampling.

Some cities finance the operation of a stormwater utility that pays for permit compliance by assessing a stormwater fee (drainage tax) on the properties. Initially, some U.S. municipalities chose to implement a flat tax for all property owners, based on the tax value of their property. Because only the impervious area of a property contributes to stormwater runoff, many cities used a more equitable approach that assessed the tax in proportion to the impervious area of each property. Accurate calculation and tracking of impervious areas from conventional methods (e.g., from survey or paper maps) is cumbersome and costly. GIS allows accurate and inexpensive capture of impervious surfaces from aerial photographs, orthophotos, scanned site plans, and parcel maps.

GIS can be used to develop stormwater user fees using the following steps:

1. Delineate property land covers using digital orthophotos.
2. Assign a percent imperviousness factor to each land cover. For example:
   - Roofs, 100%
   - Concrete driveway, 100%
   - Gravel driveway, 75%
   - Parking lot, 90%

3. Estimate land-cover area-weighted mean percent imperviousness of each property.
4. Determine stormwater rates based on mean percent imperviousness of a property rather than the total impervious area.

For example, the Texas legislature passed a law allowing municipalities to create drainage utilities that assessed utility fees associated with each land parcel based on the amount of stormwater runoff it contributed. The City of Irving, Texas, started using GIS and color-infrared aerial photography in 1993 to examine and map the sources of the city's stormwater runoff. The City assumed that a simple distinction between pervious surfaces such as vegetative cover and impervious surfaces such as buildings and parking lots would be sufficient to determine the stormwater runoff of each parcel with acceptable accuracy. To determine the area of each surface type with individual parcels, the tax-parcel layer was overlaid with the pervious/impervious layer. This operation created a list of each parcel's tax identification number and the associated pervious/impervious area. This table was then linked to the City's water utility billing system to calculate the amount due from each property owner and include that amount in the monthly utility bill (*American City&County*, 1994).

The City and County of Denver, Colorado, has a storm drainage utility that assesses a fee on all properties in Denver based on the amount of impervious surface present on each property, as well as on the percentage of the total area of each property that the impervious surface represents. Initially, Denver used field measurements but did not find them cost-effective. In 2002, they hired the Denver firm of Elroi Consulting, Inc., to implement an impervious surface GIS for the County. Initially, the system was implemented using ArcGIS 8.1 and a personal geodatabase that required only ArcView licenses. The system was later upgraded to work with an ArcSDE geodatabase, complete with versioning and multiuser editing. The system builds on the ArcMap component of ArcGIS, both removing unnecessary toolbars from the user interface and adding several custom toolbars. The user-friendly interface enables even the non-GIS users (e.g., field inspectors) to use the system. Impervious surfaces are digitized directly into the GIS, thus making impervious surface fee assessments defensible. The impervious surface GIS was subsequently linked to Denver's stormwater billing system for rapid database update. With this system, Denver now collects over $12 million annually in impervious surface fees (Elroi, 2002).

Oakland County, Michigan, which has more than 440,000 parcels, uses high-density spot elevation and break-line data in GIS to create triangular irregular network (TIN) surface models. These models help the county drain commissioner's office to visualize the terrain and delineate catchment areas. This approach identifies precise drainage patterns and the land that contributes runoff to a storm drain. The catchments define the drainage district boundaries that are used to assess the appropriate drainage tax in an equitable manner (Gay, 2003).

The conventional paper-based permit compliance approach can be very hectic for large cities. GIS is being used in many U.S. cities to meet the stormwater permit requirements system in a user-friendly environment. For example, SQL, Avenue, and Dialog Designer have been utilized to develop an interface between ArcView GIS and Microsoft Access for developing an NPDES compliance application (Huey, 1998). This application is helping both the management of stormwater features such

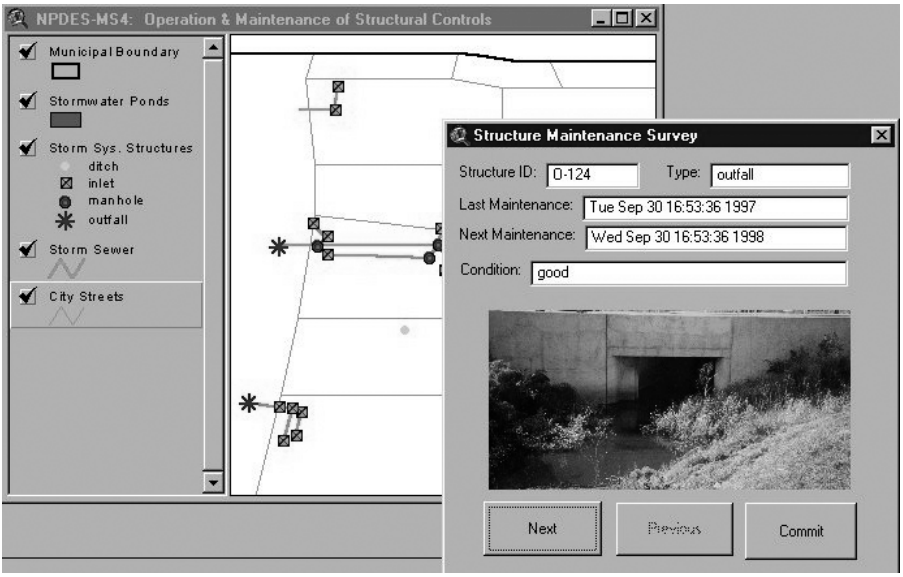

Figure 9.8 Utilization of dialogs to monitor and update structure-maintenance activities.

as sewer lines and outfalls, and preparation of complex NPDES Annual Reports. The report requires summarizing all stormwater management program goals and efforts toward meeting those goals. An example of the use of dialogs and custom-programmed icon buttons for query is shown in Figure 9.8.

CHAPTER SUMMARY

Paper maps are useful but their applications are limited. In most cases, mapmaking alone cannot justify the continued financial support for a GIS department. GIS maps and associated databases can be manipulated in a variety of ways to develop applications that automate and simplify the routine tasks. GIS maps are the starting point for developing GIS applications: no maps, no applications. In this chapter we learned about some basic applications of GIS maps. Advanced applications will be presented in subsequent chapters.

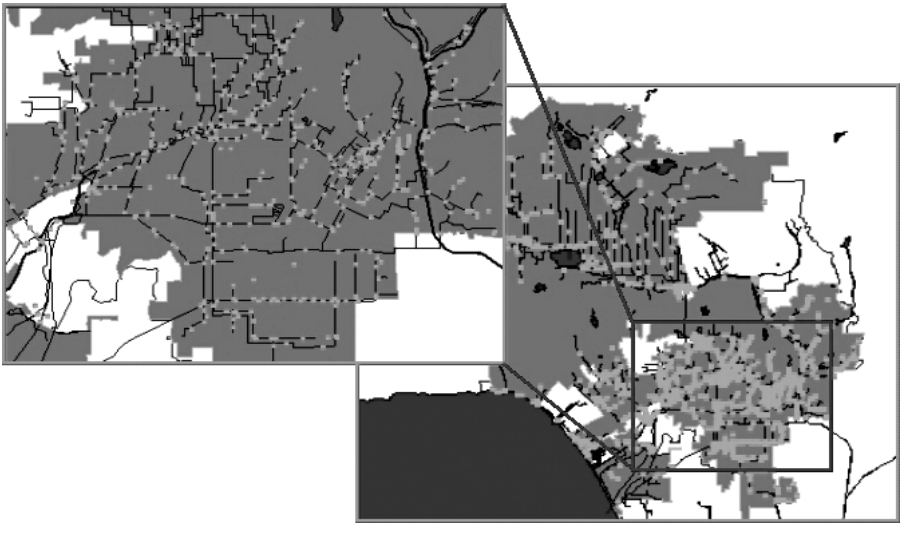
CHAPTER QUESTIONS

1. What is the meaning of "beyond mapping?" Why is it important to go beyond mapping?
2. Compile a list of ten mapping applications.
3. Using literature review or the Internet, write a 200-word example of a mapping application for a water distribution system not described in this chapter.
4. Repeat Question 3 for a wastewater collection system.
5. Repeat Question 3 for a storm drain system.

CHAPTER 10

Monitoring Applications

GIS is ideally suited to install, maintain, and query monitoring equipment such as, rain gauges, flow meters, and water quality samplers for system physical and hydraulic characterization. GIS allows display and analysis of monitoring data simply by clicking on a map of monitoring sites.



Gauging and inspection stations in the city of Los Angeles, California.

LEARNING OBJECTIVE

The learning objective of this chapter is to familiarize ourselves with GIS applications in monitoring data for effective operation and management of water, wastewater, and stormwater systems.

MAJOR TOPICS

- Rainfall monitoring
- Satellite and radar rainfall data
- Flow-monitoring applications
- Permit reporting applications
- Internet monitoring applications
- Infrastructure monitoring applications

WSR Weather Surveillance Radar

This book focuses on the four main applications of GIS, which are mapping, monitoring, modeling, and maintenance and are referred to as the "4M applications." In this chapter we will learn about the applications of the second *M* (monitoring).

MONITORING REAL TIME RAINFALL AND STREAM-FLOW DATA IN AURORA

The city of Aurora, Colorado, is a community of approximately 247,000 people located in the southeast Denver metro area. The City's Utilities Department used ESRI's ArcInfo and ArcView software to analyze and display real time rain-gauge and stream-flow data from the City's ALERT Flood Warning System. Data were obtained by querying a remote real time data-collection database. The Utilities Department was able to access and analyze both historical and current real time rainfall and stream-flow data from an easy-to-use graphical interface. ArcView's Spatial Analyst Extension was used to develop a continuous areal rainfall surface from the point rainfall data. This allowed a better and clearer understanding of a particular storm and allowed a

more complex analysis of the true impact of the storm event. Applications of this program included studies in emergency flood response, location of flood reports, routine maintenance for storm sewers, and National Pollution Discharge Elimination System (NPDES) compliance for water quality (Rindahl, 1996).

MONITORING BASICS

Monitoring of various types of data is essential to the effective management of water, wastewater, and stormwater systems. Generally, two types of data are required: (1) physical characterization data and (2) hydraulic characterization data. Physical characterization data describe the physical condition of the infrastructure, such as pipe and manhole conditions. Examples of physical characterization data sources include closed-circuit television (CCTV) inspection of pipes, manhole inspections, and smoke-testing of buildings. GIS applications for these types of data are described in Chapter 15 (Maintenance Applications).

Hydraulic characterization data describe the quantity and quality of flow through pipes and open channels as well as meteorological factors impacting the flow, such as precipitation.

Wastewater and stormwater systems typically require data on flow quantity (depth, velocity, flow rate, and volume), quality (e.g., suspended solids and bacteria), and rainfall. Figure 10.1 shows a flowmeter and weir installation in a combined sewer system overflow manhole. The flowmeter (Flo-Dar from Marsh-McBirney, Inc.) shown on the left records incoming combined sewage depth, velocity, and flow data. The weir shown on the right collects outgoing overflows. Some wastewater and stormwater hydrologic and hydraulic (H&H) models require data on additional meteorological parameters such as ambient temperature, evaporation rate, and wind speed. Water distribution systems typically require water pressure and water quality data. In many projects, monitoring tasks make up a significant portion of the scope of work and could cost 20 to 30% of the total budget. Careful installation of monitors and effective management of monitoring data is, therefore, highly desirable for the on-time and on-budget completion of monitoring projects.

GIS is ideally suited for selecting the best sites for installing various hydraulic characterization monitors. Once the monitors have been installed, GIS can be used to query the monitored data simply by clicking on a map of monitoring sites. GIS can also be used to study the spatial trends in the monitored data. GIS is especially useful in processing and integrating radar rainfall data with H&H models of sewage collection systems and watersheds. This chapter will present the methods and examples of how to use GIS for installing and maintaining the monitors, and for querying and analyzing the monitoring data.

REMOTELY SENSED RAINFALL DATA

Many watersheds, especially those smaller than 1000 km^2, do not have recording rain gauges capable of recording at hourly or subhourly intervals. Sometimes rain gauges exist, but data are found missing due to equipment malfunction. Quite often,

Figure 10.1 Flowmeter and weir installation in a manhole for monitoring incoming and outgoing flows.

rain-gauge density is not adequate to accurately capture the spatial distribution of storm events. Such data gaps can be filled by the rainfall data provided by weather satellites and radars, as described in the following subsections.

Satellite Rainfall Data

Direct measurement of rainfall from satellites is not feasible because satellites cannot penetrate the cloud cover. However, improved analysis of rainfall can be achieved by combining satellite and conventional rain-gauge data. Meteorological satellites such as the NOAA-N series, those of the Defense Meteorological Satellite Program, and U.S. geostationary satellites can observe the characteristics of clouds with precipitation-producing potential and the rates of changes in cloud area and shape. Rainfall data can now be estimated by relating these cloud characteristics to instantaneous rainfall rates and cumulative rainfall over time. Cloud area and temperature can be used to develop a temperature-weighted cloud cover index. This index can be transformed to estimate mean monthly runoff values. Satellite rainfall estimating methods are especially valuable when few or no rain gauges are available (ASCE, 1999).

Radar Rainfall Data

Weather radars provide quantitative estimates of precipitation, which can be used as input to H&H models. Radar rainfall estimates augmented with data from sparse rain-gauge networks are useful in H&H modeling. Weather radars provide real time, spatially distributed rainfall data that can be extremely valuable for flood forecasting and flood warning.

NEXRAD Rainfall Data

The U.S. National Weather Service (NWS) has a group of weather radars called the Next Generation Weather Radar (NEXRAD) system. NEXRAD comprises approximately 160 Weather Surveillance Radar–1988 Doppler (WSR-88D) sites throughout the U.S. and selected overseas locations. This system is a joint effort of the U.S. Departments of Commerce (DOC), Defense (DOD), and Transportation (DOT). The controlling agencies are the NWS, Air Weather Service (AWS), and Federal Aviation Administration (FAA), respectively. Level II data provide three meteorological base data quantities: reflectivity, mean radial velocity, and spectrum width. These quantities are processed to generate numerous meteorological analysis products known as Level III data. Level II data are recorded at all NWS and most AWS and FAA WSR-88D sites. Level III products are recorded at the 120 NWS sites. The data are sent to the National Climatic Data Center (NCDC) for archiving and dissemination.

NEXRAD Level III Data

There are a total of 24 Level III products routinely available from NCDC, including 7 graphic products in clear-air mode, 11 in precipitation mode, 5 graphic overlays, and 1 alphanumeric product. Each product includes state, county, and city background maps. Level III graphic products are available as color hard copy, grayscale hard copy, or acetate overlay copies. A brief description and possible uses of these products are given below:

- Base Reflectivity (R): A display of echo intensity measured in dBZ (decibels of Z, where Z represents the energy reflected back to the radar). This product is used to detect precipitation, evaluate storm structure, locate boundaries, and determine hail potential.
- Base Spectrum Width (SW): A measure of velocity dispersion within the radar sample volume. The primary use of this product is to estimate the turbulence associated with mesocyclones and boundaries.
- Base Velocity (V): A measure of the radial component of the wind either toward the radar (negative values) or away from the radar (positive values). Negative values are represented by cool colors (green), whereas positive values are represented by warm colors (red). This product is used to estimate wind speed and direction, locate boundaries, locate severe weather signatures, and identify suspected areas of turbulence.

- Composite Reflectivity (CR): A display of maximum reflectivity for the total volume within the range of the radar. This product is used to reveal the highest reflectivities in all echoes, examine storm structure features, and determine the intensity of storms.
- Echo Tops (ET): An image of the echo top heights color-coded in user-defined increments. This product is used for a quick estimation of the most intense convection and higher echo tops, as an aid in identification of storm structure features, and for pilot briefing purposes.
- Hail Index Overlay (HI): A product designed to locate storms that have the potential to produce hail. Hail potential is labeled as either probable (hollow green triangle) or positive (filled green triangle). Probable means the storm is probably producing hail and positive means the storm is producing hail.
- Mesocyclone Overlay (M): This product is designed to display information regarding the existence and nature of rotations associated with thunderstorms. Numerical output includes azimuth, range, and height of the mesocyclone.
- One-Hour Precipitation (OHP): A map of estimated 1-h precipitation accumulation on a 1.1 nmi × 1.1 nmi grid. This product is used to assess rainfall intensities for flash flood warnings, urban flood statements, and special weather statements.
- Severe Weather Probability Overlay (SWP): A measure of a storm's relative severity as compared with those around it. The values are directly related to the horizontal extent of vertically integrated liquid (VIL) values greater than a specified threshold. This product is used for quick identification of the strongest storms.
- Storm Structure (SS) (alphanumeric product): A table displaying information on storm attributes that include maximum reflectivity, maximum velocity at lowest elevation angle, storm overhang, mass-weighted storm volume, storm area base and top, storm position, and storm tilt.
- Storm Total Precipitation (STP): A map of estimated storm total-precipitation accumulation continuously updated since the last 1-h break over the entire scope. This product is used to locate flood potential over urban or rural areas, estimate total basin runoff, and provide rainfall data 24 h a day.
- Storm Tracking Information Overlay (STI): A product that shows a plot of the past hour's movement, current location, and forecast movement for the next hour or less for each identified thunderstorm cell. This product is used to determine reliable storm movement.
- Tornadic Vortex Signature Overlay (TVS): A product that shows an intense gate-to-gate azimuthal shear associated with tornadic-scale rotation. It is depicted by a red triangle with numerical output of location and height.
- VAD Wind Profile (VWP): A graphic display of wind barbs plotted on a height staff in 500-ft or 1000-ft increments. The current (far right) and up to ten previous plots may be displayed simultaneously. This product is an excellent tool for meteorologists in weather forecasting, severe weather, and aviation.
- Vertically Integrated Liquid (VIL): The water content of a 2.2 nmi × 2.2 nmi column of air, which is color-coded and plotted on a 124 nmi map. This product is used as an effective hail indicator to locate most significant storms and to identify areas of heavy rainfall.

NEXRAD data and various visualization and analysis software tools are available from NCDC and commercial vendors.

Estimating Rainfall Using GIS

Because rainfall is a critical component in conducting H&H analyses, the quality of rainfall data is critical for accurate system hydraulic characterization. It is often the case that the spatial distribution of rain-gauges over a collection system is too sparse to accurately estimate the rainfall over a given basin. Radar rainfall technology can be used to obtain high-resolution rainfall data over an approximately 2 km $\times$ 2 km area (called a pixel). GIS can be used to display and process the radar rainfall data.

NEXRAD Level III data from Doppler radar measurements provide spatially dense rainfall data. These data are similar to those commonly seen on weather maps. Such data do not require interpolation between point data from widely scattered rain-gauges because they provide continuous rainfall measurements throughout a watershed or sewershed (Slawecki et al., 2001).

WRS-88D radar images have a mean resolution of 4 km $\times$ 4 km. They are registered to the Hydrologic Rainfall Analysis Project (HRAP) map projection system. The radar rainfall data can be incorporated in a GIS-based distributed hydrologic model by importing it in a raster grid format. However, this may require reprojecting the rainfall grid from the HRAP coordinate system to the coordinate system being used by the model.

The accuracy of radar rainfall estimates can be improved substantially by calibrating the radars using the point rain-gauge observations. Generating NEXRAD rainfall estimates requires extensive expertise and computational resources (ASCE, 1999). Hourly NEXRAD rainfall data called hourly digital precipitation array (DPA) are available from several NWS-authorized commercial data vendors, such as WSI Corporation and Paramax Systems Corporation. Weather data vendors such as DTN Weather Services (now part of Meteorlogix, Inc.) provide continuously updated, real time, GIS-ready, georeferenced weather data in ESRI GRID (raster) and Shapefile (vector) formats and georegistered TIFF format to weather-enable the GIS applications for water and wastewater utilities. The DTN data include 5-min NEXRAD updates and storm cell type, severity, speed, and direction. Meteorlogix provides weather extensions for ESRI's ArcGIS software package. NEXRAIN Corporation (Orangevale, California) provides georeferenced polygon Shapefiles of radar pixels over a given study area. Each radar pixel is given a unique ID field, which can be used to visualize and analyze rainfall data from a separate text or database file. Shapefiles are projected into the user-specified coordinate system. NEXRAIN-2k product is extracted from a national mosaicked data set of 2-km radar data, updated every 15 min. Figure 10.2 shows a Shapefile of the NEXRAIN-2k radar pixels in Colorado State Plane Central (NAD83 ft) over Colorado Springs, Colorado, for a storm event on August 31, 2001. The top-left window shows rainfall distribution at 2 A.M.; the top-right window shows rainfall distribution at 5 P.M.; the bottom-left window shows rainfall distribution at 8 P.M.; the bottom-right window shows the attribute table; the top-center window shows the results of a pixel query; and the bottom-center insert shows a rainfall map overlaid on a street map.

WSI Corporation, a supplier of weather data in the U.S., provides the WSI PRECIP data over these pixels in 15-min time increments. These data can be obtained

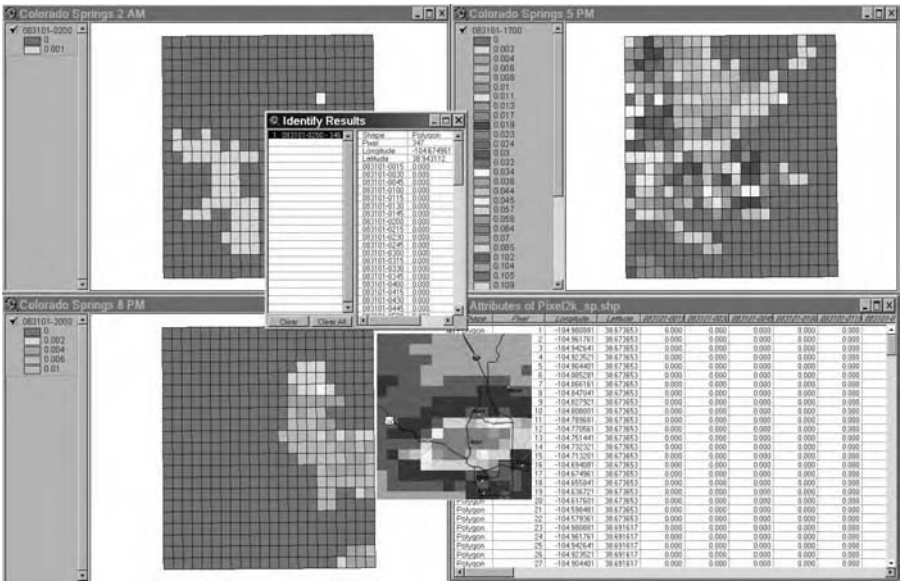

Figure 10.2 Shapefile of the NEXRAIN-2k radar pixels for Colorado Springs, CO, on August 31, 2001. Top left: rainfall at 2 A.M.; top right: rainfall at 5 P.M.; bottom left: rainfall at 8 P.M.; bottom right: attribute table; top center: pixel query window; bottom center: rainfall overlaid on street map.

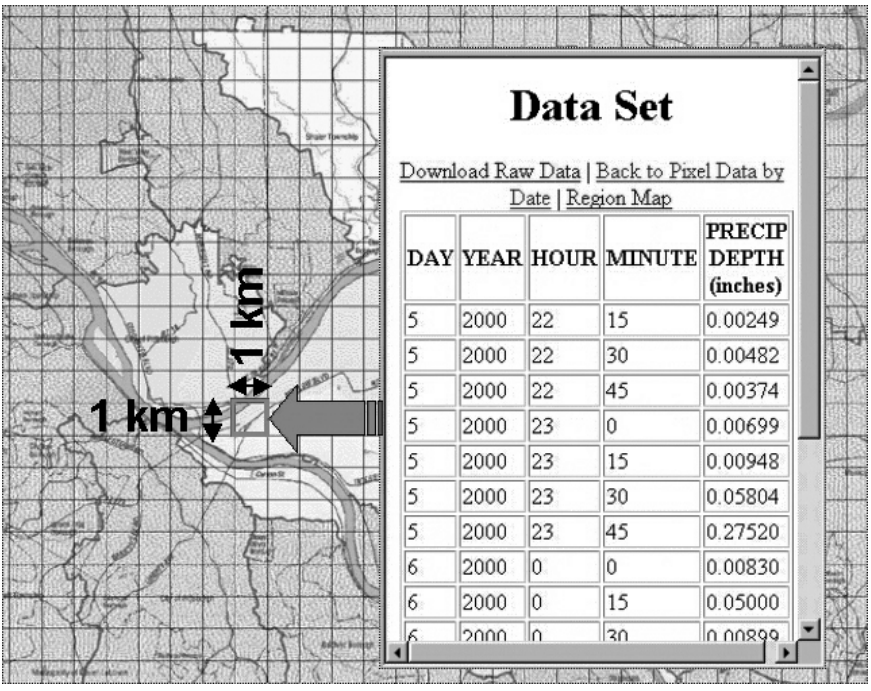
through commercial vendors and adjusted to reliable ground gauges, if necessary. Hence, the radar rainfall volume adjusted through calibration with ground gauge, combined with high-resolution spatial distribution, provides modelers with a very accurate local estimate of rainfall. These estimates can be used with their flowmetering to characterize the basin of interest (Hamid and Nelson, 2001).

Radar Rainfall Application: Virtual Rain-Gauge Case Study

Precipitation varies with time and across a watershed. GIS can easily create a rainfall contour map from point rainfall values. Unfortunately, point rainfall values are generally scarce due to inadequate rain-gauge density. Many watersheds have few or no rain gauges to accurately measure the spatial rainfall distribution. In this case, a hydrologist may have to use the precipitation data from a nearby watershed. Many watersheds do not have recording-type rain gauges to measure the hourly variation of precipitation. In this case, a hydrologist may need to apply the temporal distribution of a nearby watershed. The recent availability of radar precipitation data via the Internet eliminates these problems by providing subhourly precipitation data anywhere in the watershed.

Three Rivers Wet Weather Demonstration Program (3RWWDP) is a nonprofit organization located in Pittsburgh, Pennsylvania. It was created in 1998 to help Allegheny County (Pennsylvania) municipalities address the region's aging and deteriorating sewer infrastructure to meet the requirements of the federal Clean Water Act.



Data Set

Figure 10.3 Radar-based virtual rain-gauge map and retrieved rainfall data.

Funded by federal grants and local matching funds, 3RWWDP strives to assist communities through education, financial grants, and outreach efforts. In 1999, 3RWWDP developed an Internet-based precipitation atlas for Allegheny County. The atlas consisted of clickable maps that provided 15-min precipitation data every 1 km^2 from the CALAMAR system. CALAMAR is a software and NEXRAD radar service package that integrates high-resolution radar data with precipitation measurements collected from a network of 21 rain-gauges to produce accurate, dependable precipitation maps. Each 1 km $\times$ 1 km pixel of the rainfall atlas is equivalent to a virtual rain-gauge. The users can click on any of the 2276 pixels to retrieve the 15-min rainfall data in HTML or spreadsheet (Excel) format. This is equivalent to having 2276 virtual rain gauges in the County. This powerful tool revolutionizes collection system planning, modeling, and management by providing the critical missing link in urban hydrology — accurate local precipitation data. The rainfall atlas for a watershed near the city of Pittsburgh is shown in Figure 10.3. The figure also shows the clickable pixel cells and retrieved 15-min-interval rainfall data for November 2000 for one pixel.

Vieux & Associates (Norman, Oklahoma) provides basin-averaged radar hyetographs at user-defined time increments (5, 15, 30, 60 min, or daily). Spatial resolutions smaller than 1 km with data precision at 256 levels can be achieved. A real time archive provides access to the radar rainfall estimates. Data are provided in

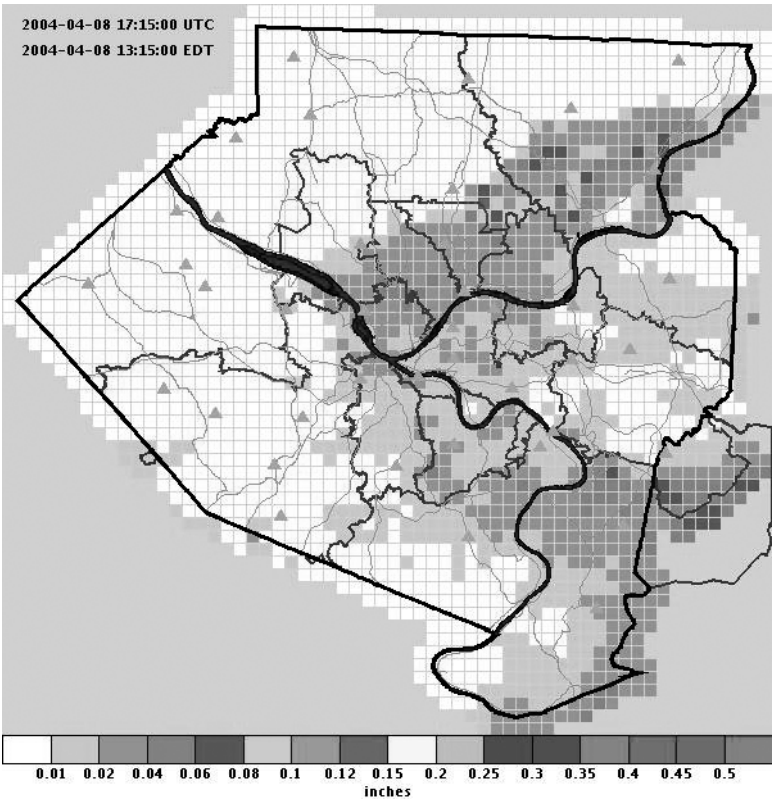

Figure 10.4 RainVieux radar rainfall data for Pittsburgh.

GIS-ready (Shapefile) and hydrologic-model-ready formats. Figure 10.4 shows a sample image from the RainVieux Web site tailored for 3RWDDP. It provides historic and real time radar rainfall measurements that can be queried from a Web site. Radar and rain-gauge measurements are used for cost-effective design of sewer rehabilitation projects in the Pittsburgh Metro area.

Mandated by an EPA consent decree, Miami-Dade Water and Sewer Department (MDWASD), which operates a 317-MGD wastewater treatment plant, implemented a hydraulic computer model to reduce sanitary sewer overflows (SSOs). In order to provide rainfall input to the computer model, MDWASD implemented a virtual rain-gauge system similar to 3RWWDP. A grid-system GIS coverage was created, which yielded 256 virtual rain gauges of 2 km $\times$ 2 km size each. The rainfall data are captured every 15 min and downloaded to a database. The grid is joined with the rainfall database, which allows quantification of impacts of individual rainfall events on specific regions within the system. This approach improves the accuracy of modeled flow estimates that are used to design appropriate SSO control measures (Day, 1998).

FLOW-MONITORING APPLICATIONS

GIS is ideally suited to selecting the best sites for installing flowmeters, water quality samplers, and rain gauges. The following case study illustrates a GIS application for selecting appropriate flow-monitoring sites.

The city of Huntington, WV, has a combined sewer system with 23 combined sewer overflow (CSO) discharge points permitted under the NPDES program. The sewer system is operated by the Huntington Sanitary Board (HSB). One of the CSO requirements specified in the NPDES permit was to monitor each CSO event for cause, frequency, duration, quantity, and quality of flow. As a first alternative to complying with this requirement, the feasibility of monitoring all the 23 CSO locations was studied in 1993. This option required purchase, installation, monitoring, and maintenance of flow monitors, water quality samplers, and rain gauges for each CSO site. This option was ruled out because of its excessive cost, estimated at over a million dollars, and other problems such as adverse environmental conditions in the CSO structures, difficult access issues, and new federal requirements for confined space entry. The second option consisted of a combination of monitoring and modeling. In this option, a representative subset of CSOs can be monitored temporarily to collect sufficient calibration data and develop a calibrated model for each monitored CSO area. Calibrated model parameters could subsequently be applied to the models of unmonitored CSO areas. CSO models can eventually be used to predict the quantity and quality of CSO discharges from observed rainfall data. This option, costing approximately one third of the first option, was preferred by both the HSB and the EPA (Region V), and was selected for implementation.

In 1994, ArcView was used to select a representative subset of the 23 CSO sites to be monitored. Selecting the representative sites is a complex process. The objective is to maximize the extent and value of the data for use in model calibration and provide a uniform distribution of flowmeters, samplers, and rain gauges throughout the system so that all parts of the service area are equally covered. Other factors such as providing coverage to all land uses, known problem CSO areas, and all types of diversion chambers, as well as access for installation and maintenance of monitoring equipment should be thoroughly studied. Using these selection criteria, a total of six sites were finally selected for sampling and monitoring. Figure 10.5 presents an ArcView plot showing the monitored vs. unmonitored CSOs and CSO areas. The map indicates that by monitoring only 25% of the total number of CSOs, approximately 70% of the study area was covered.

SCADA Integration

Real time monitoring systems called supervisory control and data acquisition systems (SCADA) monitor field operations or remote sites for water and wastewater utilities. Also referred to as telemetry, SCADA is a sophisticated means of monitoring, reporting, and controlling the operation of modern water and wastewater systems and treatment plants.

GIS stores the system design and operation data. A link between SCADA and the GIS database can be established to use the GIS for real time decision making. For

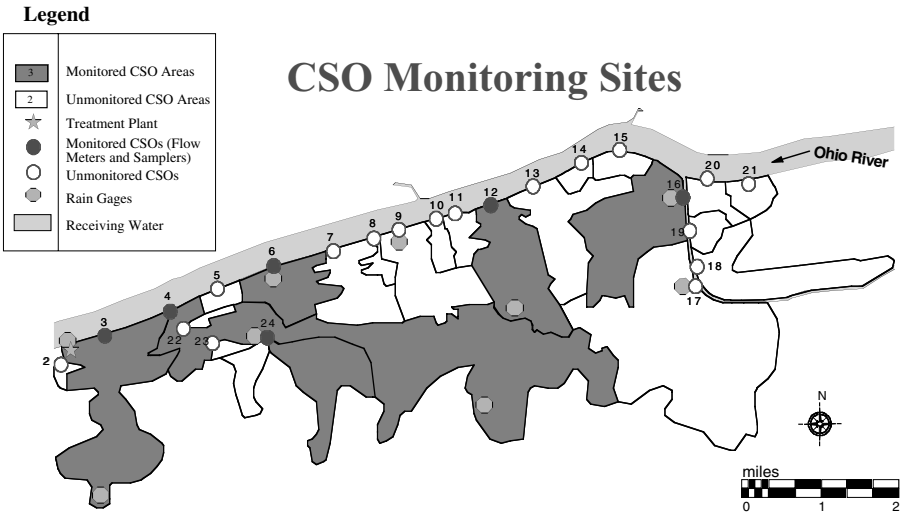

Figure 10.5 Flow-monitoring sites selected by using GIS.

example, real time or near-real time rainfall data can be used in a raster GIS to estimate the subbasin mean aerial rainfall. Real time subbasin rainfall data can be used to estimate real time surface runoff, for flood forecasting, or to estimate real time sewer flows to optimize storage and pumping operations for wet-weather overflow control.

Pidpa is a European company that produces and distributes drinking water to more than 1.1 million people throughout the Antwerp province in Belgium (Flanders). Pidpa used ESRI's ArcIMS technology to create a Web site named GeoLink as the central application to retrieve GIS data linked to corporate data. In the GIS viewer of GeoLink, water storage tanks have a hyperlink that opens the SCADA Web interface. The interface shows the real time water level or 24-hour history of the water level for the selected tank (Horemans and Reynaert, 2003).

SCADA Connect from Haestad Methods (acquired by Bentley Systems in August 2004) is a commercially available software product for dynamically connecting a wide range of SCADA systems with Haestad Methods' WaterCAD, WaterGEMS, and SewerCAD software programs. Using SCADA Connect, information can be automatically queried from the SCADA system and passed to the WaterGEMS database, eliminating manual processes. For example, tank levels and pump and valve settings can be updated in WaterGEMS based on the SCADA database, so that the next time WaterGEMS is run, it will reflect the current field conditions. SCADA Connect has been deployed for the City of Bethlehem, Pennsylvania's Bristol Babcock SCADA system and City of Casselberry, Florida's Citect SCADA system (Haestad Methods, 2004).

NPDES-PERMIT REPORTING APPLICATIONS

The well-known GIS magazine *Geospatial Solutions* holds an "Applications Contest" each year (Geospatial Solutions, 2001a). The entries are judged based on

interest, technology, and importance. The first place winner for the 2001 contest was a stormwater pollutant load modeling application for Los Angeles, California.

As a condition of its NPDES Municipal Stormwater permit, the Los Angeles County Department of Public Works is required to calculate and report pollutant load for more than 256 contaminants. The County maintains a network of stormwater monitoring devices to determine and report pollutant load for more than 256 contaminants. But, in addition to providing data about monitoring system locations and readings, the County also has to estimate the pollutant load to the Pacific Ocean from unmonitored drainage areas. The manual calculation of this information took engineers 250 working hours for an area one quarter of the required study area. The County, therefore, turned to GIS to create an automated model for calculating pollutant load. Relying on an existing public-works GIS, a collaborative team added several data layers to the system to integrate information about rainfall depth, drainage area, land use, imperviousness, and mean countywide concentrations for all the 256 pollutants based on monitoring-station data.

With that information, the team developed a modeling algorithm and refined its operations (the weighting and correlations of different variables) by running models for areas with known pollutant loads and comparing the results with monitoring-station readings. After several iterations, the calibrated model estimated pollutant loads with 95% accuracy. The team then developed an integrated menu-driven interface that walks the user through the process of creating and setting parameters and generating reports of pollutant load.

After specifying that he or she wants to perform a new load run, the user identifies a study area by interactively defining a polygon on the screen. The program then processes information in the background, extracting land-use information for the study area stored in a land-use/imperviousness table. Next, the user selects a rainfall year and event, which specifies the tabular database to use for the modeling, to identify the inches of rainfall at each monitoring station. The application then generates a rainfall grid using the tabular data for the specified rainfall year and event to calculate the pollutant load. The final parameter the user specifies is the pollutants. A dialog box enables interactive selection of the 256 pollutants (the program automatically selects a default set of 64 pollutants). Once all the parameters are defined, the user can calculate the pollutant load and generate maps and reports for print using built-in templates. The program also automatically saves the selected parameters and model results in a database table so that others can retrieve the load run without having to reset all the parameters.

The project team used ESRI's ArcView and Spatial Analyst for GIS analysis and an automated report generation process from Crystal Decisions' Crystal Reports.

MONITORING VIA INTERNET

Integration of GIS and Internet technologies is allowing users to click on a GIS map and see the real time data from any type of Web-connected sensor, from stream gauges to space and airborne Earth-imaging devices. Referred to as the Sensor Web, the sharing of sensor data via the Internet represents a revolution in the discovery

and use of live monitoring data. For example, data from the SAIC (a research and engineering company in San Diego, California) Weather Monitoring System is supplied from an Open GIS Consortium (OGC) Web Collection Service to a mapping client, overlaying geographic information coming from an OGC Web Map Service. The weather data are encoded in OGC Observation and Measurements Language, which is an extension of Geography Markup Language (GML) (Reichardt, 2004).

MONITORING THE INFRASTRUCTURE

From 1998 to 2000, the City of Toronto (Ontario, Canada) collected water pipe and soil samples to investigate the condition of its water distribution network. The City hoped that this effort would explain the causes of water main deterioration and guide the City in its water main rehabilitation efforts. The GIS data used in this project consisted of three layers: (1) Geocoded street center lines, (2) sample locations, and (3) surface soils. Eighty-four pipe and associated soil samples (resistivity, pH, and sulfide content) were collected, tested, and plotted on the street and soil maps using the GIS' address-matching capability. Using the GIS, a spatial analysis of the data collected was performed to identify any trends between the data samples and their locations. For example, water mains located in the clay-silt deposit near lakeshores were suspected to be at greater risk for corrosion, and there was no evident relationship between pH and soil formation (Doyle and Grabinsky, 2003).

Address geocoding is a GIS process that locates street addresses as points on a map, using a reference layer (usually a geocoded street layer). *Address matching* is the comparison of a street address to the address ranges in the reference layer. When an address matches the address range of a street segment, an interpolation is performed to locate and assign real-world coordinates to the address.

A Massachusetts water utility, puzzled by abnormally high lead and copper levels in its distribution system, found that interpretations of water quality problems based on aggregate monitoring data can be very misleading unless analysis is performed at the appropriate scale. Incorporation of system and monitoring-site physical characteristics data as well as the monitoring results into a GIS could have saved them considerable investigatory effort (Schock and Clement, 1995).

CHAPTER SUMMARY

This chapter presented the methods and examples of GIS applications in installing and maintaining various types of hydraulic characterization monitors (e.g., flowmeters and rain gauges) and querying and analyzing the monitoring data. The examples and case studies presented in this paper indicate that GIS is ideally suited for selecting the best sites for installing the monitors. Once the monitors have been installed, GIS allows user-friendly query of the monitoring data simply by clicking on a map of monitoring sites. GIS facilitates studying the spatial trends in the monitoring data. GIS is especially useful in processing and integrating radar rainfall data with H&H models of sewage collection systems and watersheds.

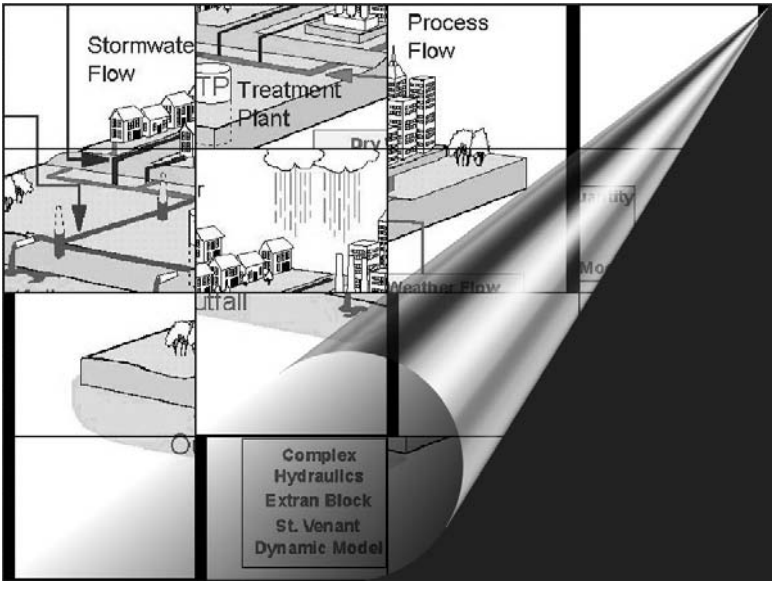
CHAPTER QUESTIONS

1. What are radar rainfall data? How are they used in H&H modeling? How does GIS help in processing them for H&H models?
2. How does GIS help in selecting the feasible flow-monitoring sites?
3. How does GIS allow a trend analysis of spatial patterns in monitoring data?

CHAPTER 11

Modeling Applications

GIS and H&H model integration allows the users to be more productive. Users can devote more time to solving the problems and less time on the mechanical tasks of inputting data and interpreting reams of model output. More than just text outputs, models become automated system-evaluation tools. GIS integration saves time and money.



GIS integration is ideally suited to solve the computer modeling puzzle.

LEARNING OBJECTIVES

The learning objectives of this chapter are to classify the methods of linking water, wastewater, and stormwater system computer models with GIS, and to understand the differences between various linkage methods.

MAJOR TOPICS

- GIS applications in H&H modeling
- Modeling application methods
  - Interchange method
  - Interface method
  - Integration method
- Examples and case studies of the preceding methods

This book focuses on the four main applications of GIS, which are mapping, monitoring, modeling, and maintenance and are referred to as the "4M applications." In this chapter we will learn about the applications of the third *M* (modeling).

TEMPORAL-SPATIAL MODELING IN WESTCHESTER COUNTY

GIS software	ArcInfo
Modeling software	Rational method and kinematic wave model

GIS data	Land use (from low-altitude infrared color photography), USGS DEM (1:24,000 scale), NRCS soils (1:12,000 and 1:24,000 scales), streams, and watersheds
Study area	0.14 mi^2 (0.36 km^2) Malcolm Brook watershed, Westchester County, New York
Organization	New York City Department of Environmental Protection

Lateral flow is an explicit component of the kinematic wave routing equation, yet some kinematic wave models such as HEC-HMS do not include lateral flow. The lateral flow component can be accounted for by using GIS. Until recently, it was considered impossible to conduct time-varying computations within a GIS. In this case study, lateral flows were derived from GIS output for each segment of the stream and at each time interval of the rain storm and were routed using the kinematic wave routing method. Rather than a raster GIS that uses a constant cell size, a vector GIS was used to define hydrologic response units that divide the stream channel into segments that vary in size according to the combined characteristics for land use, slope, and soil type. This approach permitted vector-based spatially distributed modeling of stream flow during storm events. GIS was used to map and visualize contributing areas around a stream channel. During each calculation of the discharge, a graphical image of the watershed and contributing areas was captured as a Graphics Interchange Format (GIF) image. A series of these images were displayed in sequence to produce a continuous animation (Gorokhovich et al., 2000).

H&H MODELING

No one said mathematical modeling would be easy, but the preparation of input data and interpretation of output results required by the ever-changing complexities of sophisticated hydrologic and hydraulic (H&H) models have been mind boggling. The good news is that model building and interpretation of results are now easier than ever before thanks to recent advances in computer hardware and software. The assembly of model input data by traditional, manual map measurements is just too time consuming and difficult to justify, now that personal computers are affordable and powerful. It is much easier to see a color-coded map of surcharged sewers to pinpoint the areas of flooding and surcharging than to digest reams of computer output, especially for nonmodelers. Nonmodelers are those people who are not expert modelers but who need to know the modeling results, such as clients of consulting firms, project managers, elected officials, and regulatory agencies. After all, as advocated in Chapter 1 (GIS Applications), GIS technology is an effective means of bridging the gap between information and its recipients.

Rapidly developing computer technology has continued to improve modeling methods for water, wastewater, and stormwater systems. GIS applications provide an accurate and manageable way of estimating model input parameters such as node demands, sewage flows, and runoff curve numbers. GIS-based modeling, as a side benefit, also provides an updated database that can be used for nonmodeling activities such as planning and facilities management.

There are two fundamental requirements in most H&H modeling projects: a suitable model and input data for the model. It is often difficult to select a modeling approach because of trade-offs between models and data. For instance, a detailed model requires a large amount of input data that is often too difficult to obtain or is too expensive. On the other hand, a simple model that requires little data may not provide a detailed insight into the problem at hand. Modelers must, therefore, use an optimal combination of model complexity (or simplicity) and available data. The recent growth in computational hydraulics has made it increasingly difficult for practitioners to choose the most effective computational tool from among a variety of very simple to very complex H&H models. Fortunately, thanks to the advances in GIS applications, creation of input data sets is easier than ever before.

This chapter serves as a guide to help professionals select the most appropriate GIS applications for their modeling needs. It presents an overview of the GIS and computer modeling integration approaches and software. The chapter also shows how to estimate the physical input parameters of H&H models using GIS. The chapter largely uses watershed hydrologic modeling examples to explain modeling integration concepts. However, the integration methods presented here are equally applicable to modeling of water and wastewater systems. Water system modeling applications and examples are presented in Chapter 12 (Water Models). Sewer system modeling applications and examples are presented separately in Chapter 13 (Sewer Models).

APPLICATION METHODS

There are two types of hydrologic models: lumped and distributed. Lumped-parameter models lump the input parameters of a study area over polygons and use vector GIS applications. Distributed models distribute the input parameters of a study area over grid cells and use raster GIS applications. Application of GIS technology to H&H modeling requires careful planning and extensive data manipulation work. In general, the following three major steps are required:

1. Development of spatial database
2. Extraction of model layers
3. Linkage to computer models

H&H models, databases, and GIS applications are critical in efficiently and effectively completing large modeling studies. The models and GIS can be linked to other databases for data sharing purposes. For example, data can be imported from other sources like AutoCAD, edited and modified within the application, and exported or linked to other databases. Database files can be saved in .dbf format and linked or imported into Microsoft Access for further data manipulation. For example, ArcView GIS provides Open Database Connectivity (ODBC) features that can be used to link ArcView tables with other tables and queries in Microsoft Access or other database programs, without actually going through any import and export exercises. Such procedures eliminate the data redundancies and user errors typically associated

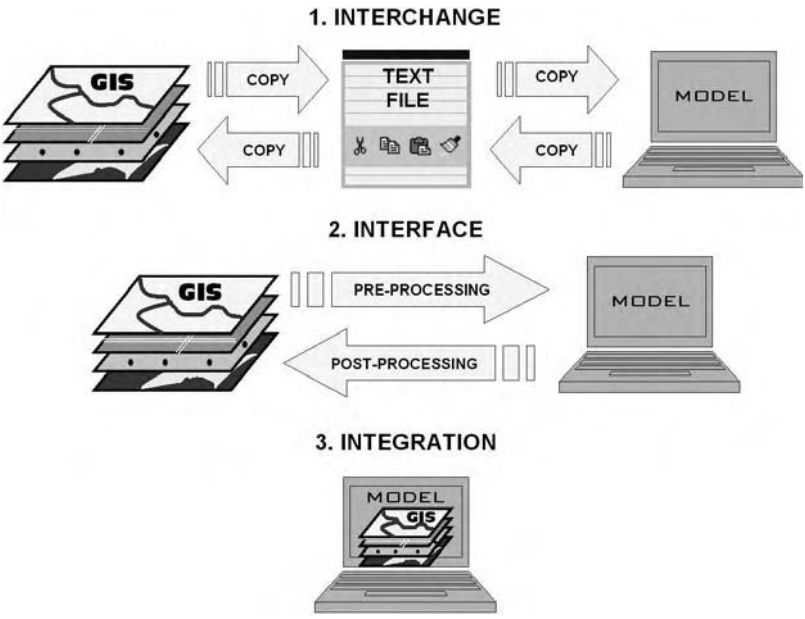

Figure 11.1 Three methods of GIS applications in H&H modeling.

with such cumbersome tasks. This has proven to be beneficial and time-saving during alternative analysis of systems where a large number of scenarios are modeled and reviewed using the same data connectivity and templates for maps (Hamid and Nelson, 2001).

A useful taxonomy to define the different ways a GIS can be linked to computer models was developed by Shamsi (1998, 1999). The three methods of GIS linkage defined by Shamsi are:

1. Interchange method
2. Interface method
3. Integration method

Figure 11.1 shows the differences between the three methods. Each method is discussed in the following text with the help of examples and case studies. As described in Chapter 1 (GIS Applications), advanced applications such as the capability to automatically create a model input file always require writing a computer program using a scripting language like Visual Basic for Applications (VBA).

INTERCHANGE METHOD

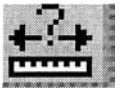
Preprocessing is defined as the transfer of data from the GIS to the model. Postprocessing is defined as the transfer of data from the model to the GIS. The interchange method employs a batch-process approach to interchange (transfer) data

between a GIS and a computer model. In this method, there is no direct link between the GIS and the model. Both are run separately and independently. The GIS database is preprocessed to extract model input parameters, which are manually copied into a model input file. Similarly, model output data are manually copied in a GIS as a new spatial layer for presentation-mapping purposes. Script programming is not necessary for this method, but it may be done to automate some manual operations such as derivation of runoff curve numbers (described in the following text). This is the easiest method of using GIS in computer models and is the most commonly utilized method at the present time.

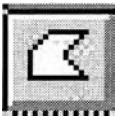
In this method GIS is essentially used to generate model input files and display model output data. Any GIS software can be used in the interchange method. A GIS with both vector and raster capabilities provides more interchange options. Representative examples of the interchange method are described in the following subsections.

Subbasin Parameter Estimation

Most H&H models need input data for subbasin parameters such as area, overland flow width, and slope. If subbasins are represented as polygons, GIS can automatically calculate the area as a layer attribute. Overland flow width can be measured interactively in any direction (e.g., along a stream or a sewer) by using the measurement tools available in most GIS packages. For example, ArcView 3.x provides a Measure Tool



that can be used for on-screen measurement of distance. It also provides a Drawing Tool



that can be used for on-screen measurement of polygon area. Subbasin slope can be estimated from digital elevation models (DEMs) as described in Chapter 4 (DEM Applications).

GIS estimation of subbasin runoff curve number, a critical input parameter in many rainfall-runoff models, is perhaps the best example of the interchange method.

Runoff Curve Number Estimation

Runoff curve numbers are a set of standard empirical curves that are used to estimate stormwater runoff. Accurate estimation of curve number values is critical to accurate runoff modeling because the quantity of runoff is very sensitive to runoff curve number values. GIS estimation of subbasin runoff curve number, a critical input parameter in many rainfall-runoff models, is perhaps the best example of the interchange method. The estimation approach is based on the land use, hydrologic soil group (HSG), and runoff curve number relationships developed by U.S. Natural Resources Conservation Service (NRCS), formerly known as the Soil Conservation Service (SCS). These relationships are available in the form of runoff curve number tables (U.S. Department of Agriculture, 1986). These tables provide runoff curve numbers for a large number of land uses and four hydrologic soil groups: A, B, C, and D. They also list average percent imperviousness values for various land-use classes. Table 11.1 shows selected data from the NRCS tables for percent imperviousness and runoff curve number for typical land-use classes. If existing land-use classifications are not consistent with SCS taxonomy, they may be replaced with an equivalent SCS land-use class shown in Table 11.2.

Table 11.1 SCS Runoff Curve Numbers

Land-Use Class	Average Percent Imperviousness	Runoff Curve Number for Hydrologic Soil Group			
		A	B	C	D
Fully Developed Urban Areas (Vegetation Established)					
Open space (lawns, parks, golf courses, etc.)	—	49	69	79	84
Paved parking lots, roofs, driveways, etc.	—	98	98	98	98
Paved streets and roads	—	98	98	98	98
Dirt roads	—	72	82	87	89
Commercial and business	85	89	92	94	95
Industrial	72	81	88	91	93
Residential: lots 1/8 acres or less (town houses)	65	77	85	90	92
Residential: lots 1/4 acres	38	61	75	83	87
Residential: lots 1/2 acres	25	54	70	80	85
Residential: lots 1 acres	20	51	68	79	84
Residential: lots 2 acres	12	46	65	77	82
Developing Urban Areas					
Newly graded areas		77	86	91	94
Idle lands		77	86	91	94
Nonurban Areas					
Row crops (straight row, poor condition)	—	72	81	88	91
Row crops (straight row, good condition)	—	67	78	85	89
Meadow (continuous grass, no grazing)	—	30	58	71	78
Brush (fair condition)	—	35	56	70	77
Woods (fair condition)	—	36	60	73	79
Farmsteads (buildings, driveways, and lots)	—	59	74	82	86

Table 11.2 Equivalent SCS Land-Use Classes

Land-Use Class	SCS Equivalent Land-Use Class	Average Percent Imperviousness	Runoff Curve Number for Hydrologic Soil Group			
			A	B	C	D
Parks, cemeteries, ball fields, etc.	Open space	0	39	61	74	80
High-density residential	Average lot 506–1012 m^2 (0.125–0.25 acres)	51	69	80	87	90
Medium-density residential	Average lot 1349–2024 m^2 (1/3–1/2 acres)	28	56	71	81	86
Low-density residential	Average lot 4047–8094 m^2 (1–2 acres)	16	49	66	78	83
Schools	Average lot 1349–2024 m^2 (1/3–1/2 acres)	28	56	71	81	86
Agricultural	Row crops average	0	64	75	83	87
Disturbed	Newly graded areas	35	77	86	91	94

A vector layer for subbasin runoff curve numbers is created by overlaying the layers for subbasins, soils, and land use to delineate the runoff curve number polygons. Each resulting polygon should have at least three attributes: subbasin ID, land use, and HSG. The NRCS landuse-HSG-curve number matrix (Table 11.1 or Table 11.2) can now be used to assign runoff curve numbers to each polygon according to its land use and HSG. Polygon runoff curve number values are then area-weighted to compute the mean runoff curve number for each subbasin. These subbasin-runoff curve numbers can now be entered into the model input file. The runoff curve number estimation technique is shown in Figure 11.2 to Figure 11.5. Figure 11.2 shows the layers for subbasins and land use. Figure 11.3 shows the layers for subbasins and HSGs. Figure 11.4 shows the computed runoff curve number polygons. Figure 11.5 shows the average runoff curve numbers for the subbasins.

Some H&H models also need an input for the subbasin percent imperviousness, which can be estimated in GIS using the NRCS runoff curve number tables. A layer for the subbasin percent imperviousness can be created by overlaying the layers for subbasins and land use to delineate the percent imperviousness polygons. The land-use percent imperviousness matrix can then be used to assign percent impervious values to the polygons. Finally, polygon percent imperviousness values are area-weighted to compute the mean percent imperviousness value for each subbasin.

Water Quality Modeling Data Estimation

Some urban-runoff quality models such as the TRANSPORT Block of SWMM need curb length as a model input parameter, which can be estimated from a GIS layer of road or street centerlines. Subbasin curb length can be estimated by performing

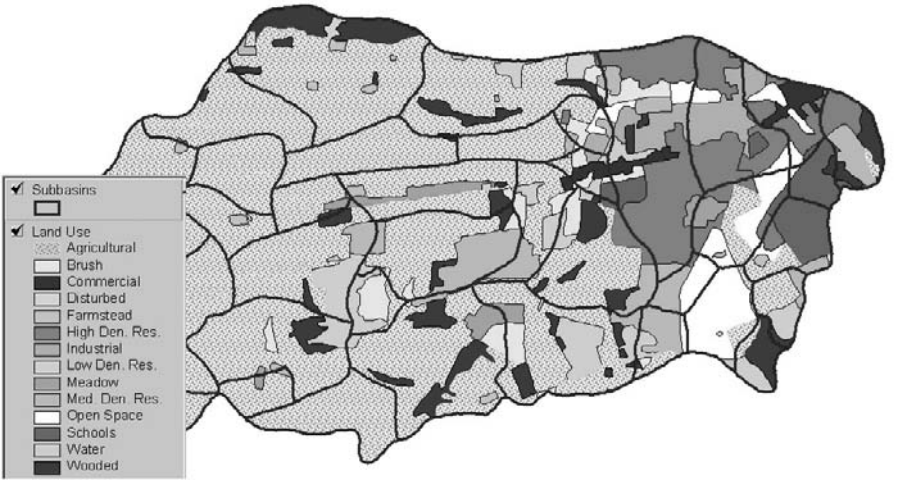


Figure 11.2 Layers for subbasins and land use for runoff curve number estimation.

an overlay analysis of street and subbasin layers. For example, in ArcView 3.x, curb length can be estimated by performing a *theme-on-theme* selection using roads as the target theme and subbasins as the selector theme. Alternatively, for large areas such tasks can be handled more efficiently in ArcView's Network Analyst extension, which has been designed for transportation network applications. Network Analyst is an optional extension that must be purchased separately.

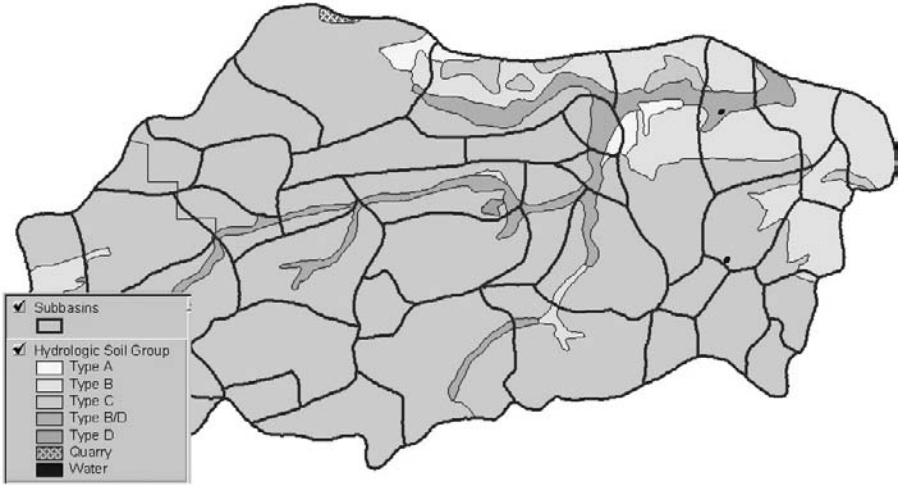

Figure 11.3 Layers for subbasins and HSGs for runoff curve number estimation.

Figure 11.4 Computed runoff curve number polygons.

Demographic Data Estimation

Demographic data can be used for the following modeling tasks:

1. Estimation of quantity and quality sanitary sewage flow
2. Estimation of present and potential future development
3. Creation of auxiliary layers for visualization and presentation purposes

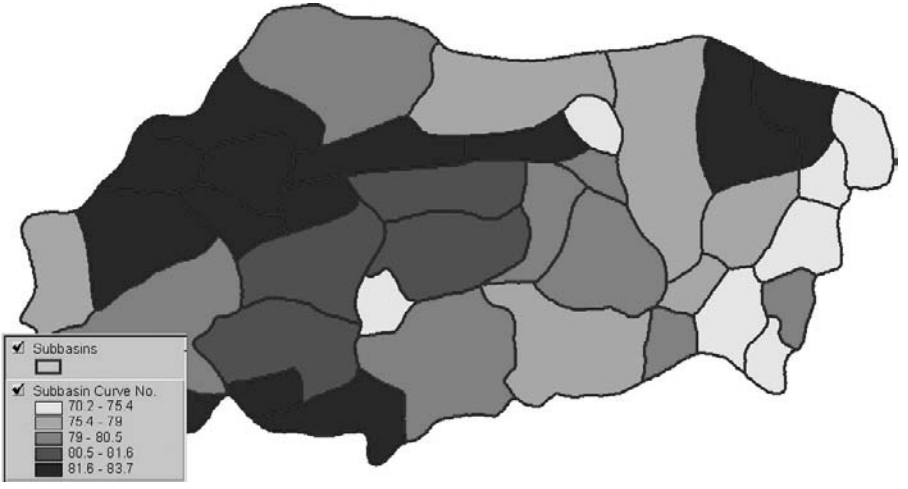

Figure 11.5 Subbasin runoff curve number map.

The first task is required when modeling both combined and sanitary sewer areas in urban sewersheds. For example, SWMM's TRANSPORT Block (Version 4.x) needs inputs for some or all of the following demographic parameters:

1. Dwelling units
2. Persons per dwelling unit
3. Market value of average dwelling unit
4. Average family income

A GIS can compute such demographic parameters from the U.S. Census Bureau's TIGER data (Shamsi, 2002). To estimate subbasin demographic parameters, census-block attribute data files from TIGER files are linked to the polygon topology of the census blocks. Only those attributes pertinent to the model are retained within the working layers. The population (or other demographic parameters) within each subbasin is estimated by determining the census blocks or their portions making up each subbasin. Block data are area-weighted to estimate the mean or total subbasin values of demographic parameters. For example, this can be done in ArcView 3.x from *polygon-on-polygon* selection using census blocks as the target theme and subbasins as the selector theme. Figure 11.6 shows an ArcView map of subbasins, census blocks, and census block groups for a SWMM-based sewer system model.

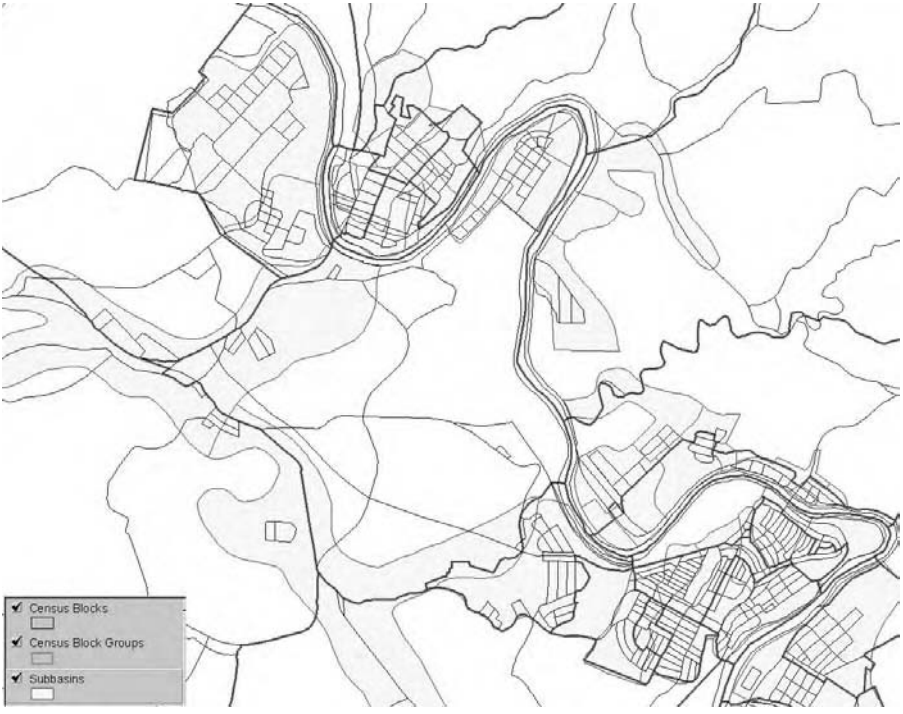

Figure 11.6 Sample census block and block group layers for estimating subbasin population.

Land-Use Data Estimation

Dry- and wet-weather flows from sewersheds depend on land use. Most rainfall-runoff models, therefore, need land-use information. In some models such as SWMM's TRANSPORT Block, land-use type is input directly. In others, such as Penn State Runoff Model (PSRM) and SWMM's RUNOFF Block, land-use type is needed to derive certain model parameters such as percent imperviousness. TRANSPORT needs input data for the the land-use designation of modeled subbasins. The subbasins should be classified as having one of the five land-use classes:

1. Single-family residential
2. Multifamily residential
3. Commercial
4. Industrial
5. Open space

Most land-use maps and layers have more than these five land-use classes. However, this is not a problem in GIS because the existing classes can be easily consolidated into the five land-use classes mentioned above. Figure 11.7 shows an ArcView 3.x screenshot for subbasin and land-use layers for a SWMM-based sewer system model. The land-use layer was prepared from classification of 30-m-resolution Landsat Thematic Mapper (TM) satellite imagery of the study area. Initially, the layer contained 19 land-use classes. Subsequently, the initial land-use classes were reclassified into the five land-use types required for TRANSPORT input. In order to refine the land-use classification, the layer was combined with the census-block layer

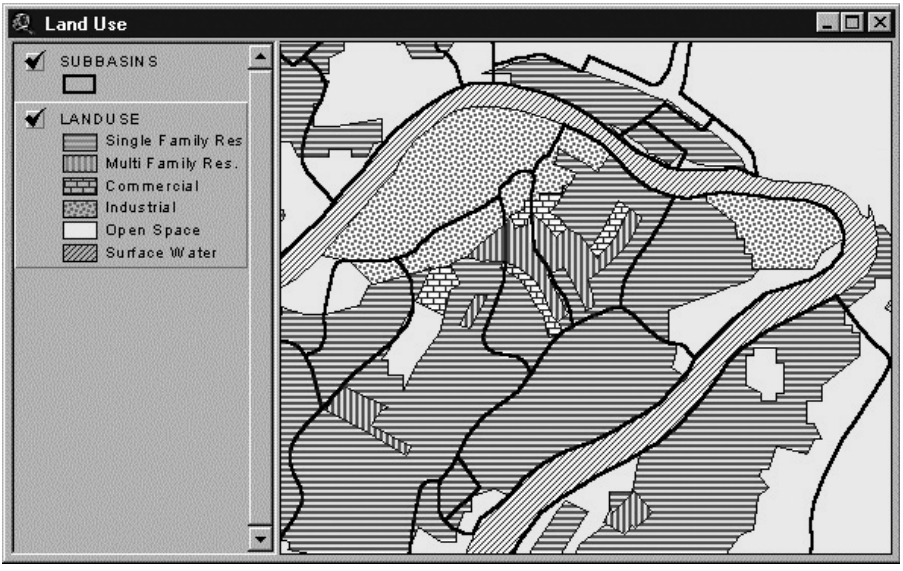

Figure 11.7 Estimating land use using interchange method.

to determine where population densities indicated residential districts. This was done in two ways. First, all nonresidential classed areas were examined to determine if population densities in the local census blocks were below or above a threshold of ten persons per acre. This threshold was chosen as a conservative breakpoint that would allow a reasonable portion of the classification to be correctly reclassified. The areas corresponding to any blocks with densities above the threshold were changed to the residential class. Second, the census blocks of all residential areas were examined to determine in which blocks single-family or multi-family residential units were the majority. On this basis polygons of the residential class were divided into single-family residential or multi-family residential classes.

INTERFACE METHOD

The interface method provides a direct link to transfer information between the GIS and a model. The interface method consists of at least the following two components: (1) a preprocessor that analyzes and exports the GIS data to create model input files and (2) a postprocessor that imports the model output and displays it as a GIS theme. Processing of the model input and output files requires computer programming using the GIS software's scripting language (such as Avenue or VBA). User routines and scripts are incorporated in the GIS by calling them through new pull-down menus and icons.

The interface method basically automates the data interchange method. The automation is accomplished by adding model-specific menus or buttons to the GIS software. The model is executed independently of the GIS; however, the input file is created in the GIS. The main difference between the interchange and interface methods is the automatic creation of the model input file. In the data interchange method, the user finds a portion of a file and copies it. In the interface method, an interface automates this process, so that the pre- and postprocessor can find the appropriate portion of the file automatically.

Learning with examples is an effective method, so let us begin with an interface example. Let us assume that we want to create an input file for a hydrologic model by exporting GIS data to an ASCII text file. Our watershed GIS has the following data:

- Subbasins with attributes: ID, area, overland flow width, slope, and percent imperviousness.
- Reaches (streams) with attributes: ID, upstream subbasin, downstream subbasin, type (natural stream, concrete channel, or concrete pipe), condition (best, good, fair, or bad), depth, width, length, upstream elevation, and downstream elevation.

Our hydrologic model requires a text file with the following input parameters:

- Subbasin data: ID, area, overland flow width, slope, and percent imperviousness.
- Conduit data: ID, upstream subbasin, downstream subbasin, type, depth, width, length, slope, and roughness coefficient.

Table 11.3 Look-up Table for Reach Roughness Coefficient

	Reach Condition			
Reach Type	**Best**	**Good**	**Fair**	**Bad**
Natural stream	0.025	0.028	0.030	0.033
Concrete channel	0.012	0.014	0.016	0.018
Concrete pipe	0.012	0.013	0.015	0.016

Note that our GIS does not have reach attributes for slope and roughnesss coefficient, but they can be estimated in the GIS from the given attributes. For example, slope can be estimated from the upstream and downstream elevations and length using the following formula:

$$slope = \frac{upstream\ elevation - downstream\ elevation}{length}$$

The roughness coefficient can be estimated using a lookup table like Table 11.3. For example, if the reach type is natural and condition is good, then GIS can estimate the roughness coefficient as 0.028. Now that all the required subbasin and conduit parameters are available in the GIS database, the required fields of subbasin and reach theme tables can be saved as text files.

Let us further assume that we want to create model output maps in a GIS by importing model output files into it. This task can be easily accomplished by linking the model output file to a GIS layer using a common attribute (subbasin and reach IDs). For example, a thematic map of stream flow can be created by linking the modeled stream flow to the streams layer. First of all, a database table of the relevant results (stream flow) should be created from the ASCII output file. The output database file can then be joined to the streams attribute table. The linked output results can now be queried or classified with a legend to make a thematic map.

Typical modeling steps involved in using the interface method are listed below:

1. Start your GIS.
2. Export model input data from GIS to a text or database file (preprocessing).
3. Exit the GIS.
4. Start your model.
5. Import GIS data (saved in Step 2) in the model.
6. Run the model.
7. Exit the model.
8. Reenter the GIS and import the model output (postprocessing).

It can be seen from these steps that the interface method does not run the model inside the GIS. The model must be run outside the GIS by the user. Some interface examples are given in the following text. Additional examples are presented in Chapter 12 and Chapter 13.

HEC-GEO Interface

The Hydrologic Engineering Center (HEC) is an office of the U.S. Army Corps of Engineers (COE) established to support the nation's hydrologic engineering and water resources planning and management needs. To accomplish this goal, HEC develops state-of-the-art, comprehensive computer programs that are also available to the public. HEC-1 and HEC-2 are COE's legacy DOS programs for hydrologic and hydraulic modeling, respectively. Recently HEC-1 and HEC-2 have been replaced with Windows programs called the Hydrologic Modeling System (HEC-HMS) and River Analysis System (HEC-RAS), respectively. HEC Geo-HMS and HEC Geo-RAS have been developed as geospatial hydrology toolkits for HEC-HMS and HEC-RAS users, respectively. They allow users to expediently create hydrologic input data for HEC-HMS and HEC-RAS models. Free downloads of these programs are available from the HEC software Web site.

HEC-GeoHMS

HEC-GeoHMS is an ArcView 3.x GIS extension specifically designed to process geospatial data for use with HEC-HMS. It allows users to visualize spatial information, delineate watersheds and streams, extract physical watershed and stream characteristics, perform spatial analyses, and create HEC-HMS model input files. HEC-GeoHMS uses ArcView's Spatial Analyst Extension to develop a number of hydrologic modeling inputs. Analyzing digital terrain information, HEC-GeoHMS transforms drainage paths and watershed boundaries into a hydrologic data structure that represents watershed's response to precipitation. In addition to the hydrologic data structure, capabilities include the development of grid-based data for linear quasi-distributed runoff transformation (ModClark), the HEC-HMS basin model, and the background map file.

HEC-GeoHMS provides an integrated work environment with data management and customized toolkit capabilities, which includes a graphical user interface (GUI) with menus, tools, and buttons. The program features terrain-preprocessing capabilities in both interactive and batch modes. Additional interactive capabilities allow users to construct a hydrologic schematic of the watershed at stream gauges, hydraulic structures, and other control points. The hydrologic results from HEC-GeoHMS are then imported by HEC-HMS, where simulation is performed. HEC-GeoHMS works with Windows 95/98/NT/2000 operating systems.

HEC-GeoRAS

HEC-GeoRAS (formerly named AV/RAS) for ArcView is an ArcView 3.x GIS extension specifically designed to process geospatial data for use with HEC-RAS. The extension allows users to create an HEC-RAS import file containing geometric attribute data from an existing digital terrain model (DTM) and complementary data sets. HEC-GeoRAS automates the extraction of spatial parameters for HEC-RAS input, primarily the 3D stream network and the 3D cross-section definition. Results exported from HEC-RAS may also be processed in HEC-GeoRAS. ArcView 3D

Analyst extension is required to use HEC-GeoRAS. Spatial Analyst is recommended. An ArcInfo 7.x version of HEC-GeoRAS is also available.

Haestad Methods' HEC-GIS system combines COE's HEC-RAS floodplain modeling program with ArcInfo. HEC-GIS is an Arc Macro Language (AML) program that allows importing floodplain cross-section data from a DEM within ArcInfo, in the form of triangular irregular networks (TINs). It also allows importing HEC-RAS water surface profiles back into HEC-GIS to perform additional spatial analyses and mapping.

Watershed Modeling System

Watershed Modeling System (WMS) is a comprehensive hydrologic modeling package developed by the Environmental Modeling Research Laboratory (EMRL) of Brigham Young University in cooperation with the U.S. Army COE Waterways Experiment Station (WES) (WMS, 2000; Nelson et al., 1993). The focus of WMS is to provide a single application that integrates digital terrain models with industry-standard lumped-parameter hydrologic models such as HEC-1 and TR-20. In this way, hydrologic data developed in ArcInfo, ArcView, or WMS can be directly linked to many common hydrologic models. WMS includes an interface to HEC-1, TR-20, and the Rational Method programs used by many hydrologic engineers to model the rainfall-runoff process.

WMS can import and export GIS data. WMS' GIS interface is accomplished through its map module. Map module data is structured after ArcInfo 7.x, which makes it easy to import and use vector data created inside ArcInfo or any other GIS that can export an ArcInfo GENERATE file. WMS includes an ArcView 3.x extension that facilitates the movement of data from GIS to WMS for hydrologic model development. The interface allows for automatic development of a topological model from TINs. Furthermore, any geometric parameters computed by WMS are supplied to the corresponding model input fields. The extension preprocesses the GIS data to export hydrologic modeling data. WMS then reads a single file (describing the relevant themes exported) to obtain data from the GIS. These data can then be used in WMS to create an initial model for any of the hydrologic programs supported by WMS. WMS itself is integrated with the hydrologic models. Data entry for the hydrologic model — including rainfall, job control, or any other parameters not defined as attributes in GIS Shapefiles — can be completed using WMS' hydrologic modeling interface. WMS can be used to postprocess and then import model results in the GIS software. A screenshot of the WMS interface is shown in Figure 11.8. Unlike some HEC programs such as HEC-HMS and HEC-RAS, WMS is not free. A demo version can be downloaded from the BYU Web site.

GISHydro Modules

GISHydro is a collection of programs, demos, exercises, data, reports, and information designed to support the use of GIS in hydrology and water resources studies. These materials are mostly drawn from the work of Professor David R. Maidment and a community of his graduate students, research scientists, and faculty

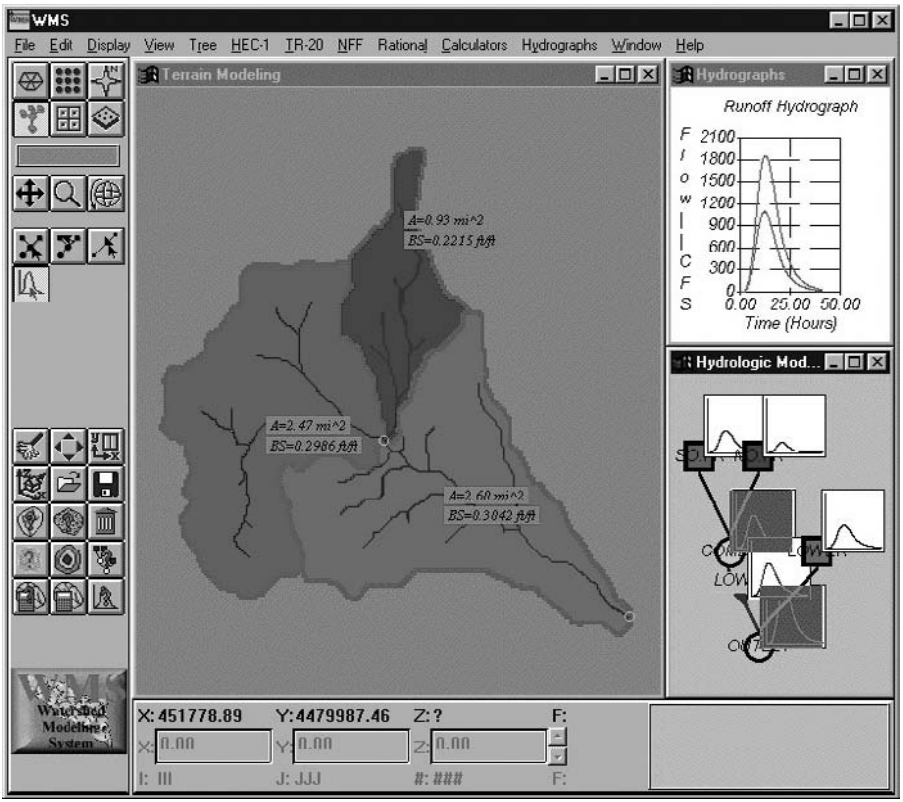

Figure 11.8 WMS interface.

in the Center for Research in Water Resources (CRWR) and the Department of Civil Engineering of the University of Texas at Austin. Initially, CRWR developed a prototype Spatial Hydrology Analysis System (Maidment, 1997) consisting of eight GISHydro modules. These modules, more than just computer programs, are a methodological approach to solving specific types of hydrologic problems using GIS. They contain ArcView and ArcInfo extensions, Avenue and AML scripts, sample data, user instructions, and example exercises. Two GISHydro modules are described in the following subsections:

GISHydro Prepro

This module is a procedure for connecting GIS to external models. Consisting of Avenue and AML scripts, it is designed to transform a subbasins-and-streams network into a schematic model of the hydrologic elements of a watershed. It was initially developed as a preprocessor for COE's new Hydrologic Modeling System (HEC-HMS), which replaced the old HEC-1 model. GH-Prepro takes stream and subbasin GIS data layers and analyzes them to produce a schematic model that

defines and spatially connects seven types of hydrologic elements in the landscape: subbasins, reaches, junctions, diversions, reservoirs, sources, and sinks.

GISHydro Runoff

This module provides articles, reports, exercises, and a sample ArcView 3.x extension to compute watershed parameters and runoff at the outlet of a watershed. The ArcView extension uses the Texas Department of Transportation (TxDOT) statewide regional rural regression equations for estimating stormwater runoff. Figure 11.9 shows a screenshot of the TxDOT extension (Olivera and Bao, 1997).

ArcInfo Interface with HEC Programs

Another example of the interface method is the ArcInfo and HEC-1 and HEC-2 interface developed by Woolpert, Inc. (Phipps, 1995). In HEC-1, the interface model uses vector layers for streams and open channels and the ArcInfo networking function to show the locations of and the relationships between different types of flows: sheet flow, shallow channel flow, and concentrated channel flow. The ArcInfo and HEC-1

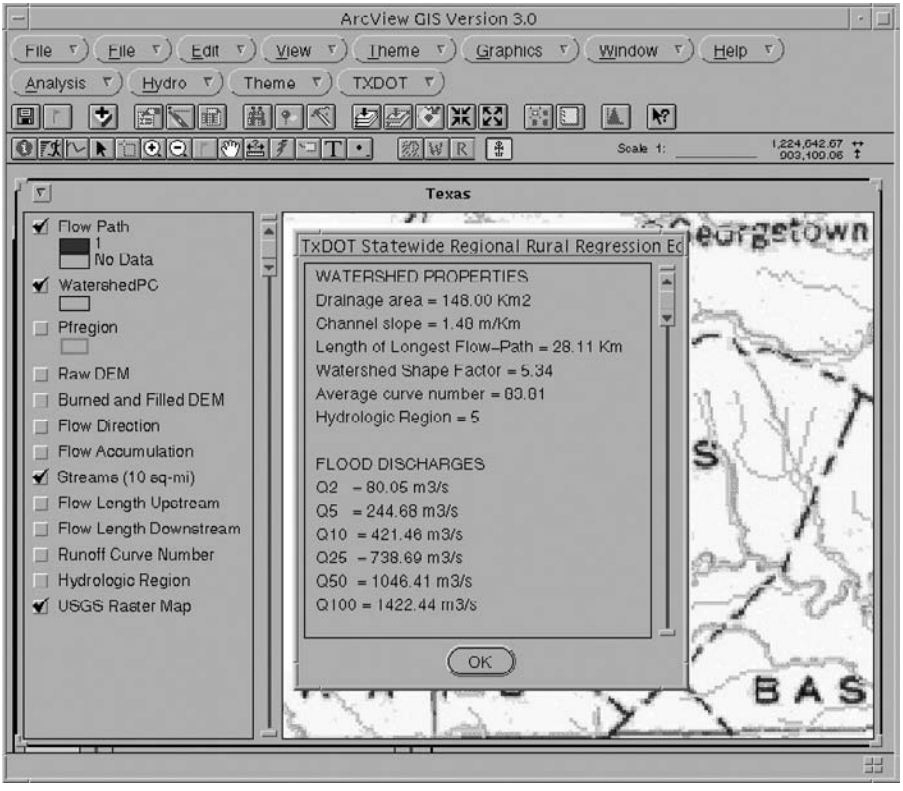

Figure 11.9 GISHydro TxDOT extension.

linkage allows users to see graphically, on a map, how fast the three flow types are moving at different locations within the model (volume/time). The unit hydrographs generated in the HEC-1 hydrologic model are then used to feed the HEC-2 hydraulic model. The ArcInfo and HEC-2 interface allows graphical display of the 2-, 10-, 25-, 50-, 100-, and 500-year frequency flood profiles for the streams and open channels within the watershed. It was found that this interface allowed for easier model development and calibration, which resulted in substantial savings in the cost of modeling tasks.

Intermediate Data Management Programs

Some commercial modeling products use an intermediate data management program to facilitate data transfer between the GIS and a model. This program is written specifically to import data from a variety of common third-party GIS software and export data to a model data set. Under certain conditions this approach could be defined as an interface, but generally it is not. In relation to the Shamsi taxonomy, this method lies between the interchange and interface methods (Heaney et al., 1999). Haestad Methods' GIS connection wizards for the company's WaterCAD, SewerCAD, and StormCAD programs (described elsewhere in this book) are typical examples of this method. Figure 11.10 shows WaterCAD's Import Shapefile wizard,

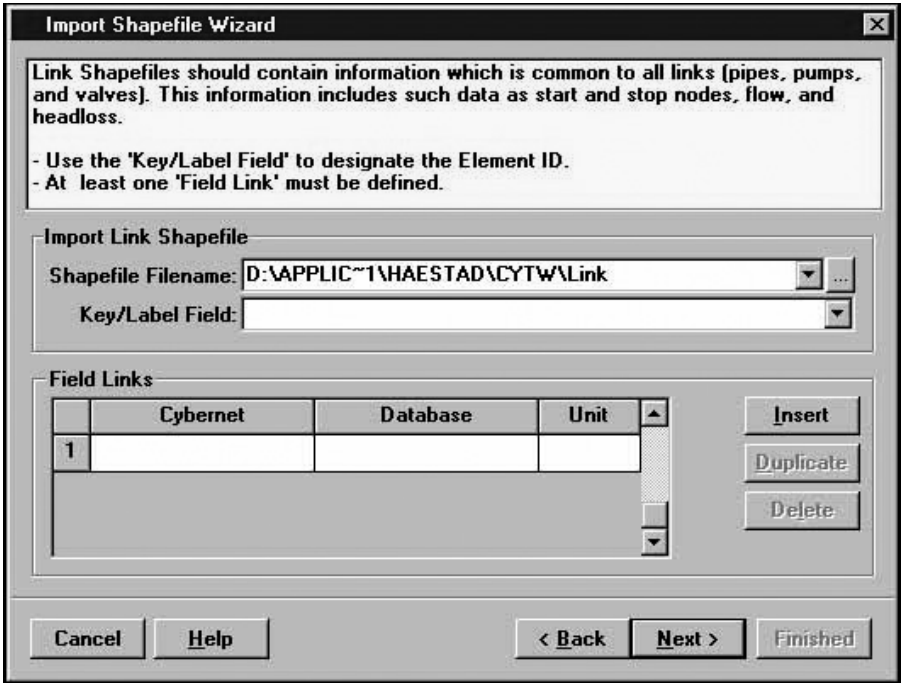

Figure 11.10 WaterCAD's Import Shapefile wizard.

which is used to import WaterCAD model input parameters from ArcView GIS Shapefiles.

Interface Method Case Study

GIS software	ArcInfo
Modeling software	Rhea, an orographic precipitation model developed at the Colorado State University (Rhea, 1977). The Rhea model simulates the interaction of air layers with underlying topography by allowing vertical displacement of the air column while keeping track of the resulting condensate or evaporation.
Other software	Data Explorer (DX), a Scientific Visualization System (SVS) software from IBM
GIS data	DEM grid, city locations, rivers, and rain-gauge locations
GIS format	Raster and vector
Study area	20,530 km^2 Gunnison River Basin in southwestern Colorado
Organization	U.S. Geological Survey

Very often, the software required to solve complex hydrologic problems is available only in separate pieces rather than as an integrated package. Simulation models and GIS and SVS packages are individually strong in specific aspects of spatial analysis but inadequate in cross-functional analysis of complex hydrologic problems. An integrated system consisting of a hydroclimatic simulation model (Rhea), a GIS (ArcInfo), and an SVS (DX) was developed to facilitate model development, calibration, and verification and visual representations of precipitation across space and time. AML tools translated ArcInfo data into a format that could be read by DX. The converted DX file was used to generate animated, interactive displays using DX software. The integrated system provided improved understanding of hydroclimatic processes in mountainous regions. An additional benefit of the integrated system, the value of which is often underestimated, is the improved ability to communicate model results (Hay and Knapp, 1996).

INTEGRATION METHOD

In the interface method, options for data editing and launching the model from within the GIS software are not available. An interface simply adds new menus or buttons to a GIS to automate the transfer of data between a computer model and a GIS. GIS integration, on the other hand, is a combination of a model and a GIS such that the combined program offers both GIS and modeling functions. This method represents the closest relationship between a GIS and a model. Two integration approaches are possible:

1. GIS-based integration: In this approach, modeling modules are developed in or are called from within a GIS. All the four tasks of creating model input, editing

data, running the model, and displaying output results are available in the GIS. There is no need to exit the GIS to edit the data file or run the model. Because development and customization tools within most GISs provide relatively simple programming capability, this approach provides limited modeling power. It offers full GIS functionality and simplistic modeling capability. It is often more popular because of the availability of computer code for a large number of public-domain legacy computer models, such as SWMM and EPANET, which can be easily customized for GIS integration.

2. Model-based integration: In this method, GIS modules are developed in or are called from a computer model. It provides GIS-like functionality to computer models. Because it is difficult to program all the GIS functions into a computer model, this approach provides limited GIS capability. In this method, GIS is essentially used as a mapping tool. Sophisticated data management and data visualization capabilities are not present. PCSWMM GIS [described in Chapter 13 (Sewer Models)] and Runoff97 (Ritter and Gallie, 1998) are examples of the model-based integration method. In this method, GIS and models are integrated through a common interface that requires extensive computer programming using conventional computer languages (e.g., FORTRAN), and/or GIS macro and scripting languages (e.g., AML, Avenue or VBA).

Representative examples of the integration method are given in the following subsections.

EPA's BASINS Program

EPA's BASINS program is the best example of GIS integration with multiple models.

The best example of GIS integration with multiple models is the Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) program. Originally released in September 1996, BASINS was developed by TetraTech, Inc., for the U.S. Environmental Protection Agency (EPA). BASINS supports the development of total maximum daily loads (TMDLs) using a watershed-based approach that integrates both point and nonpoint sources. BASINS integrates ArcView 3.x GIS with national watershed data and state-of-the-art environmental assessment and modeling tools into one convenient package. The heart of BASINS is its suite of interrelated components essential for performing watershed and water quality analysis. These components are grouped into the following five categories:

1. National databases
2. Assessment tools for evaluating water quality and point source loadings at a variety of scales
3. Utilities, such as land-use and DEM reclassification and watershed delineation
4. Watershed and water quality models including NPSM, TOXIROUTE, and QUAL2E
5. Postprocessing output tools for interpreting model results

What Is TMDL?

According to EPA, TMDL is defined as "a calculation of the maximum amount of a pollutant that a water body can receive and still meet water quality standards, and the allocation of that amount to the pollutant's sources." Technically, TMDL can be defined with the help of the following equation:

$$\text{TMDL} = \text{WLAP} + \text{LAN} + \text{RC} + \text{FOS}$$

where:

WLAP = waste load allocations for point sources
LAN = load allocations for nonpoint sources
RC = reserve capacity for future growth
FOS = factor of safety

BASINS integrates three models within an ArcView GIS environment: NPSM (HSPF), TOXIROUTE, and QUAL2E. Nonpoint Source Model (NPSM) estimates land-use-specific NPS loadings for selected pollutants at a watershed (cataloging unit or user-defined subwatershed) scale. The model uses landscape data such as watershed boundaries and land-use distribution to automatically prepare many of the required input data parameters. NPSM combines a Windows-based interface with EPA's HSPF and is linked to ArcView. HSPF is a model for developing NPS loads and is the backbone of the BASINS modeling system. TOXIROUTE is a screening-level stream-routing model that performs simple dilution and decay calculations under mean- or low-flow conditions for a stream system. QUAL2E is a one-dimensional, steady-state water quality and eutrophication model. It is integrated with ArcView through a Windows-based interface. It allows fate and transport modeling for both point and nonpoint sources. Both TOXIROUTE and QUAL2E can use NPS loadings calculated by HSPF.

Overcoming the lack of integration, limited coordination, and time-intensive execution typical of more traditional assessment tools, BASINS makes watershed and water quality studies easier by bringing key data and analytical components together under one roof. The simulation models run in a Windows environment using data input files generated in ArcView. By using GIS, a user can visualize, explore, and query to bring a watershed to life. This allows the user to assess watershed loadings and receiving-water impacts at various levels of complexity. ArcView geographic data preparation, selection routines, and visual output streamline the use of the models. A postprocessor graphically displays model results. Figure 11.11 shows a screenshot of the BASINS program showing an example of delineated watersheds.

BASINS is distributed on a CD-ROM containing the BASINS program and data for an EPA region of interest. It can also be downloaded from the BASINS Web site. BASINS Version 1.0 was released in September 1996 (Lahlou, et al., 1996) for ArcView Version 2.1. BASINS Version 2.0 was released in December 1998 for ArcView 3.0. It included a national data set on the attributes listed in Table 11.4 (Battin et al., 1998). BASINS Version 3.0 was released in 2001 for ArcView 3.2.

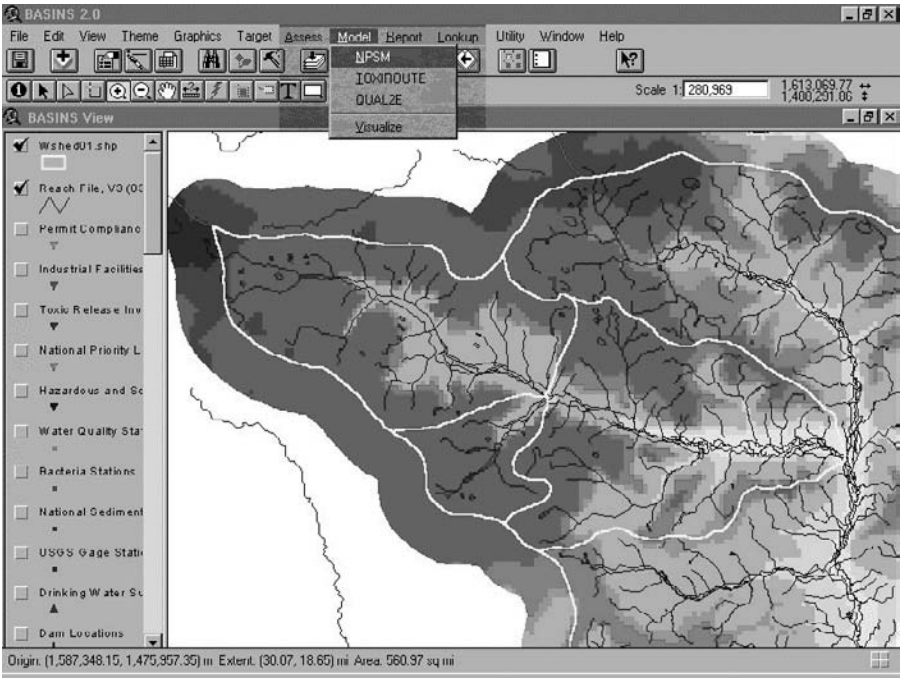

Figure 11.11 BASINS screenshot showing an example of delineated watersheds.

Table 11.4 BASINS Database Attributes

Spatially Distributed Data	
Land use/land cover	USGS hydrologic unit boundaries
Urbanized areas	Drinking water supplies
Populated place location	Dam sites
Reach File, Version 1 (RF1)	EPA region boundaries
Reach File, Version 3 (RF3)	State boundaries
Soils (STATSGO)	County boundaries
Elevation (DEM)	Federal and Indian lands
Major roads	Ecoregions
Environmental Monitoring Data	
Water quality monitoring station summaries	USGS gauging stations
Water quality observation data	Fish and wildlife advisories
Bacteria monitoring station summaries	National Sediment Inventory (NSI)
Weather station sites (477)	Shellfish contamination inventory
Clean water needs survey	—
Point-Source Data	
Permit compliance system	Industrial Facilities Discharge (IFD) sites
Toxic Release Inventory (TRI) sites	Superfund national priority list sites
Mineral availability system/mineral industry location	Resource Conservation and Recovery Act (RCRA) sites

BASINS 2.0 included a watershed delineation tool, a land-use reclassification tool, an HSPF interface, a watershed characterization report on STORET water quality data, DEM elevation data, and USEPA Reach File Version 3 Alpha (RF3 Alpha). Using the import tool, users can add their own data for watershed boundaries, streams, elevation, land use, and observed water quality into the BASINS system. Using the land-use reclassification tool, users can reclassify part of the land-use theme or the entire theme interactively to create more detailed levels of land use. This feature can be used to study the potential impact of land-use changes on water quality. The watershed-delineation tool allows users to interactively subdivide a USGS 8-digit watershed into smaller subwatersheds using mouse point-and-click inputs. Subdelineated watersheds and underlying data are then available for more detailed modeling.

BASINS 3.0 is the latest (year 2001) release at the time of this writing. This release includes additional functional capabilities as well as an updated and expanded set of national data layers. New data and functions include 1° DEM grids, an automatic delineation tool that creates watershed boundaries based on DEM grids, and a new watershed report function for land use, topography, and hydrologic response units. In addition, a new watershed model, the Soil and Water Assessment Tool (SWAT), has been added. SWAT is a watershed-scale model developed to predict the impact of land management practices on water, sediment, and agricultural chemical yields in large complex watersheds with varying soils, land use, and management conditions over long periods of time.

BASINS 3.0 also demonstrates an important change in the development philosophy of BASINS. It is distributed as a core system with several ArcView extensions. All BASINS data management utilities, assessment tools, report tools, and models were converted as extensions. This modular and open architecture offers numerous advantages both to users and developers. For instance, users may customize their BASINS project to include only extensions that are needed. Moreover, it will be easier for developers to maintain and provide updates of individual extensions because it will not involve changing and reissuing a patch or new version for the entire system. This makes it easier for users to upgrade their system. It also encourages the development of extensions for BASINS by users and developers.

BASINS 3.0 installation software contains the new BASINS Version 3.0 system and the tutorial data set (HUC-05010007). In addition to BASINS 3.0, the installation program installs WinHSPF, GenScn, WDMUtil, and PLOAD. WinHSPF is a new interface to HSPF Version 12, which is replacing NPSM from BASINS 2.0. GenScn is a model postprocessing and scenario-analysis tool that is used to analyze output from HSPF and SWAT. WDMUtil is used to manage and create watershed data management files (WDMs) that contain the meteorological data and other time-series data used by HSPF. PLOAD is a GIS and spreadsheet tool to calculate nonpoint sources of pollution in watersheds.

EPA plans to release an update (Version 3.1) in 2004 on the existing ArcView 3.x platform. EPA is currently working on pieces of BASINS for the ArcGIS environment. After the BASINS 3.1 release, EPA plans to port it onto the ArcGIS platform based on the work done by the Center for Research in Water Resources at the University of Texas at Austin, Water Resources Consortium, and ESRI. Future releases of BASINS may include EPA's SWMM program, automatic model calibration, and a reach-indexing tool

for georeferencing. A redesign of the BASINS system using RDBMS, Internet, MapObjects, and Java technologies is also anticipated. This move toward a more fully integrated GIS and database system will provide many more BASINS applications. The watershed tool will evolve into a more component-based architecture, so that users will need to install only the components required for their specific analytical needs, including their own legacy models (Whittemore and Beebe, 2000).

BASINS is a valuable tool that integrates environmental data, analytical tools, and modeling programs to support the development of cost-effective approaches to environmental protection. However, BASINS' seamless integration power is not without some disadvantages. BASINS' simplistic modeling approach and user-friendly tools may encourage inexperienced users to become instant modelers, which could be undesirable. The inexperienced users' overreliance on default model segmentation and model coefficients, without an understanding of the underlying assumptions, may result in inaccurate and unrealistic TMDLs (Thuman and Mooney, 2000). BASINS builds upon federal databases of water quality conditions and point-source loadings for numerous parameters where quality assurance is suspect in some cases (Whittemore and Beebe, 2000).

BASINS Examples

Most of the BASINS work and modeling have been on a watershed- or regional-level scale. An example for the BASINS data set for Boulder, Colorado, is shown in Figure 11.12. The size of this file relative to the area it represents reflects a scale

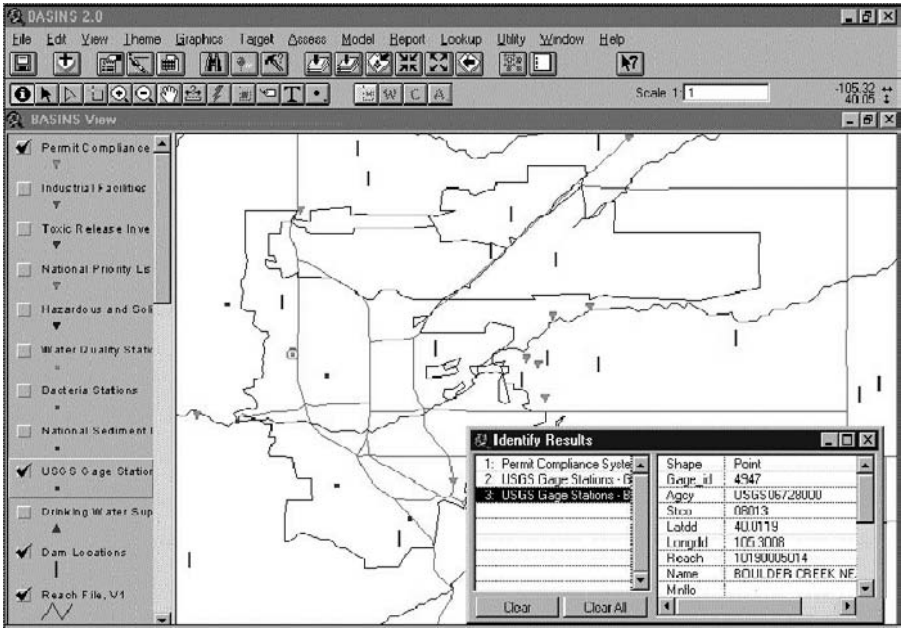

Figure 11.12 BASINS GIS layers for Boulder, Colorado.

of about 1:2000 (Heaney et al., 1999). The Columbus Water Works of Columbus, Georgia, developed a BASINS 2 model for the 2400 mi^2 (3600 km^2) Middle Chattahoochee River Watershed. The main objectives of the model were to formulate TMDL allocation requirements of the Clean Water Act and to demonstrate compliance with EPA's National Combined Sewer Overflow (CSO) Policy. They used monitoring and data management methodologies to calibrate their BASINS model and to perform source-water assessments and protection through provisions of early-warning systems for drinking-water intake operations (Turner et al., 2000).

MIKE BASIN

Danish Hydraulic Institute's (DHI) MIKE BASIN is an ArcView-based decision support system for water resources planning and management. It serves as a generalized river basin network simulation modeling system for regional water resources allocation of complex systems. MIKE BASIN can be used to analyze water supply capabilities in connection with water rights for municipal and industrial water supply, irrigation, and many multipurpose reservoir operations.

MIKE BASIN is fully integrated into ArcView 3.x. It uses a graphical user interface, which links MIKE BASIN to ArcView. It is developed using the object-oriented C++ programming language, which allows for easy implementation of new features. MIKE BASIN permits on-screen creation of models using image themes as backdrops. Figure 11.13 shows the MIKE BASIN interface.

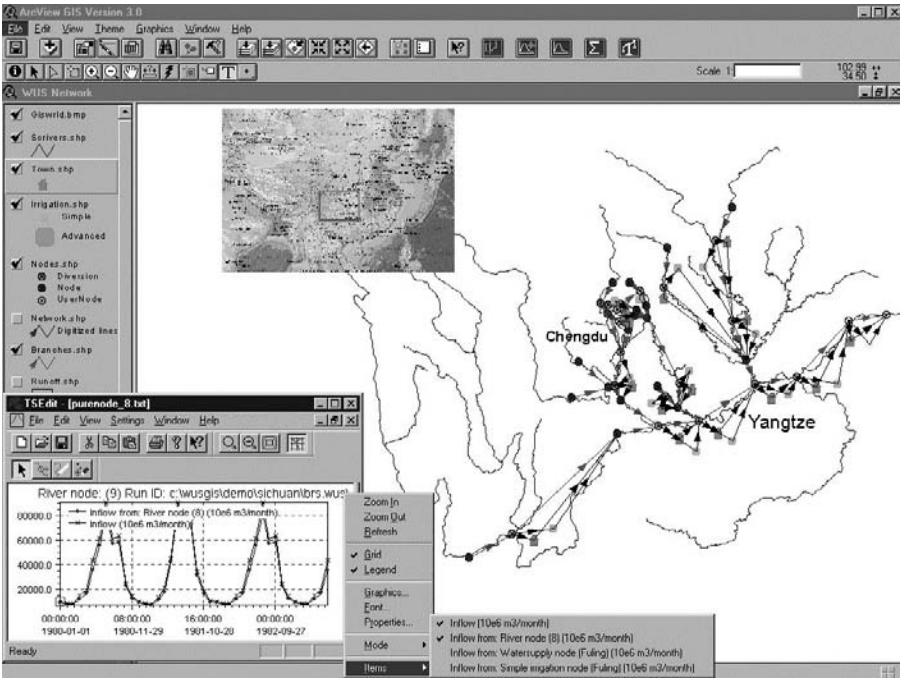

Figure 11.13 MIKE BASIN screenshot.

An important advantage of MIKE BASIN is its vertical compatibility with other DHI modeling systems, which allows the use of several modeling tools of various complexities at different stages of a project cycle. MIKE BASIN can be used in conjunction with other DHI models when detailed studies of specific problems are required. For example, MIKE SHE can be used for modeling runoff quality and quantity, including interaction with surface water systems, MIKE 11 can be used for detailed modeling of river hydrodynamics and water quality, and MIKE 21 can be used for modeling bays and estuaries.

Geo-STORM Integration

An early example of ArcInfo 7.x and modeling integration is the Geo-STORM package developed by Innovative System Developers, Inc., Columbia, Maryland. Geo-STORM computed subbasin runoff, performed flow routing through reach and reservoir networks, and analyzed river hydraulics using SCS Technical Release 20 (TR-20) and Technical Release 55 (TR-55) programs, and COE's HEC-2 computer programs. All these models were contained within a GUI environment within ArcInfo GIS. The software was written in AML, the ArcInfo scripting language. There were external calls to the operating system only to execute the computer programs. The common interface provided easy interaction between the models and switching between the models was hardly noticeable, and output from one model was used as input for another model. The TR-55 model was embedded within the TR-20 model. The output from TR-55 became input for TR-20. The TR-20 model provided discharge values for input to the HEC-2 model, and output from HEC-2 could be directly inserted into TR-20 as rating-table information. All modeling applications were integrated in Geo-GUIDE, a graphical interface that made working with ArcInfo easier. The computer models were embedded within Geo-GUIDE, which provided plotting, reporting, and querying capabilities for the stormwater modeling software suite. The GeoSTORM system was considered to be a database repository for stormwater-related geography and facilities. Using programs like Geo-STORM translated into productivity gains realized by eliminating tedious tasks such as manual map measurements, data entry, and tabular-report interpretation. Geo-STORM automated these time-consuming processes, drawing model inputs from the GIS database. This in time improved the quality and accuracy of model results. Figure 11.14 shows a screenshot of Geo-STORM (Thomas, 1995).

ARC/HEC-2 Integration

ARC/HEC-2 was one of the earliest integrations of ArcInfo and HEC-2, developed at the University of Texas at Austin. ARC/HEC-2 facilitated floodplain analysis in a GIS environment. It allowed direct usage of ArcInfo coverages for development of HEC-2 input, running HEC-2 from within ArcInfo, and for conversion of HEC-2 water-surface elevations computed at each cross section into an ArcInfo coverage representing the floodplain. There were two main data requirements for ARC/HEC-2 to operate: (1) a terrain representation in the form of constructed TIN or contours, and (2) channel centerline (thalweg). ARC/HEC-2 consisted of three separate modules: preprocessor,

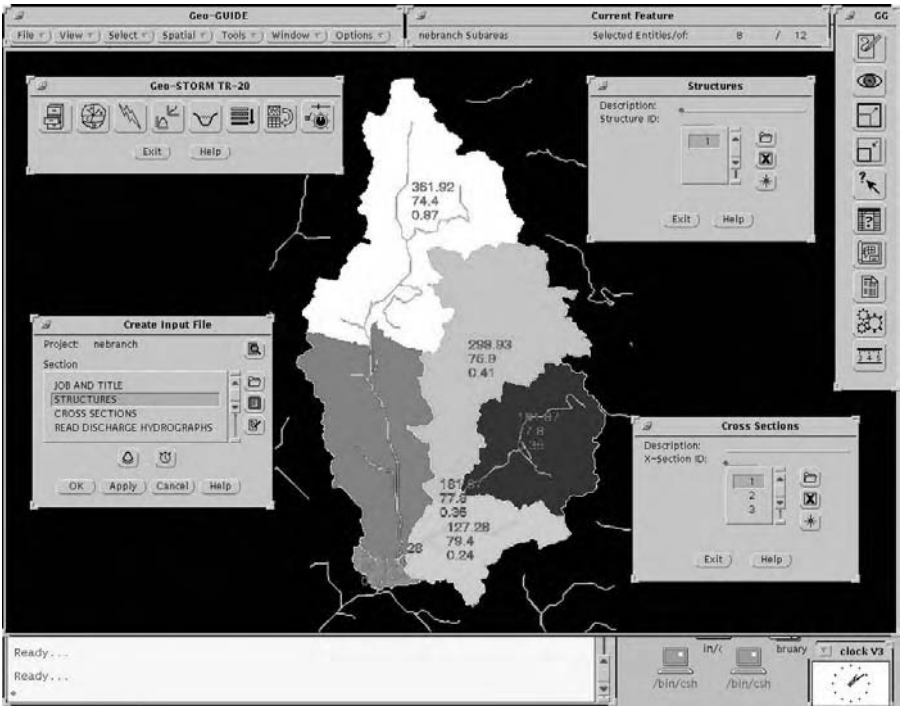

Figure 11.14 Geo-STORM screenshot showing ArcInfo and TR-20 integration.

postprocessor, and viewer. The preprocessor created a complete HEC-2 input file ready to run. For complex HEC-2 models, manual editing of the input file was required, in which case ARC/HEC-2 served as an interface rather than an integration. The postprocessor used the HEC-2 output to determine water surface elevation at each cross section and, based on that information, found the outline of the flooded area in the form of a lattice and a polygon layer. This lattice and coverage could be used in ArcInfo with all other pertinent coverages for the area. Viewer was an AML application that allowed viewing of the main input and output coverages in 2D and 3D formats (Djokic et al., 1993).

Integration Method Case Study

GIS software	ArcView and Spatial Analyst Extension
Modeling Software	Agricultural Nonpoint Source Pollution Model (AGNPS)
GIS data	Soil (STATSGO), USGS DEM (1:250,000 scale), land use, hydrography, watersheds, and crop management
Study area	280 mi^2 (810 km^2) Dowagiac River Watershed located in southwestern Michigan
Organization	Western Michigan University, Kalamazoo, Michigan

Successful implementation of environmental modeling databases involves the integration of GIS, remote sensing, multiple databases, and visualization tools for

extraction of the needed model input parameters and for analysis and visualization of the simulated results. Although it was obvious that GIS technology was ideally suited to accomplish these goals, current GIS packages were found to be difficult to use and offered limited functions to support environmental modeling. It was also noted that in current practice, GIS and hydrologic models were just used together, not really integrated. Therefore, a custom interface called ArcView Nonpoint Source Pollution Modeling (AVNPSM) was developed between ArcView GIS and AGNPS in support of agricultural watershed analysis and nonpoint source pollution management.

AGNPS (Version 5.0) is a single storm event based simulation model for evaluating sediment and nutrient (nitrogen, phosphorus, and chemical oxygen demand or COD) transport from agricultural watersheds. It represents the landscape of a watershed by discretizing the study area into individual grid cells. The PC Windows-based interface developed using Avenue scripts and Dialogue Designer consists of seven modules: the AGNPS utility, parameter generator, input file processor, model executor, output visualizer, statistical analyzer, and land-use simulator. Each module is incorporated into ArcView through pull-down menus and icons. The input file processor menu produces an input file that is compatible with AGNPS input format requirements. The AGNPS model is executed either within Windows using the model executor menu or run separately in simulated DOS mode. The output visualizer menu shows the simulated results of hydrology, sediment, and nutrients in tabular or map format. The calibrated model indicated that development of about 1240 acres of nonurban land caused little increase in the peak flow rate and sediment yield at the mouth of the river and had almost no impact on the runoff volume and nutrient yields. The case study concluded that integration of GIS and simulation models facilitates the development and application of environmental simulation models and enhances the capabilities of GIS packages (He et al., 2001).

WHICH LINKAGE METHOD TO USE?

Each method has its pros and cons. Table 11.5 lists the advantages and disadvantages of the three methods of linking H&H models with GIS. Integrated systems are easy to learn and use and make the excruciating task of H&H modeling a fun

Table 11.5 Comparison of GIS Linkage Methods

Feature	Interchange Method	Interface Method	Integration Method
Automation	Low	Medium	High
User-friendliness	None	Medium	High
Ease of use	Cumbersome	Easy	Easiest
Learning curve	Long	Medium	Quick
Data-entry error potential	High	Medium	Low
Data-error tracking	Easy	Complex	Difficult
Misuse potential by inexperienced users	Low	Medium	High
Development effort	Low	Medium	High
Computer programming	Low	Medium	Extensive

activity. Integrated systems save model development and interpretation time and make modeling cost-effective.

Seamless model integration with GIS is not without some disadvantages. The simplistic modeling approach and user-friendly tools provided by integrated systems like BASINS may encourage inexperienced users to become instant modelers, which could be undesirable (Thuman and Mooney, 2000). GIS can easily convert reams of computer output into colorful thematic maps that can both expose and hide data errors. The user-friendly interface of an integrated package may incorrectly make a complex model appear quite simple, which may lead to misapplication of the model by inexperienced users. Modeling should not be made easy at the expense of good science. Modeling, for all the new tools emerging in the 1990s, is still an art that is done well by only a select few (Whittemore and Beebe, 2000).

The inexperienced users' overreliance on default model parameters may result in inaccurate modeling results. Inexperienced H&H modelers should exercise caution when using integrated systems, make sure to browse the model input and output files for obvious errors, and avoid overreliance on thematic mapping and graphing of model output. Modification and recompilation of computer codes of existing legacy programs like SWMM or EPANET to create integrated systems should be avoided. If recoding is necessary, developers should be extremely cautious to avoid coding errors and the associated liability. Users should remember that a difficult-to-use model is much better than an inaccurate model (Shamsi, 2001).

The development of a GIS for use in urban H&H modeling is an expensive investment (Heaney et al., 1999). Typically the most advanced tools are created for advanced applications, where a full-fledge GIS is in place. For some applications, a DOS-based model may still be the most appropriate. However, as more urban areas create GIS layers, the integration of modeling software and GIS software will become more useful and prevalent.

CHAPTER SUMMARY

This chapter described GIS applications that have revolutionized the way H&H modeling is performed. It showed how GIS can be used to develop H&H models, and also provided a software review of GIS application programs. From the material presented in this chapter, it can be concluded that GIS applications allow modelers to be more productive. Users devote more time to understanding the problem and less time to mechanical tasks of data input and checking, getting the program to run, and interpreting reams of output. More than just tabular outputs, models become an automated system evaluation tool. There are three modeling application methods:

interchange, interface, and integration. Interchange is the simplest method but offers limited benefits. Interchange systems have existed since 1980s in all domains. The interface method's benefits lie between those of the interchange and the integration methods. There are a few interface systems in the public domain and many in commercial and proprietary domains. The integration method offers the maximum productivity benefits. BASINS is the only public-domain modeling system that uses the integration method. A few integrated commercial systems are available starting at $5000. There are many in-house and proprietary integrated systems. The number of public-domain and commercial integration packages is expected to grow steadily in the near future.

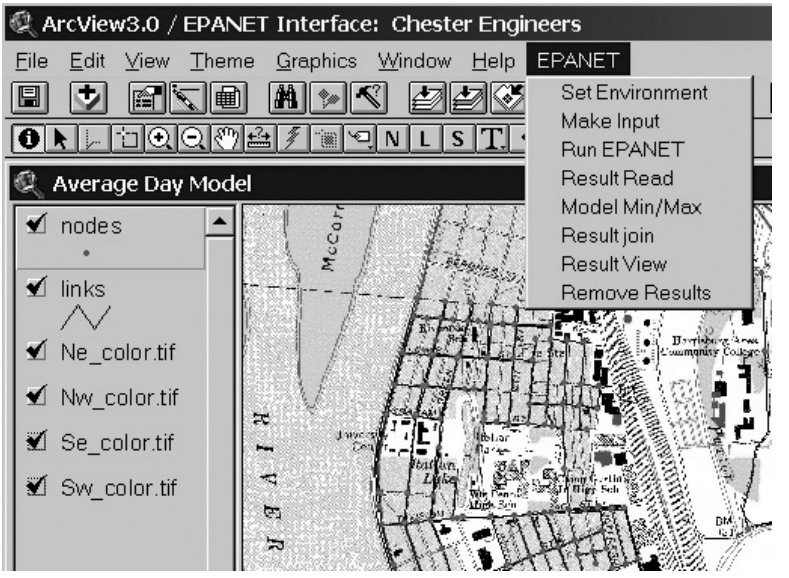
CHAPTER QUESTIONS

1. What are the GIS applications in computer modeling of water, wastewater, and stormwater systems?
2. What are computer modeling application methods?
3. Give an example of each application method using programs other than those described in this chapter.
4. Which GIS application method is the easiest to use? Why?
5. Which GIS application method is the easiest to implement? Why?
6. List the typical steps used in the interface method.
7. Make a list of the H&H models used in your organization and the type of GIS application method used by each.

CHAPTER 12

Water Models

GIS saves time and money in developing water distribution system hydraulic models for simulating flows and pressures in the system. GIS also helps in presenting the model results to non-technical audiences.



EPANET and ArcView GIS integration.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand how GIS can be applied in developing water distribution system hydraulic models and presenting the results of the hydraulic models.

MAJOR TOPICS

- Development of hydraulic models
- Software examples
- EPANET model
- Network simplification (skeletonization)
- Estimation of node demands
- Estimation of node elevations
- Delineation of pressure zones
- Mapping the model output results
- GIS application examples and case studies

CITY OF GERMANTOWN'S WATER MODEL

Application	Water distribution system mapping and modeling
GIS software	ArcGIS, ArcGIS Water Utilities Data Model (formerly ArcFM Water Data Model), and MapObjects
Other software	WaterCAD
GIS layers	Digital orthophotos, pipes, hydrants, valves, manholes, pumps, meters, fittings, sampling stations, and monitoring wells
Hardware	Two Dell Precision 220 computers
Study area	City of Germantown, Tennessee
Organization	City of Germantown, Tennessee

The City of Germantown (Tennessee) water distribution system serves 40,000 people through 12,000 installations in a 17.5 mi^2 area. The system has approximately 95,000 ft of water pipes.

The City used ESRI's geodatabase, an object-oriented GIS data model, to design a database. The database design was done with minimal customization of ESRI's ArcGIS Water Utilities Data Model. This approach helped complete the database design in a few weeks instead of several months. ESRI's MapObjects was used to create a custom utility tool set for developing the water distribution network. Valve and hydrant locations from the digital orthophotos and planimetric mapping were used with the existing 1 in. = 500 ft-scale paper map of the water system as the basis for connecting water pipes.

The GIS layers (Figure 12.1) were initially developed using the ArcView Shapefiles. The Shapefiles were then migrated to a geodatabase. To ease the data migration, connectivity rules were stored in ArcCatalog rather than directly in the model. ArcMap "flag and solver" tracing tools were used to ensure topological integrity of the migrated data. ArcMap also provided the City with out-of-the-box network analysis functionality such as tracing paths and water main isolation.

For the development of the hydraulic model, the City did not have to create a modeling network from scratch. GIS was used to skeletonize the network for input to the Haestad Method's WaterCAD 4.1 hydraulic model. Spatial operations available in ArcGIS were used to assign customer-demand data — obtained from the City's billing database and stored in parcel centroids — to modeling nodes. Node elevations were extracted from the City's DEM.

The hydraulic model was run to assess the future system expansion and capital improvement needs of the City. The model indicated that the system needed a new elevated storage tank and a larger pipe to deliver acceptable pressure under peak demand conditions (ESRI, 2002b).

GIS APPLICATIONS FOR WATER DISTRIBUTION SYSTEMS

GIS has wide applicability for water distribution system studies. Representation and analysis of water-related phenomena by GIS facilitates their management. The GIS applications that are of particular importance for water utilities include mapping, modeling, facilities management, work-order management, and short- and long-term planning. Additional examples include (Shamsi, 2002):

- Conducting hydraulic modeling of water distribution systems.
- Estimating node demands from land use, census data, or billing records.
- Estimating node elevations from digital elevation model (DEM) data.
- Performing model simplification or skeletonization for reducing the number of nodes and links to be included in the hydraulic model.
- Conducting a water main isolation trace to identify valves that must be closed to isolate a broken water main for repair. Identifying dry pipes for locating customers or buildings that would not have any water due to a broken water main. This application is described in Chapter 15 (Maintenance Applications).
- Prepare work orders by clicking on features on a map. This application is described in Chapter 14 (AM/FM/GIS Applications).
- Identifying valves and pumps that should be closed to isolate a contaminated part of the system due to acts of terrorism. Recommending a flushing strategy to clean the contaminated parts of the system. This application is described in Chapter 16 (Security Planning Vulnerability Assessment).

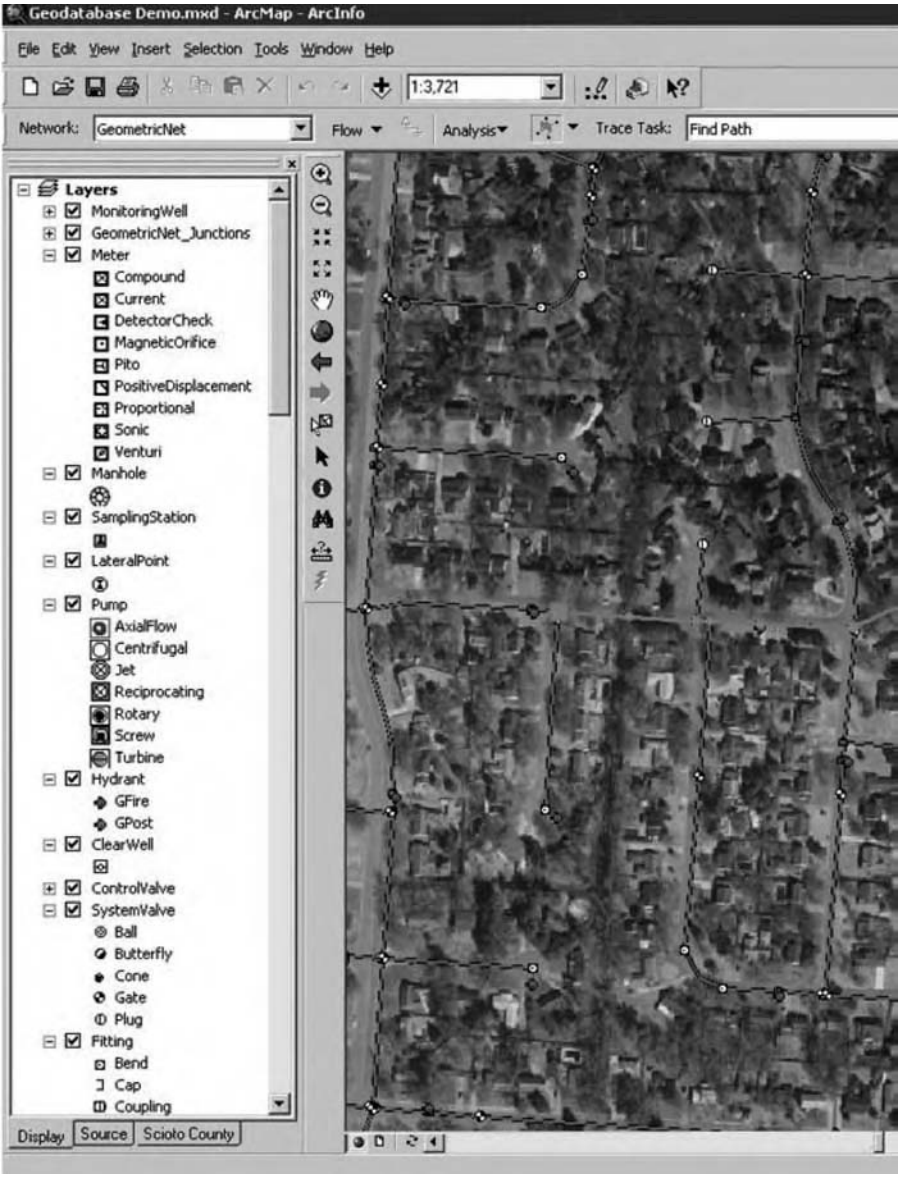

Figure 12.1 Germantown water distribution system layers in ArcGIS.

- Providing the basis for investigating the occurrence of regulated contaminants for estimating the compliance cost or evaluating human health impacts (Schock and Clement, 1995).
- Investigating process changes for a water utility to determine the effectiveness of treatment methods such as corrosion control or chlorination.
- Assessing the feasibility and impact of system expansion.
- Developing wellhead protection plans.

By using information obtained with these applications, a water system manager can develop a detailed capital improvement program or operations and maintenance plan (Morgan and Polcari, 1991). The planning activities of a water distribution system can be greatly improved through the integration of these applications.

In this chapter, we will focus on the applications related to hydraulic modeling of water distribution systems.

DEVELOPMENT OF HYDRAULIC MODELS

The most common use of a water distribution system hydraulic model is to determine pipe sizes for system improvement, expansion, and rehabilitation. Models are also used to assess water quality and age and investigate strategies for reducing detention time. Models also allow engineers to quickly assess the distribution network during critical periods such as treatment plant outages and major water main breaks.

Today, hydraulic models are also being used for vulnerability assessment and protection against terrorist attacks.

Hydraulic models that are created to tackle a specific problem gather dust on a shelf until they are needed again years later. This requires a comprehensive and often expensive update of the model to reflect what has changed within the water system. A direct connection to a GIS database allows the model to always remain live and updated.

Denver Water Department, Colorado, installed one of the first AM/FM/GIS systems in the U.S. in 1986. In the early 1990s, the department installed the $60,000 SWS water model from the Stoner Associates (now Advantica Stoner, Inc.). Around the same time, Genesee County Division of Water and Waste Services in Flint, Michigan, started developing a countywide GIS database. The division envisioned creating sewer and water layers on top of a base map and integrating the GIS layers with their water and sewer models (Lang, 1992).

GIS applications reduce modeling development and analysis time. GIS can be used to design optimal water distribution systems. An optimal design considers both cost-effectiveness and reliability (Quimpo and Shamsi, 1991; Shamsi, 2002a) simultaneously. It minimizes the cost of the system while satisfying hydraulic criteria (acceptable flow and pressures). Taher and Labadie (1996) developed a prototype model for optimal design of water distribution networks using GIS. They integrated GIS for spatial database management and analysis with optimization theory to develop a computer-aided decision support system called WADSOP (Water Distribution System Optimization Program). WADSOP employed a nonlinear programming technique as the network solver, which offers certain advantages over conventional methods such as Hardy-Cross, Newton Raphson, and linear system theory for balancing looped water supply systems. WADSOP created a linkage between a GIS and the optimization model, which provided the ability to capture model input data; build network topology; verify, modify, and update spatial data; perform spatial analysis; and provide both hard-copy reporting and graphical display of model results. The GIS analysis was conducted in PC ARC/INFO. The ROUTE and ALLOCATE programs of the NETWORK module

of PC ARC/INFO were found to be very helpful. Computational time savings of 80 to 99% were observed over the other programs.

Generally, there are four main tasks in GIS applications to water system modeling:

1. Synchronize the model's network to match the GIS network.
2. Transfer the model input data from a GIS to the model.
3. Establish the model execution conditions and run the model.
4. Transfer the model output results to GIS.

As described in Chapter 11 (Modeling Applications), GIS is extremely useful in creating the input for hydraulic models and presenting the output. A hydraulic modeler who spends hundreds of hours extracting input data from paper maps can accomplish the same task with a few mouse clicks inside a GIS (provided that the required data layers are available). GIS can be used to present hydraulic modeling results in the form of thematic maps that are easy for nontechnical audiences to understand. Additional information about GIS integration methods is provided in Chapter 11, which provided a taxonomy developed by Shamsi (1998, 1999) to define the different ways a GIS can be linked to hydraulic models. According to Shamsi's classification, the three methods of developing GIS-based modeling applications are interchange, interface, and integration. For GIS integration of water distribution system hydraulic models, one needs a hydraulic modeling software package. The software can run either inside or outside the GIS. As explained in Chapter 11, when modeling software is run inside a GIS, it is considered "seamlessly integrated" into the GIS. Most modeling programs run in stand-alone mode outside the GIS, in which case the application software simply shares GIS data. This method of running applications is called a "GIS interface."

The interchange method offers the most basic application of GIS in hydraulic modeling of water distribution systems. In 1995, the Charlotte–Mecklenburg Utility Department (CMUD) used this method to develop a KYPIPE model for an area serving 140,000 customers from 2,500 mi of water pipes ranging in size from 2 in. to 54 in. (Stalford and Townsend, 1995). The modeling was started by creating an AutoCAD drawing of all pipes 12 in. and larger. The pipes were drawn as polylines and joined at the intersections. The AutoCAD drawing was converted to a facilities management database by placing nodes at the hydraulic intersections of the pipes, breaking the polylines as needed, adding extended attributes to the polylines from the defined nodes, extracting this information into external tables, and adding the nongraphical information to the tables. Then, by using ArcCAD inside AutoCAD, coverages were created for the pipes and nodes, which could be viewed inside ArcView. Although this method was considered state-of-the-art in 1995, it is not a very efficient GIS integration method by today's standards. The EPANET integration case study presented later in the chapter exemplifies application of the more efficient integration method.

In the simplest application of the integration method, it should be possible to use a GIS to modify the configuration of the water distribution network, compile model input files reflecting those changes, run the hydraulic model from within the GIS, use the GIS to map the model results, and graphically display the results of the simulation

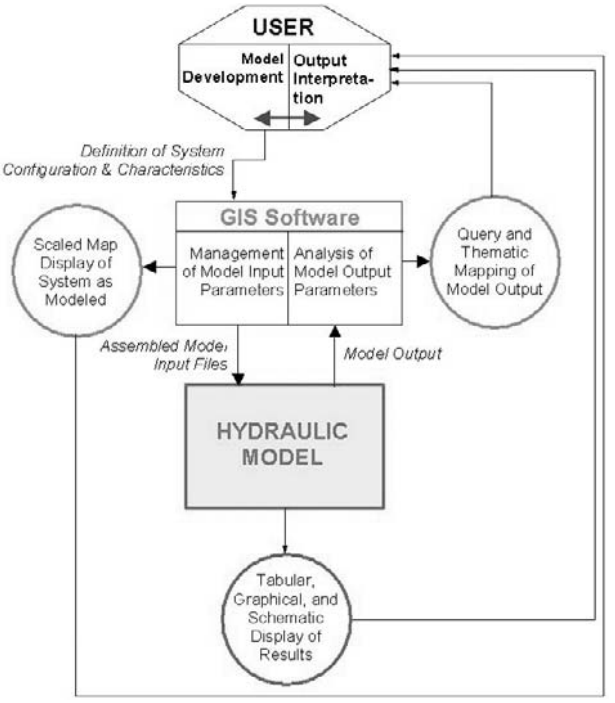

Figure 12.2 Integration method interrelationships.

on a georeferenced base map. The integration method interrelationships among the user, the hydraulic model, and the GIS software are illustrated in Figure 12.2.

SOFTWARE EXAMPLES

Table 12.1 lists representative water distribution system modeling packages and their GIS capabilities, vendors, and Web sites. The salient GIS features of these programs are described in the following subsections.

EPANET

EPANET was developed by the Water Supply and Water Resources Division (formerly the Drinking Water Research Division) of the U.S. Environmental Protection Agency's National Risk Management Research Laboratory (Rossman, 2000). It is a public-domain software that may be freely copied and distributed.

EPANET is a Windows 95/98/2K/NT program that performs extended-period simulation of hydraulic and water quality behavior within pressurized pipe networks. A network can consist of pipes, nodes (pipe junctions), pumps, valves, and storage tanks or reservoirs. EPANET tracks the flow of water in each pipe, the pressure at each node, the height of water in each tank, and the concentration of a chemical species

Table 12.1 Water Distribution System Modeling Software

throughout the network during a simulation period made up of multiple time steps. In addition to chemical species, water age and source tracing can also be simulated.

The Windows version of EPANET provides an integrated environment for editing network input data, running hydraulic and water quality simulations, and viewing the results in a variety of formats. These include color-coded network maps, data tables, time-series graphs, and contour plots. Figure 12.3 shows an EPANET screenshot displaying pipes color-coded by head-loss and nodes color-coded by pressure.

The EPANET Programmer's Toolkit is a dynamic link library (DLL) of functions that allow developers to customize EPANET's computational engine for their own specific needs. The functions can be incorporated into 32-bit Windows applications written in C/C++, Delphi Pascal, Visual Basic, or any other language that can call functions within a Windows DLL. There are over 50 functions that can be used to open a network description file, read and modify various network design and operating parameters, run multiple extended-period simulations accessing results as they are generated or saving them to file, and write selected results to file in a user-specified format. The toolkit should prove useful for developing specialized applications, such as optimization models or automated calibration models, that require running many network analyses while selected input parameters are iteratively modified. It also can simplify adding analysis capabilities to integrated network modeling environments based on CAD, GIS, and database management packages (Rossman, 2000a).

The current version of EPANET (Version 2.0) has neither a built-in GIS interface nor integration. Therefore, users must develop their own interfaces (or integration) or rely on the interchange method to manually extract model input parameters from GIS data layers.

H_2ONET™ and H_2OMAP™

MWH Soft, Inc. (Broomfield, Colorado), provides infrastructure software and professional solutions for utilities, cities, municipalities, industries, and engineering organizations. The company was founded in 1996 as a subsidiary of the global

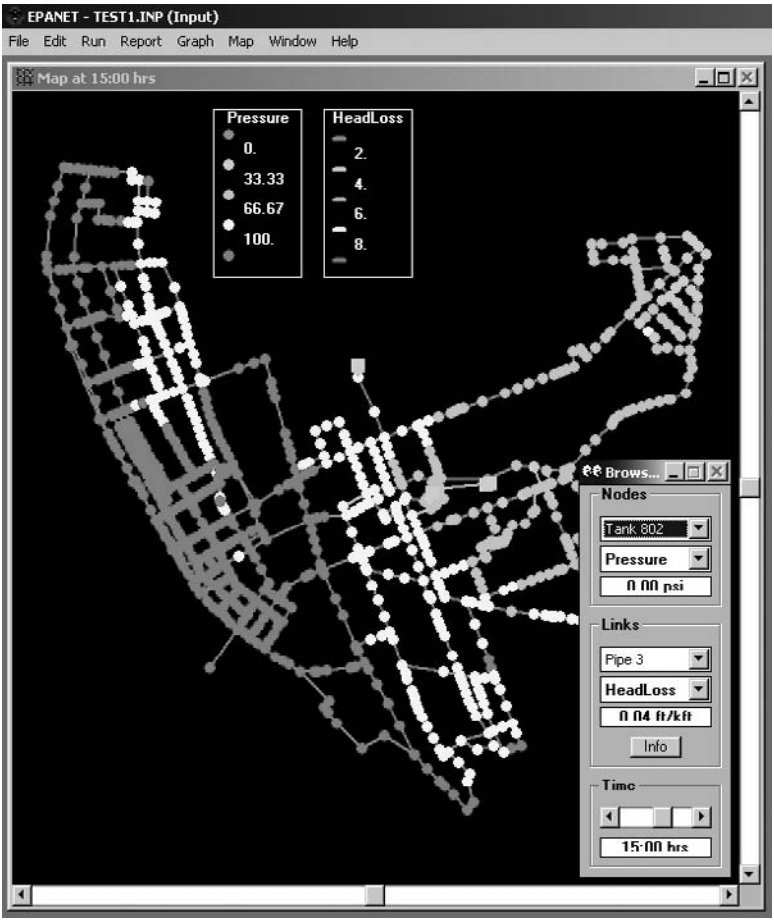

Figure 12.3 EPANET screenshot (Harrisburg, Pennsylvania, model).

environmental engineering, design, construction, technology, and investment firm MWH Global, Inc. The company's CAD- and GIS-enabled products are designed to manage, design, maintain, and operate efficient and reliable infrastructure systems. MWH Soft, provides the following water distribution system modeling software:

- H_2ONET
- H_2OMAP Water
- InfoWater
- H_2OVIEW Water

H_2ONET is a fully integrated CAD framework for hydraulic modeling, network optimization, graphical editing, results presentation, database management, and enterprise-wide data sharing and exchange. It runs from inside AutoCAD and, therefore, requires AutoCAD installation.

Built using the advanced object-oriented geospatial component model, H_2OMAP Water provides a powerful and practical GIS platform for water utility solutions. As a stand-alone GIS-based program, H_2OMAP Water combines spatial analysis tools and mapping functions with network modeling for infrastructure asset management and business planning. H_2OMAP Water supports geocoding and multiple mapping layers that can be imported from one of many data sources including CAD drawings (e.g., DWG, DGN, and DXF) and standard GIS formats (Shapefiles, Generate files, MID/MIF files, and ArcInfo coverages). The program also supports the new geodatabase standard of ArcGIS through an ArcSDE connection.

InfoWater is a GIS-integrated water distribution modeling and management software application. Built on top of ArcGIS using the latest Microsoft .NET and ESRI ArcObjects component technologies, InfoWater integrates water network modeling and optimization functionality with ArcGIS.

H_2OVIEW Water is an ArcIMS-based (Web-enabled) geospatial data viewer and data distribution software. It enables deployment and analysis of GIS data and modeling results over the Internet and intranets. Figure 12.4 shows a screenshot of H_2OVIEW Water.

Various GIS-related modules of H_2O products are described in the following subsections.

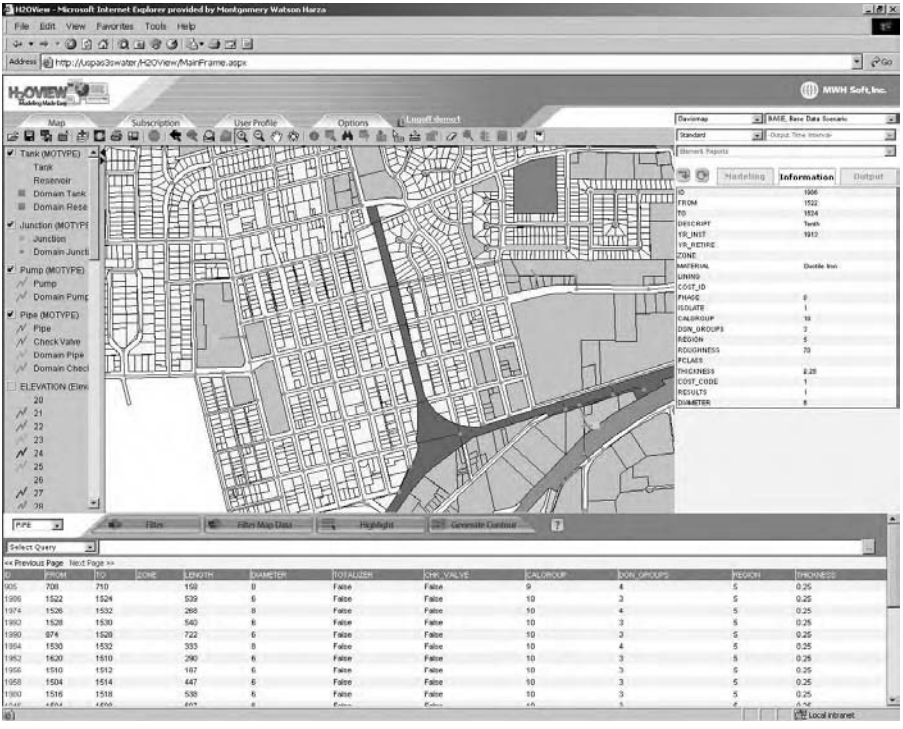

Figure 12.4 H_2OVIEW screenshot (Screenshot courtesy of MWH Soft).

Demand Allocator

Automatically computes and geographically allocates water demand data throughout the water distribution network model.

Skeletonizer

Automates GIS segmentation (data reduction, skeletonization, and trimming) to construct hydraulic network models and reallocates node demands directly from the GIS.

Tracer

H_2ONET Tracer is a network tracing tool that locates all valves which need to be closed to isolate a portion of the network, visually identify all customers affected by loss or reduction in service, and determine the best response strategy. It is a valuable tool for vulnerability analysis and security planning to protect systems against terrorist attacks.

WaterCAD™ and WaterGEMS™

Haestad Methods, Inc. (Waterbury, Connecticut), provides a wide range of H&H computer models, publishes books, and offers continuing education for the civil engineering community. Haestad Methods is a growing company with more than 100,000 users in more than 160 countries around the world. Haestad Methods was acquired by Bentley Systems (Exton, Pennsylvania) in August 2004. Haestad Methods provides the following water distribution system modeling software:

- WaterCAD Stand-alone
- WaterCAD for AutoCAD
- WaterGEMS for ArcGIS

WaterCAD is Haestad Method's water distribution analysis and design tool. It can analyze water quality, determine fire flow requirements, and calibrate large distribution networks. The stand-alone version does not require a CAD or GIS package to run. The AutoCAD version runs from inside AutoCAD and, therefore, requires AutoCAD.

Shapefile Wizard, the ArcView GIS interface module for WaterCAD, is sold separately. The wizard provides import and export capability to transfer data between GIS and WaterCAD models. For example, Import Shapefile Wizard imports WaterCAD model input parameters from ArcView GIS Shapefiles. Similarly, the Export Shapefile Wizard exports hydraulic model networks to ArcView. This feature lets users build and maintain their water and sewer networks directly inside a GIS.

Geographic Engineering Modeling Systems (GEMS) is the next generation of Haestad Methods' hydraulic network modeling products. GEMS is a new product

family that combines water, wastewater, and stormwater system modeling with an open database architecture. It was developed using ESRI's ArcObjects technology and computing tools from Microsoft's .NET initiative. GEMS technology eliminates the need for a separate model database. It streamlines the process of accessing information on, for example, facilities management, zoning, topography, and gauging stations for use with the model. GEMS-based models can be run within ESRI's ArcGIS software using the geodatabase structure (Shamsi, 2001).

WaterGEMS uses a geodatabase, Water Data Model, for integrated WaterCAD modeling within the ArcGIS platform. Because WaterGEMS runs from inside ArcGIS, it requires an installation of ArcGIS software. Although WaterGEMS accommodates Shapefiles and ArcInfo coverages, it provides users with the tools to migrate to the new geodatabase format. Users can easily save an existing hydraulic model as a geodatabase.

In an interview by Haestad Methods, Jack Dangermond, president of ESRI, stated, "GEMS bridges the gap between engineering and planning departments and allows users to further leverage their GIS investment" (Haestad Methods, 2003).

MIKE NET™

DHI Water and Environment (formerly Danish Hydraulic Institute, Hørsholm, Denmark, www.dhi.dk) is a global provider of specialized consulting and numerical modeling software products for water, wastewater, river and coastal engineering, and water resources development. DHI has developed a large number of hydraulic, hydrologic, and hydrodynamic computer models for water, wastewater, and stormwater systems. The company also specializes in linking its computer models with GIS so that modelers can use both modeling and GIS technologies within a single product. Since 1998, DHI has embarked on an ambitious program to link its models with the ESRI family of GIS products. Many of DHI's modeling systems now support GIS data transfer. For example, DHI has developed ArcView GIS extensions and interface programs for a number of its products.

MIKE NET is a software package for the simulation of steady flow and pressure distribution and extended-period simulation of hydraulic and water quality behavior within drinking water distribution systems. MIKE NET was developed in cooperation with BOSS International (Madison, Wisconsin, www.bossintl.com). MIKE NET uses the EPANET 2.0 numerical engine.

Data can be shared with any standard Windows spreadsheet (e.g., Microsoft Excel) or relational database (e.g., Oracle, Microsoft SQL Server, Informix, and Sybase) either directly or using Open Database Connectivity (ODBC) links, or by simply cutting to and pasting from the Microsoft Windows clipboard.

Important GIS features of MIKE NET are described below:

- MIKE NET can read the network models directly from an ArcInfo, ArcFM, ArcView, or MapInfo GIS database. MIKE NET can build a link to a GIS database structure, using attribute mapping and geocoding. For example, a pump or valve can be represented as either a node or an arc in the originating GIS database, while still being linked with MIKE NET.
- MIKE NET can read the node elevation field from Shapefile polygons and assign it to each junction node within the polygon.

- MIKE NET can import a fire hydrants layer to automatically determine which pipe the hydrant belongs to. It temporarily inserts the hydrant into the pipe at the hydrant location, performs the fire flow simulation, and resets the network back to the original state without the hydrant.
- MIKE NET allows the user to assign nodal demands to the entire network system using the program's Distributed Demands capability. In addition, GIS layers can be used to geocode water consumption as well as multiple demand patterns from land-use and population-density aerial coverages. Multiple overlying layers can be aggregated and assigned to the appropriate junction nodes.
- It can perform automated and/or user-assisted skeletonization of the distribution network. Node demands are automatically accumulated during the skeletonization process so that the skeletal model continues to perform and respond closely to those of the original network model.

Other Programs

CEDRA AVWater from Cedra Corporation (Rochester, New York) provides an ArcView 3.x GIS extension interface to the University of Kentucky's KYPIPE and EPA's EPANET models.

The InfoWorks WS from Wallingford Software (Wallingford, United Kingdom) imports models from any data source using the InfoWorks CSV data gateway. It exchanges data with MapInfo Professional and ArcView GIS and exports data and simulation results to MapInfo Professional and ArcView. InfoNet has a multiuser database with built-in data models for water, wastewater, and stormwater infrastructure; a GIS user-interface; and a report generator. It can be integrated with GIS, Desktop Office systems, hydraulic modeling systems, maintenance management systems (MMS), field data systems, SCADA, and corporate databases.

PIPE2000 is the hydraulic modeling software from the developers of the legacy KYPIPE program from the University of Kentucky (Lexington, Kentucky). PIPE2000 uses the EPANET simulation engine for water quality simulation. The Pro version of PIPE2000 imports and exports PIPE2000 data to and from Shapefiles.

SynerGEE Water (formerly Stoner Model) is a hydraulic modeling software from Stoner Advatica, Inc. (Carlisle, Pennsylvania). Water Solver uses SynerGEE's simulation engine as a Microsoft Component Object Model (COM)-compliant component. This capability allows integration of hydraulic simulation capability into a GIS.

EPANET AND ARCVIEW INTEGRATION IN HARRISBURG

A representative example of model integration is presented in this section. Additional water system modeling case studies are provided in Chapter 17 (Applications Sampler).

Chester Engineers (Pittsburgh, Pennsylvania) developed a GIS integrated model by combining ESRI's ArcView GIS software and EPA's EPANET hydraulic modeling program (Maslanik and Smith, 1998). EPANET provides extensive capability to support decisions in the operation, management, planning, and expansion of water distribution systems. ArcView is a user-friendly desktop

Table 12.2 AVNET Functions

Function	Description
	Menu Functions
Set Environment	Enter model execution parameters (e.g., length of simulation)
Make Input	Makes EPANET input file
Run EPANET	Launches the EPANET program
Results Read	Translates the EPANET output file into GIS database files
Model Min/Max	Finds the minimum and maximum EPANET output parameters
Results Join	Joins the EPANET results for a selected hour or minimum/maximum values to a layer
Results View	Sets the legend to an EPANET output parameter
Remove Results	Removes the join of the EPANET results from a theme
	Tool Functions
N Tool	Adds a water system node
L Tool	Adds a water system main
S Tool	Splits an existing water system line and adds a node

mapping and GIS tool, which can be learned by most users without extensive training and experience. Due to its low cost, ease of use, and customization capability, ArcView was found to be a suitable tool for developing the EPANET–GIS integration.

The custom ArcView 3.x and EPANET 2.x integration is called AVNET. AVNET performs preprocessing of GIS data to create model input files. It also conducts postprocessing of model results to create GIS maps of the model output results. Both the GIS and the modeling functions are available in ArcView. There is no need to exit ArcView to edit or run the model. AVNET provides seamless model input creation, model data editing, model execution, and model output display capabilities from within ArcView GIS. Other important features of AVNET are:

- As shown in the figure on the first page of this chapter, AVNET adds a new EPANET menu to ArcView's standard interface. The AVNET menu provides eight functions listed in Table 12.2.
- As shown in Figure 12.5, AVNET adds three new editing tools to ArcView's standard interface. These tools provide three functions listed in Table 12.2. These CAD-like editing tools allow adding nodes and pipes and on-screen input of model attributes.
- AVNET uses ArcView to modify the configuration of the water distribution system.
- Water mains and links can be added interactively while maintaining the required network topology.
- AVNET compiles new EPANET model input files reflecting the edits made by the user.
- AVNET requires ArcView Shapefiles or ArcInfo coverages for nodes and pipes. The required attributes for these layers are shown in Table 12.3.

Table 12.3 AVNET Attributes

Attribute	Type	Description
	Attributes for the Node Layer	
Node	Numeric	Node ID number
X_coord	Numeric	X coordinate value
Y_coord	Numeric	Y coordinate value
Type	Character	Node type (JUNCTION or TANK)
Elev	Numeric	Node elevation
Demand	Numeric	Node demand (water consumption)
Init_level	Numeric	Initial level of water system tank
Min_level	Numeric	Minimum level of water system tank
Max_level	Numeric	Maximum level of water system tank
Diam	Numeric	Diameter of water system tank
	Attributes for the Pipe Layer	
Link	Numeric	Line ID
Start_node	Numeric	Node ID number of starting node of pipe
End_node	Numeric	Node ID number of ending node of pipe
Type	Character	Main type (PIPE or PUMP)
Length	Numeric	Pipe length
Diam	Numeric	Pipe diameter
Rough_coef	Numeric	Pipe roughness coefficient
Pump_H	Numeric	Pump design head
Pump_Q	Numeric	Pump design flow

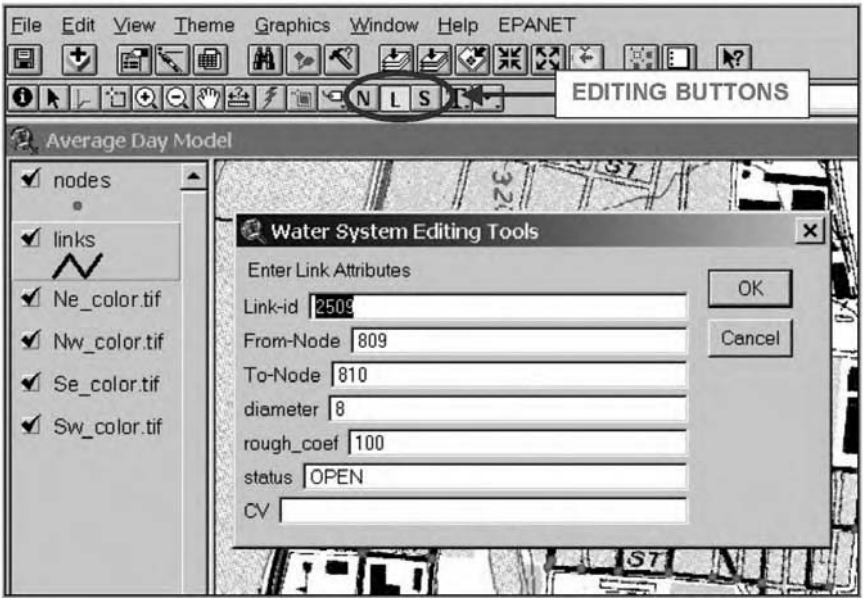

Figure 12.5 Editing pipe attributes in AVNET model.

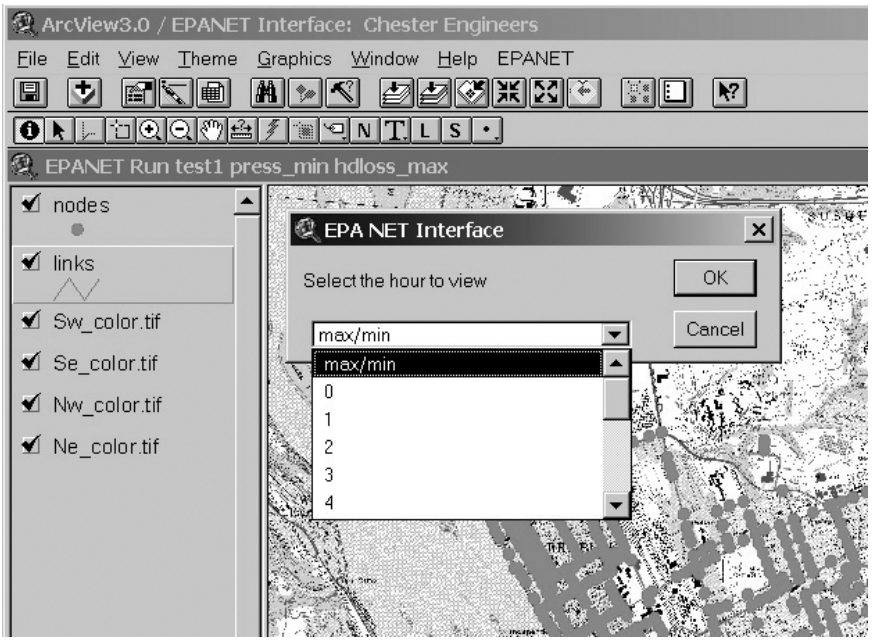

Figure 12.6 Reading the EPANET model output results in ArcView GIS.

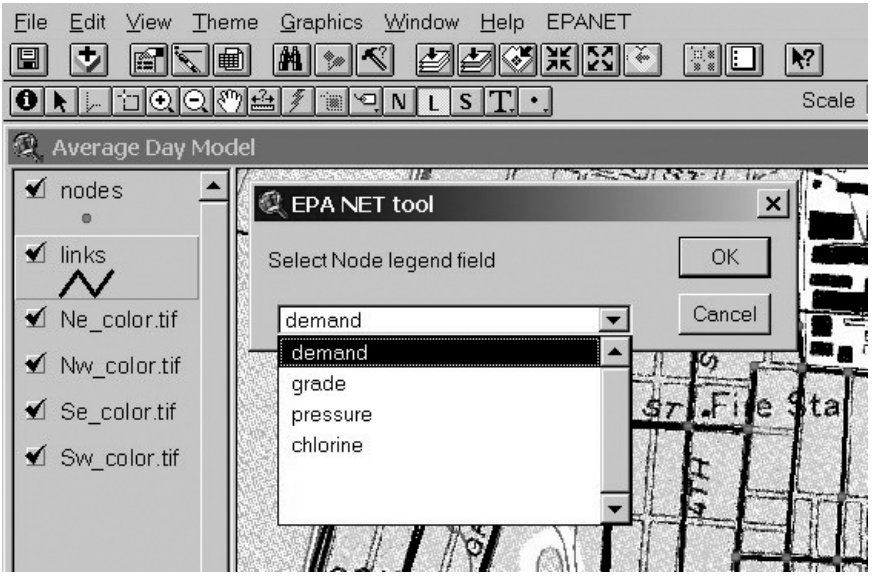

Figure 12.7 Classifying the legend to create model output thematic maps.

- AVNET creates a map file for EPANE model that contains a line for each node with the node ID and the x and y coordinates. The data are extracted from the water system node attribute table.
- AVNET runs the EPANET model from within ArcView.
- AVNET uses ArcView to map the water distribution system model and graphically display the results of the simulation on a georeferenced base map. The output file is linked to the GIS attribute files for pipes and nodes. As shown in Figure 12.6, AVNET reads the output file to extract the output parameters for minimum and maximum values or values at any user-specified simulation time step. Thematic maps of model output parameters (flows, pressures, residual chlorine, etc.) are created by classifying the ArcView theme legends (Figure 12.7).

Figure 12.8 shows the AVNET model for the city of Harrisburg, Pennsylvania. This model consists of 2500 pipes and 1650 nodes, 4 tanks, and 6 pumps. It shows layers for model nodes and links (pipes). The base-map layer consists of a USGS digital raster graphic (DRG) layer. A DRG is a TIF file of a scanned USGS 7.5-min paper topographic map.

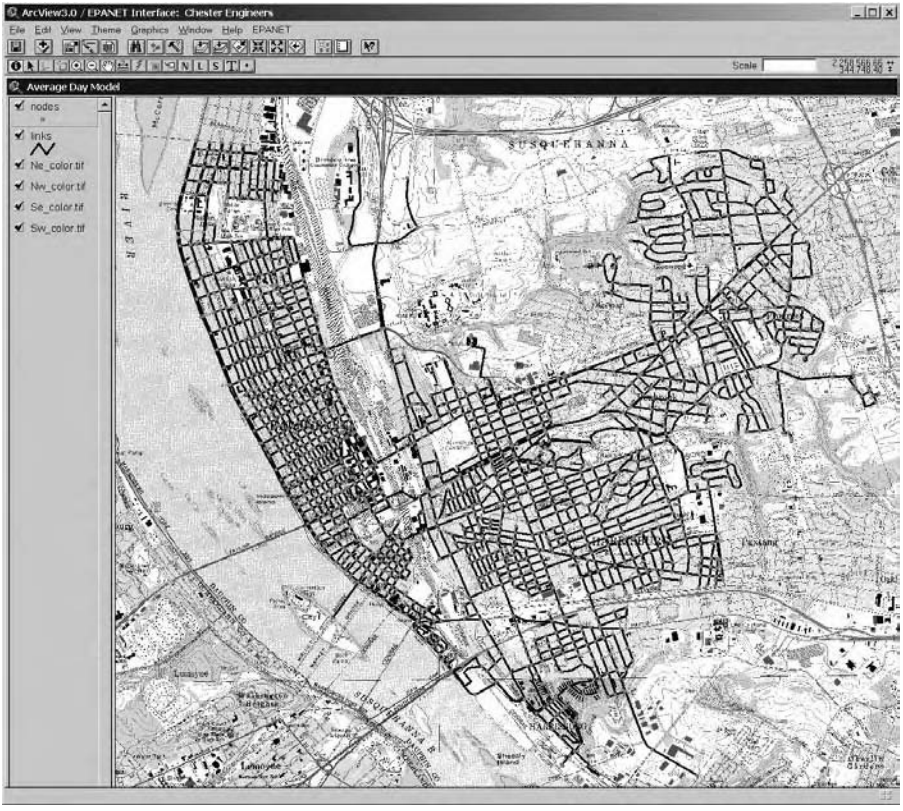

Figure 12.8 AVNET model for the City of Harrisburg, Pennsylvania.

Mapping the Model Output Results

The power of GIS gives a new meaning to the popular phrase "a picture is worth a thousand words." In fact, the thematic maps created by GIS are so effective in displaying large amounts of complex data that the popular phrase can be "plagiarized" to create a new cliché "a map is worth a thousand numbers."

The model output results in tabular or spreadsheet format are not very meaningful for nonmodelers. GIS technology is an effective means of bridging the gap between modeling information and its recipients. GIS can convert textual output results into easily interpretable thematic maps, for example, a map of pipes color-coded by flows and nodes color-coded by pressures. Figure 12.9 shows the Harrisburg model output results presented as a thematic map in ArcView GIS. The first layer (represented as dots) shows the minimum working pressures at the nodes. The second layer (represented as lines) shows the maximum head losses for the pipes. An overlay of the two layers clearly shows areas where pressures are low and head losses high. Such areas usually represent inadequate pipe sizes for delivering required flow rates and might be targeted for water main installation and replacement work. In fact, the GIS can automatically flag such hot spots for further study. The model output thematic maps are excellent for conveying modeling results to nontechnical audiences such as members of the city council or water utility board, or the general public.

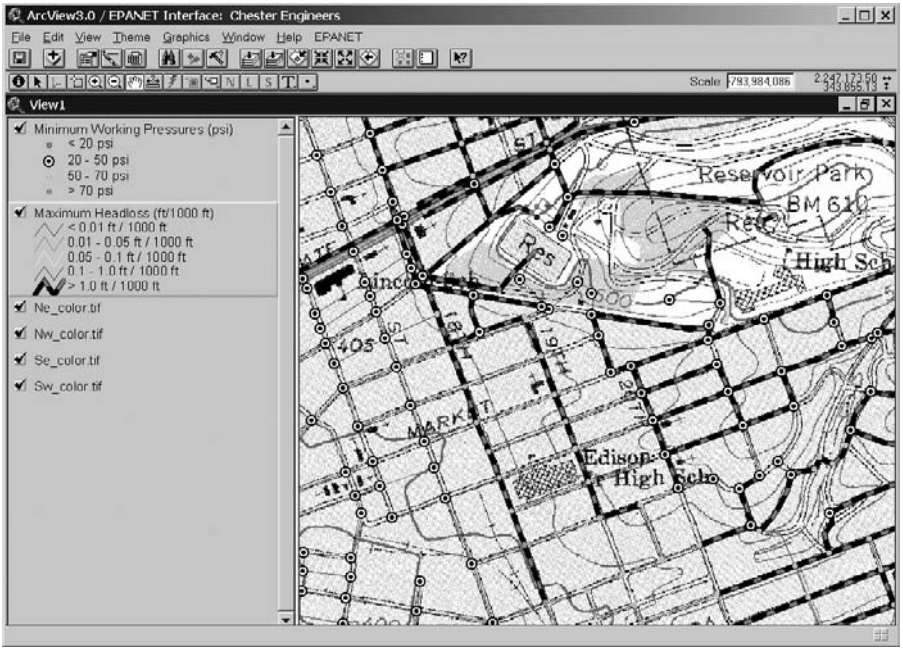

Figure 12.9 EPANET output results presented as a map in ArcView GIS.

NETWORK SKELETONIZATION

GIS and CAD layers of water distribution systems often have a level of detail that is unnecessary for analyzing system hydraulics. This can include hydrants, service connections, valves, fittings, and corner nodes. Although development of models that are an exact replica of the real system is now possible due to enormously powerful computers, the cost of purchasing, developing, and running very large models can be excessive. Attempting to include all the network elements could be a huge undertaking that may not have a significant impact on the model results (Haestad Methods, 2003). Modelers, therefore, resort to a network simplification process, which is also referred to as the "skeletonization" process.

Network simplification is needed to increase processing speed without compromising model accuracy. Manual skeletonization is a cumbersome process. Modelers, therefore, have resorted to rules-of-thumb, such as excluding all pipes smaller than a certain size. This approach requires a significant effort in locating and removing the candidate pipes. In addition, the network integrity and connectivity might be adversely impacted, with a potential to alter the output results significantly.

An example of how GIS performs skeletonization is shown in Figure 12.10 to Figure 12.16. Figure 12.10 shows a portion of the water distribution system of the city of Sycamore, Illinois. It shows the GIS layers for parcels, water mains, service lines, service valves, distribution system valves, and fire hydrants. If a modeling node is created at each pipe junction, valve, and hydrant, the resulting network model (shown in Figure 12.11) would have 93 nodes and 94 pipes (links). If this process is extended to the entire system, we could expect thousands of nodes and pipes. For large

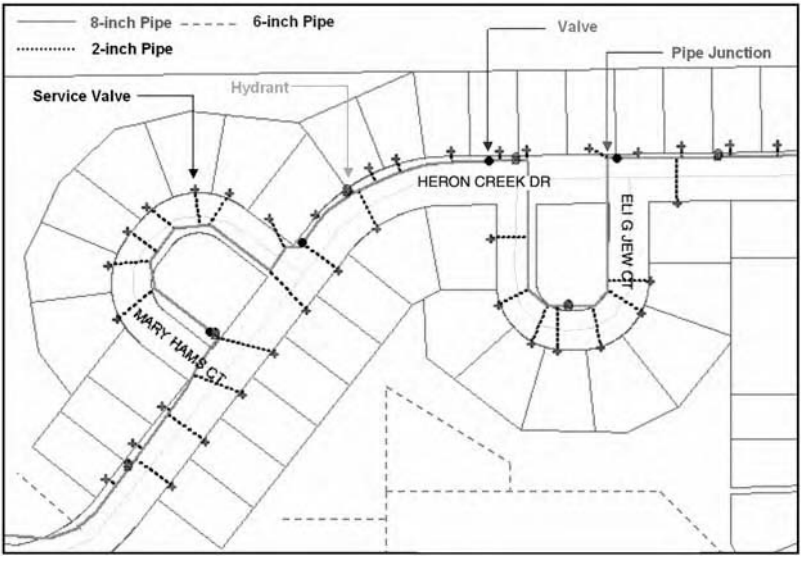

Figure 12.10 GIS layers for the Sycamore water distribution system.

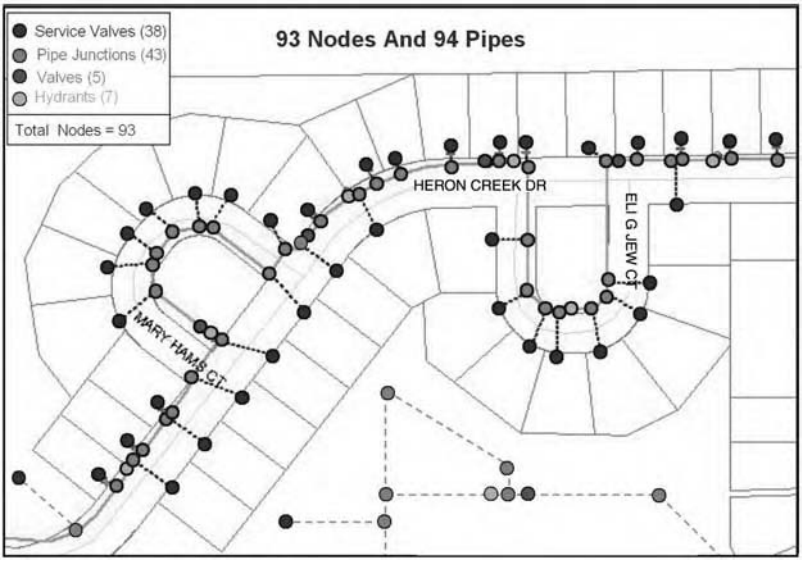

Figure 12.11 Network model without skeletonization.

systems, this process can generate several hundred thousand nodes and pipes. Skeletonization can be performed in a GIS using the following steps:

1. It is not necessary to create nodes at the fire hydrants because fire flow demand can be modeled at a nearby node. Thus, nodes corresponding to fire hydrants can be eliminated without compromising the modeling accuracy. Figure 12.12 shows the resulting skeletonized network with 86 nodes and 87 pipes. This represents an 8% reduction in the number of nodes and pipes.
2. It is not necessary to create nodes at all the distribution system valves. For example, the effect of an isolation valve (e.g., gate valves and butterfly valves) can be modeled as part of a pipe by using minor loss coefficients. In some models, closed valves and check valves can be modeled as links. Thus, nodes corresponding to most valves can be eliminated without compromising modeling accuracy. Figure 12.13 shows the skeletonized network after removing the valve nodes. It now has 81 nodes and 82 pipes representing a 13% reduction in the number of original nodes and pipes. This level of skeletonization is considered minimum.
3. It is not necessary to model corner nodes that describe actual layout of pipes. The pipe layout does not affect model output as long as the pipe length is accurate. Any potential head loss due to sharp turns and bends can be modeled using minor loss coefficients or friction factors. Thus, nodes corresponding to corner nodes can be eliminated without compromising modeling accuracy. Figure 12.14 shows the skeletonized network after removing the corner nodes. It now has 78 nodes and 79 pipes, representing a 16% reduction in the number of original nodes and pipes.

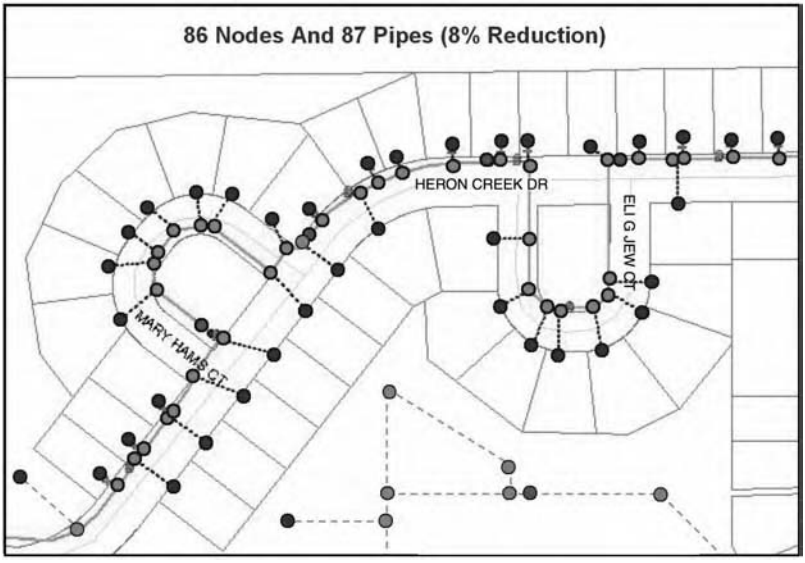

Figure 12.12 Skeletonized network model after removing nodes at fire hydrants.

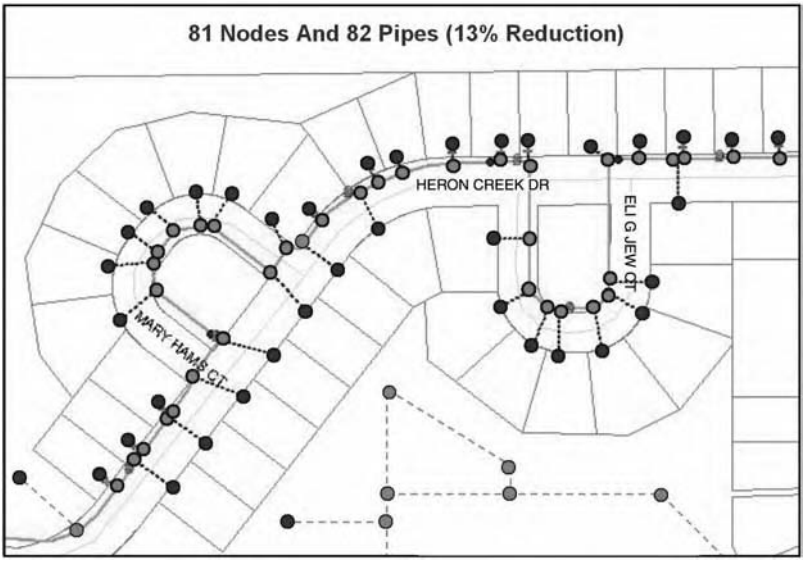

Figure 12.13 Skeletonized network model after removing nodes at valves.

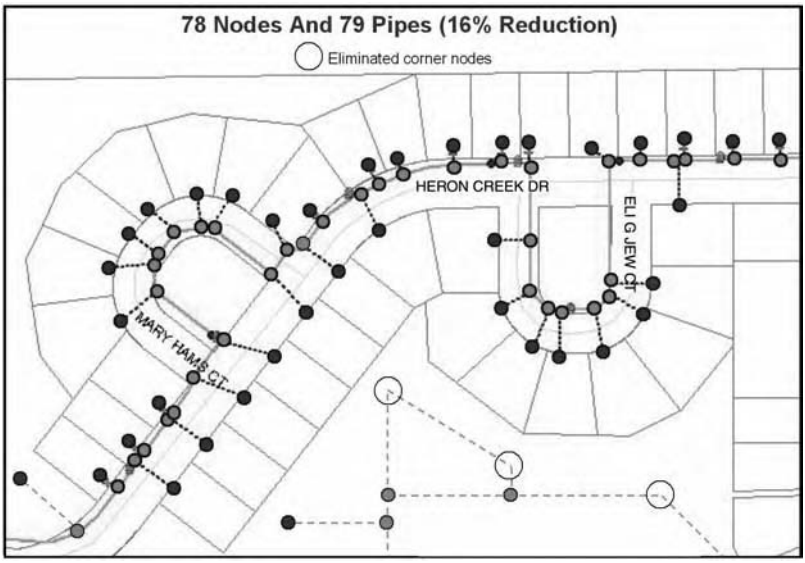

Figure 12.14 Skeletonized network model after removing corner nodes.

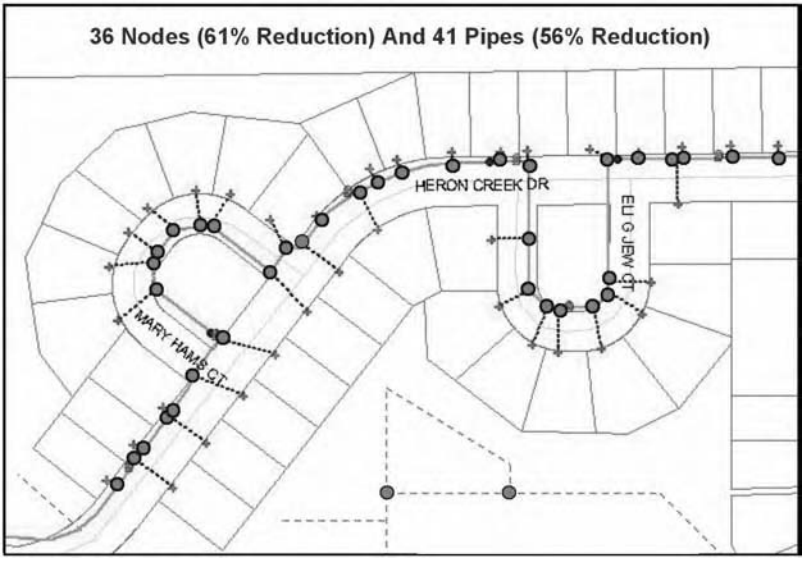

Figure 12.15 Skeletonized network model after removing pipes less than 8 in.

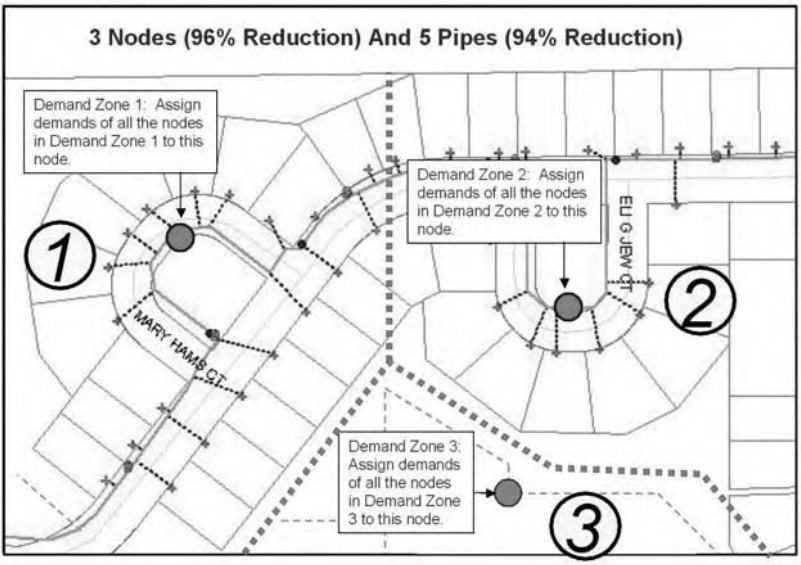

Figure 12.16 Skeletonized network model after aggregating demand nodes.

4. Small pipes with low flows can also be eliminated without significantly changing the modeling results. There are no absolute criteria for determining which pipes should be eliminated (Haestad et al., 2003). Elimination of pipes less than 6 in. or 8 in. is most common. Thus, small pipes and corresponding nodes can be eliminated for further network simplification. Figure 12.15 shows the skeletonized network after removing pipes of less than 8 in. width. The most dramatic effect of this step is the removal of all the service lines from the network model. The network now has 36 nodes and 41 pipes, representing a 56% reduction in the number of original nodes and pipes. This moderate level of skeletonization is acceptable in most cases.
5. Further reduction in the size of a network model is possible by aggregating the demands from several customers to a single node. Figure 12.16 shows the skeletonized network after dividing the network into three demand zones and assigning the total zone demand to a node inside that zone. The network now has only 3 nodes and 5 pipes, representing a 96% reduction in the number of original nodes and a 94% reduction in the number of original pipes. This high level of skeletonization can affect modeling results. For example, this model cannot model the flows and pressures at different houses within the subdivision.

Although the preceding steps can be performed manually in a GIS by editing the data layers, the process will be too cumbersome unless the system is very small. Automatic GIS-based skeletonization that can be completed quickly is now available in some software packages. Automatic skeletonization removes the complexity from the data, while maintaining the network integrity and hydraulic equivalency of the system. Reductions of 10 to 50% in the size of a network are possible. These programs allow the users to input the skeletonization criteria such as the smallest

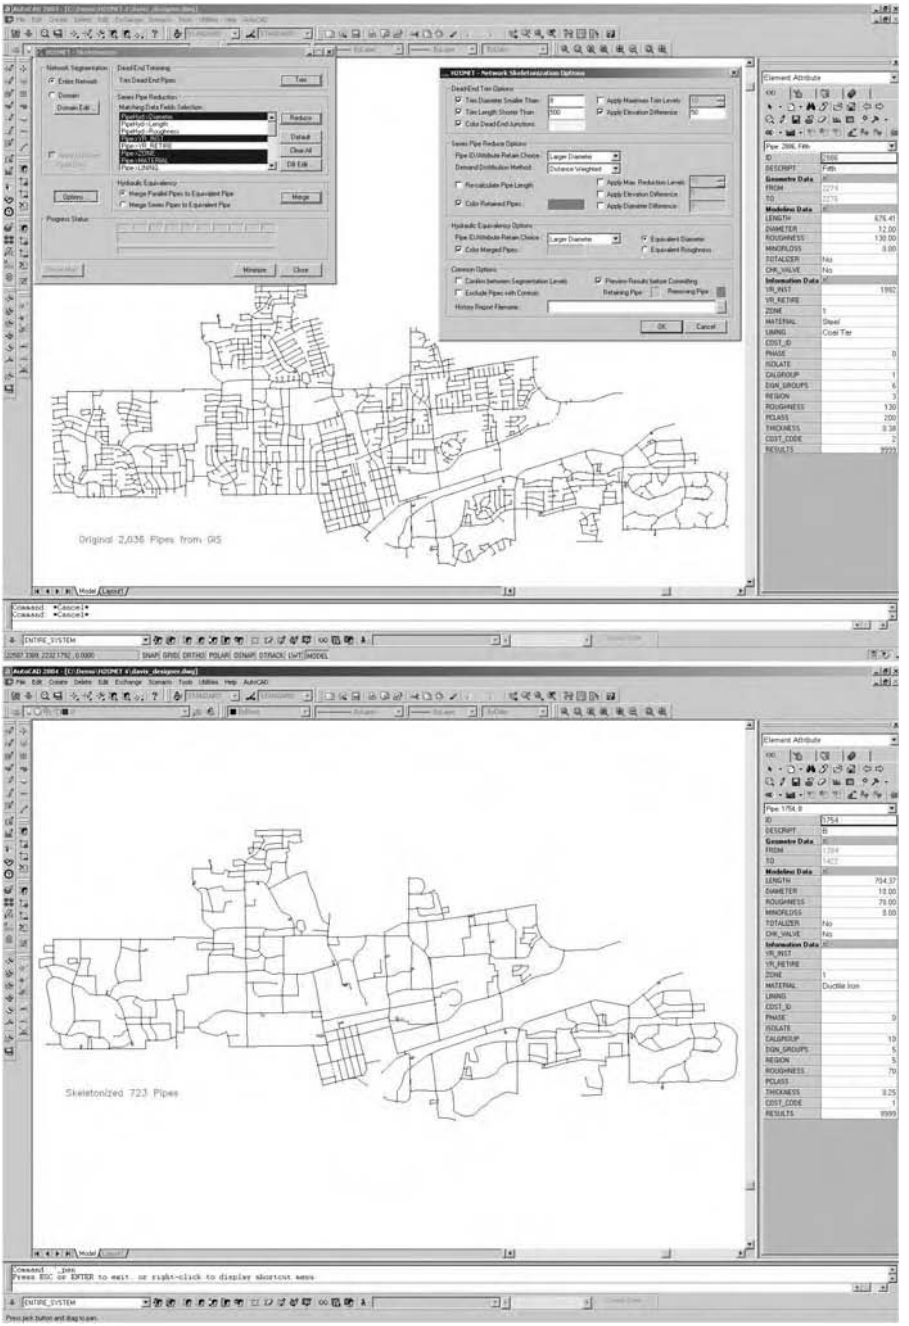

Figure 12.17 Skeletonizer's network simplification results. Top: original system with 2036 pipes. Bottom: skeletonized network with 723 pipes (65% reduction). (Maps courtesy of MWH Soft, Inc.)

pipe size that should be included in the model. The smallest-pipe-size criterion should be used carefully because both size and accuracy of the skeletonized model depend on it. A highly skeletonized model does not work well in areas where most of the water supply is through small pipes.

The Skeletonizer™ module of H_2OMap water system modeling software (MWH Soft, Inc., Broomfield, Colorado, www.mwhsoft.com) and Skelebrator™ module of WaterCAD and WaterGEMS water system modeling software (Haestad Methods, Waterbury, Connecticut, www.haestad.com) are examples of software tools that automate the skeletonization of CAD and GIS layers. Figure 12.17 shows an example of Skeletonizer skeletonization. The top screenshot shows the original network with 2036 pipes imported from a GIS. The bottom screenshot shows the skeletonized network with 723 pipes, indicating a 65% reduction in the size of the network.

Mohawk Valley Water (MVW) is a water utility serving more than 125,000 people in approximately 150 mi^2 area in central New York. In 2002, MVW created an all-pipe WaterCAD hydraulic model that was connected to a geodatabase. A reduce/skeletonize/trim (RST) process was used to eliminate hydrant laterals and private service connections to scale the hydraulic model to pipe segments 4-in. and greater. The demands, pipe attributes, and elevations were extracted from the geodatabase (DeGironimo and Schoenberg, 2002).

ESTIMATION OF NODE DEMANDS

Node demand is an important input parameter of a hydraulic model, representing the water consumption rate in units of volume/time (e.g., gallons per day or liters per second). Demands are grouped by customer type (e.g., residential, commercial, industrial, or institutional) or magnitude (e.g., average daily, maximum daily, peak hourly, or fire flow). Manual estimation of node demands from customer billing records is a cumbersome process. Modelers, therefore, have traditionally resorted to approximate methods, such as uniform distribution of the residential water use across all nodes followed by adding the nearest commercial and industrial use at various nodes. This approach requires a significant effort in fine-tuning the node demands during the model calibration phase of the project.

GIS allows implementation of more accurate demand estimation methods. One such method utilizes the GIS to geocode (or geolocate) all individual water users (defined by the address at which each meter is located) and to assign the metered water consumption rates for each meter location to the nearest node in the model. The geocoding process links a street address to a geographic location and finds the coordinates of a point location based on its street address. This method assumes that a computer file (spreadsheet or delimited text file) containing meter addresses and metered water use for specified durations (e.g., quarterly or monthly) can be produced from the utility's billing database. If this information is available, the following procedure can be used to assign demands to nodes:

1. Create a GIS layer (e.g., a Shapefile) representing all nodes in the model.
2. Obtain a street centerline layer of the system with address ranges. Such data can also be purchased from commercial GIS data vendors (Shamsi, 2002).
3. Obtain and preprocess customer meter location and consumption database.
4. Process the meter address and street address range data in the GIS to geocode the meter locations into a point layer registered to the model node layer.
5. Process the geocoded meter data to assign and aggregate individual demands to the nearest nodes.
6. Analyze the assigned metered demand to determine unaccounted-for water and metered demands that were not successfully geocoded. Uniformly distribute these remaining demands across nodes.
7. Load the node demand data into the hydraulic model.

The preceding process produces a highly accurate distribution of water use across the nodes. The intermediate product of point locations with associated demands can also be used to visualize the spatial distribution of individual demand points throughout the system. A metered demand database can also be created to include customer classes as defined in the billing system. This data can be used to assign differing demand patterns to residential, commercial, and industrial demand classes for use in extended-period simulations.

Haestad Methods' WaterGEMS hydraulic modeling software has a Loadbuilder module that allows modelers to automatically calculate and assign demands to junctions using the following three methods (Haestad Methods, 2002):

1. Customer meter data method: This method is used if geocoded customer billing data are available. It assigns the demands to nodes using any combination of the following three methods:
   - Nearest node method: This method assigns the meter demand to the nearest node.
   - Nearest pipe method: This method assigns the meter demand to the two nodes of the nearest pipe. Each node of the nearest pipe can receive equal demands or weighted demands in proportion to its distance from the meter location. Alternatively, the demand can be assigned to the pipe node closest to the meter location.
   - Meter aggregation method: This method creates *service areas* around the nodes of a hydraulic model. A service area polygon is associated with each model node, enclosing all service connections that consume their water from the node and whose consumption is aggregated to that node. Service areas can be drawn manually or using automatic methods such as the Theissen Polygon method. Programs are available for automatic delineation of Theissen Polygons in a GIS package. All the meters located within a service area are assigned to its associated node. Figure 12.18 shows the service areas created using the Thiessen Polygon method in WaterGEMS software.
2. Area water use data method: This method is used if billing meter data are not available. It assigns the demands to nodes using the following three methods:
   - Equal flow distribution: This method requires a polygon layer for various flow zones (e.g., meter routes or pressure zones) in the system. A GIS overlay of nodes and flow zone layers is conducted to divide each zone's flow equally among all the nodes within that zone.

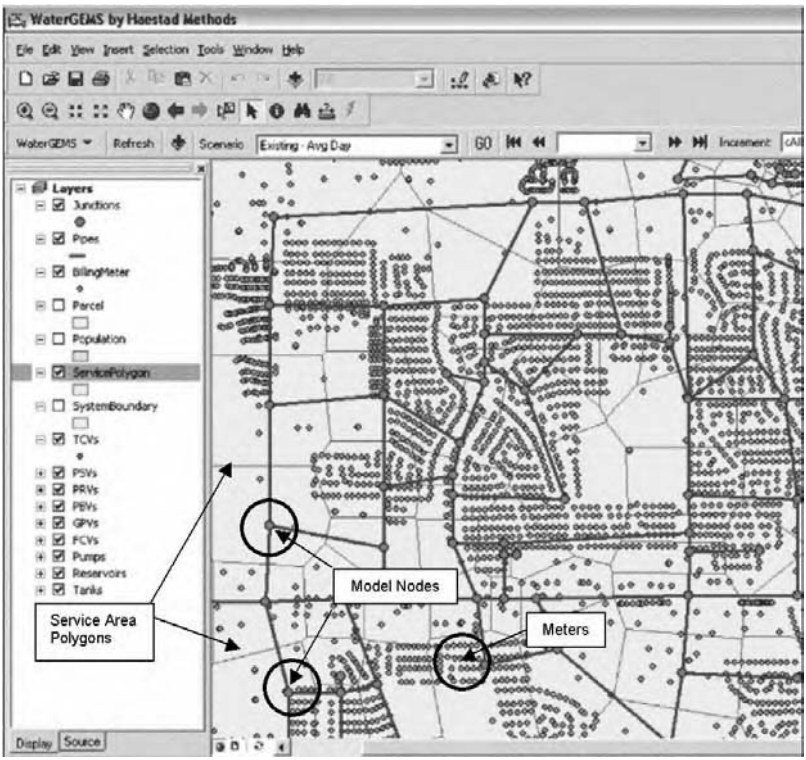

Figure 12.18 Example of meter aggregation method (WaterGEMS™ screenshot courtesy of Haestad Methods).

- Proportional distribution by area: In this method, a GIS overlay of service area (of nodes) and flow zone layers is conducted. Each zone's flow is divided among all the service area polygons within that zone in proportion to the area of service area polygons.
- Proportional distribution by population: In this method, a GIS overlay of service area (of nodes) and flow zone layers is conducted. Each zone's flow is divided among all the service area polygons within that zone in proportion to the population of service area polygons. The service area population can be calculated in GIS by conducting an overlay of service area polygons with census-block* (or census-tract) polygons.

3. Land-use/population data method: This method forecasts the future demands for nodes using the following two methods:
   - Land-use data method: This method uses future land-use polygons to forecast future demands. A GIS overlay of service area and land-use polygons is conducted to calculate the area of each land-use type within each service area. A demand factor (per unit area) is specified for each land-use type. Calculated

* Census blocks and census tracts from U.S. Bureau of Census are polygon layers of demographic data for the U.S. Additional information is available in Chapter 11.

land-use areas and demand factors are multiplied to estimate a future demand for each service area.

- Population data method: This method uses projected future population polygons to forecast future demands. A GIS overlay of service area and population polygons is conducted to calculate the future population of each service area. A demand density (gallons per capita per day) is specified by the user. Calculated future population and demand density are multiplied to estimate a future demand for each service area.

Detailed information on the preceding methods is available in *Advanced Water Distribution Modeling and Management* (Haestad et al., 2003). For future land-use mapping techniques and information on how to calculate population from U.S. Bureau of Census GIS data (e.g., Census blocks and tracts), please refer to *GIS Tools for Water, Wastewater, and Stormwater Systems* (Shamsi, 2002).

Demand-Estimation Case Studies

Newport News, Virginia

In 1996, Newport News Waterworks (Newport News, Virginia) developed a water system hydraulic model composed of 540 nodes representing approximately 110,000 service connections. The model contained all pipes 12 in. and larger and some 8 in. critical pipes. Model node demands were computed using the meter aggregation method described in the previous section. The service area polygons were drawn manually, which was found to be the largest engineering effort required by the modeling project. A GIS Demand Application was developed to create, modify, or delete model nodes and service area polygons. The application was developed using ArcTools, a collection of ArcInfo productivity tools implemented through an Arc Macro Language (AML) interface.

The demand data were extracted from a public utilities billing system. Average daily consumption of each customer was calculated by dividing the total consumption by the number of days in the billing cycle. The consumption data were loaded in a tabular GIS file. Account numbers were used to associate demands with service connections. Consumption for all service connections that geographically fell within a service area polygon were aggregated. The aggregated consumption was stored as an attribute of the model node (Sevier and Basford, 1996).

Round Rock, Texas

The City of Round Rock (Texas) used Haestad Methods' WaterCAD hydraulic modeling software, ESRI's ArcView GIS package, and Microsoft's Access billing database for estimating the node demands. Approximately 95% of the city's 22,000 water meters were assigned to precise geographic locations using geocoding. This

approach provided accurate node demand data and reduced model calibration time (Haestad Methods, 2002). The following steps were undertaken:

1. The geocoding process was performed in ArcView by linking the addresses within an existing parcels Shapefile to the billing address in the water meter database.
2. Using WaterCAD's Shapefile connection wizard, the node data from WaterCAD was synchronized to ArcView.
3. The modelers then drew polygons around the nodes and corresponding meters.
4. ArcView was used to sum the demand data for the meters in each polygon.
5. The total demand was applied to appropriate nodes.
6. The junction file with the newly calculated node demands was synced back to WaterCAD.

Lower Colorado River Authority, Texas

Pimpler and Zhan (2003) used an alternative grid-based (raster GIS) approach that worked well for estimating water demand for Lower Colorado River Authority. The Authority serves more than 1 million customers in Texas in an area spanning more than 29,800 mi^2. Their method involved four steps:

1. Divide the service area into grid–cells.
2. Calculate a score for each grid–cell based on weighted variables (e.g., land use, proximity to employment centers, etc.) considered important for water demand analysis.
3. Distribute the service area population proportionally to each grid–cell based on the score assigned to each cell.
4. Estimate water demand associated with each cell based on its allocated population.

ESTIMATION OF NODE ELEVATIONS

Node elevation is also an important input parameter for a hydraulic model. It is usually defined by the ground elevation. Because 2.31 ft of elevation corresponds to 1 psi of water pressure, modeling water pressure to 1-psi precision requires elevation data accurate to approximately 2 ft. Table 12.4 provides the accuracy of common sources of ground surface elevation. USGS topographic maps are generally acceptable because an elevation accuracy of 5 ft is adequate for most nodes (Walski, 2001).

Surveying provides the most accurate ground surface elevations. Unfortunately, surveying is very costly and time consuming and is recommended for critical model nodes such as the centerline of a pump or a model calibration node (Walski, 2001). Manual estimation of node elevations from contour maps or as-built plans is also a

Table 12.4 Accuracy of Ground Elevation Data Sources

Source	Accuracy (ft)
USGS 7.5-min 1:24,000-scale topographic maps	10
USGS 30-m DEMs	5–10
GPS survey — code phase	10
GPS survey — carrier phase	1
Digital orthophotos	1

cumbersome process. A GIS allows automatic computation of node elevations from DEM data using the following procedure:

1. Create a GIS layer (e.g., a Shapefile) for the nodes in the model.
2. Obtain a DEM layer covering the water distribution service area.
3. Georeference (georegister) the node and DEM layers (i.e., assign both layers the same map projection system).
4. Overlay the node layer over the DEM layer to assign DEM elevations to nodes. Interpolate in between the DEM grid cells (pixels) to estimate the correct elevation at each node.
5. Load the node elevation data into the model.

Figure 12.19 shows an overlay of a water distribution system layer over a DEM layer for calculating node elevations.

WaterGEMS has a TRex Wizard that automates extraction of elevation data from a DEM layer and assigns the extracted data to model nodes. TRex uses the preceding steps to calculate node elevations. It interpolates in between the DEM pixels (grid–cells) rather than using a simple spatial join. A spatial join is less accurate

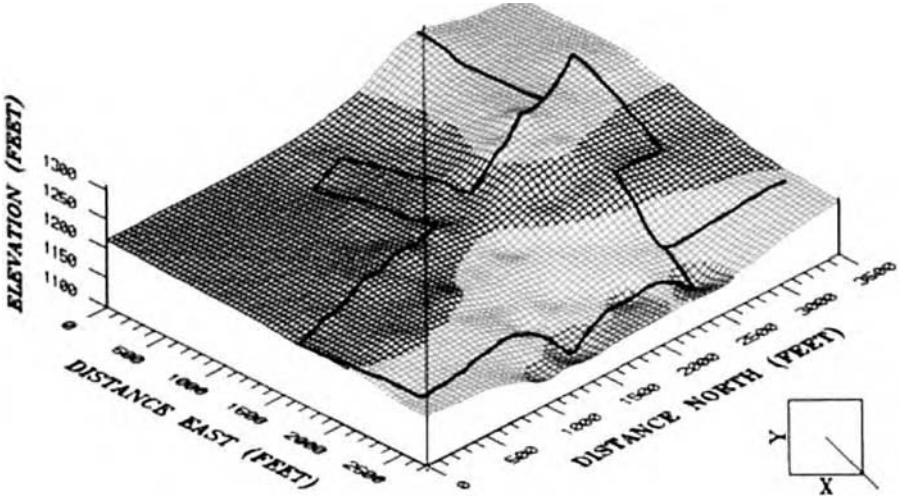

Figure 12.19 Water distribution system draped over a DEM

because nodes that fall in between the DEM pixels would be assigned the elevation of the nearest cell.

PRESSURE ZONE TRACE

A GIS also allows identification of various pressure zones in a water distribution network. This is done by selecting a network pipe or node that is part of a larger pressure zone. The GIS traces the water network in all possible directions until either sources of water or assets (e.g., pressure regulating valves — PRVs) that isolate water flow are found. All the pipes (or nodes) in the selected pressure zone are highlighted. A buffer can be created around the highlighted features to create a polygon for the pressure zone boundary. Once the trace is complete, the user can assign a pressure zone attribute to the selected pipe or node.

CHAPTER SUMMARY

This chapter shows that GIS offers many useful applications for water distribution systems. The applications described in this chapter indicate that GIS provides many powerful and efficient tools for performing various hydraulic modeling tasks such as network skeletonization, demand calculation and allocation, and elevation calculations. The case studies and examples presented in the chapter illustrate that many water utilities are successfully using GIS applications for hydraulic modeling of their water distribution systems. Various software examples presented in the chapter indicate that many commercial off-the-shelf software packages are available to help users benefit from hydraulic modeling applications of GIS.

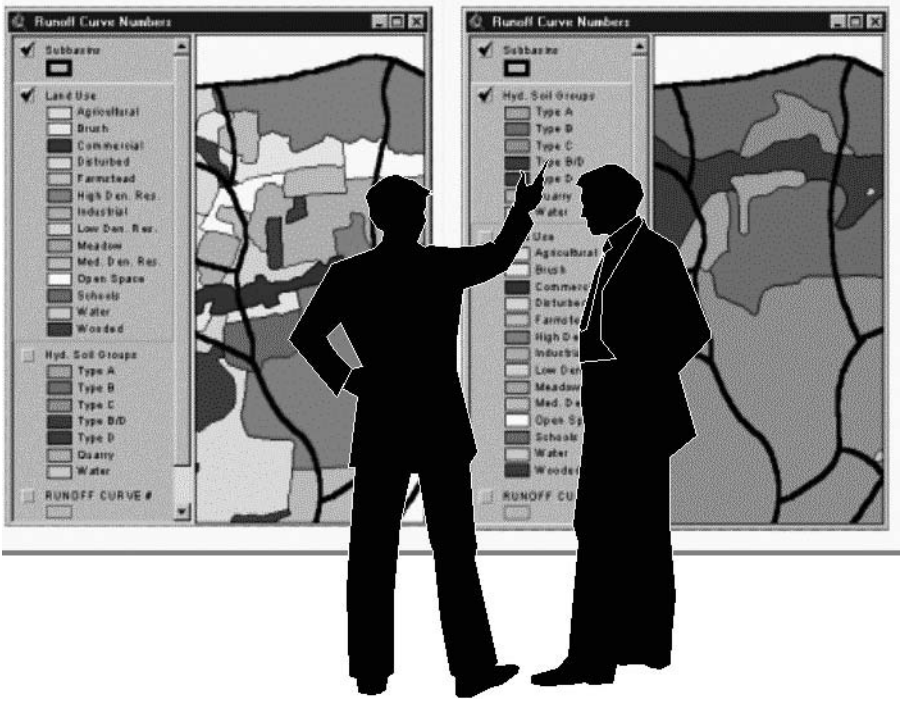
CHAPTER QUESTIONS

1. Prepare a list of GIS applications for water distribution systems.
2. Which hydraulic modeling tasks can be performed using GIS?
3. What are the typical input parameters for a water distribution system hydraulic model? Which of these parameters can be obtained from a GIS?
4. List the GIS data layers that are useful for hydraulic modeling.
5. How does a GIS help in presenting model output results?
6. What is skeletonization? How does a GIS help this task?
7. List the hydraulic models you are familiar with. Which of these models use a GIS? Which method of GIS linkage (interchange, interface, or integration) do they use?

CHAPTER 13

Sewer Models

GIS saves time and money in developing sewer system models for simulating flows and depths in the collection system. GIS also helps to prepare maps of the model results, which can be easily understood by nonmodelers.



GIS-based sewer models bridge the gap between information and its recipients.

LEARNING OBJECTIVES

The learning objectives of this chapter is to understand how GIS can be applied in developing sewer system hydraulic models, and to understand how GIS can be used to present modeling results

MAJOR TOPICS

- Representative sewer models
- Storm Water Management Model (SWMM)
- Graphical user interface (GUI)
- SWMM applications
- Data preparation
- Interface development steps
- GIS application case studies

LIST OF CHAPTER ACRONYMS

CMOM Capacity, Management, Operations, and Maintenance
CSO Combined Sewer Overflow
DSS Decision Support System
EPA (U.S.) Environmental Protection Agency
GUI Graphical User Interface
HEC Hydrologic Engineering Center
HGL Hydraulic Gradient Line
LTCP Long-Term Control Plan (for CSOs)
NMC Nine Minimum Controls (for CSOs)
NPDES National Pollution Discharge Elimination System
ODBC Open Database Connectivity
OLE Object Linking and Embedding
SHC System Hydraulic Characterization (for CSOs)
SSO Sanitary Sewer Overflow
SWMM Storm Water Management Model

MAPINFO™ AND SWMM INTERCHANGE

Application area	Basement flooding modeling using the Interchange GIS Linkage Method described in Chapter 11 (Modeling Applications)
GIS software	MapInfo
Modeling software	SWMM
Other software	Microsoft Access
GIS data	Sewer pipes, aerial photographs, buildings and parking lot polygons
GIS format	Raster and vector
Study area	City of Portland, Oregon
Organization	Bureau of Environmental Services, City of Portland, Oregon

In the late 1990s, Portland's Bureau of Environmental Services (BES) developed a suite of GIS and database tools to develop data for SWMM models. Model data were

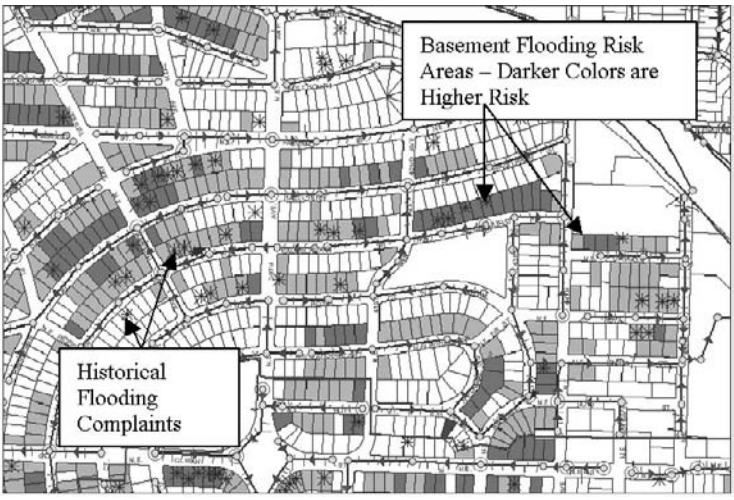


Figure 13.1 Thematic map showing flooding risk and historical complaints (map courtesy of Computational Hydraulic Int.).

developed from maps and databases with automation of many of the steps for data extraction, variable assignments, and model building. Detailed collection-system models of basins were developed to analyze local areas. These models contained essentially all of the pipes in the collection system and utilized two subcatchment definitions to place runoff into the system in the correct location. Surface water subcatchments were defined as the areas that flowed into the sewer through street inlets in the public right-of-way. Direct connection subcatchments were defined as the areas that contributed to sanitary and stormwater drainage through service laterals.

A GIS tool was developed to predict flooding of individual parcels by overlaying modeled hydraulic gradient lines (HGLs) with estimated finished floor elevations obtained from a DEM. Detailed SWMM RUNOFF and EXTRAN models were developed from facility maps and photogrammetric data with the use of a MapInfo GIS and a Microsoft Access database. The SWMM model showed that many of the system capacity problems were in the local areas at the upstream ends of the system and that the local collection system tended to hold water back from the downstream trunk sewers in the system. This better understanding of where flooding was likely to occur and where system capacity constraints actually occurred allowed BES a top-down view of the basin during alternatives analysis. Local inflow control alternatives were considered first, and pipe upsizing along with passing the problem downstream was the second alternative. Figure 13.1 shows a thematic map showing flooding risk and historical complaints (Hoffman and Crawford, 2000).

GIS APPLICATIONS FOR SEWER SYSTEMS

GIS applications for sewer systems include (Shamsi, 2002):

- Performing H&H modeling of collection systems, including:
  - Automatic delineation of watersheds, sewersheds, and tributary drainage areas

    - Model simplification or skeletonization to reduce the number of manholes and sewers to be included in the H&H model
    - Estimating surface elevation and slope from digital elevation model (DEM) data
    - Estimating dry-weather sewage flow rates from land use, census data, and billing records
    - Estimating wet-weather sewage flow rates from land use, soil, surface imperviousness, and slope
- Creating maps for wastewater National Pollution Discharge Elimination System (NPDES) permit requirements (as described in Chapter 9 [Mapping Applications]), such as:
    - U.S. Environmental Protection Agency's (EPA) combined sewer overflow (CSO) regulations, such as System Hydraulic Characterization (SHC), Nine Minimum Controls (NMC), and long-term control plan (LTCP)
    - U.S. EPA's sanitary sewer overflow (SSO) regulations, such as capacity, management, operations, and maintenance (CMOM)
- Documenting field inspection data (as described in Chapter 15 [Maintenance Applications]), including:
    - Work-order management by clicking on map features
    - Inspection and maintenance of overflow structures and manholes
    - Television (TV) inspection of sewers
    - Flow monitoring and sampling
    - Smoke-testing, dye-testing, and inflow/infiltration (I/I) investigations
- Performing and planning tasks such as assessment of the feasibility and impact of system expansion

In this chapter, we will focus on the sewer system H&H modeling applications of GIS.

SEWER SYSTEM MODELING INTEGRATION

Tight integration between a sewer model and a GIS is highly desirable.

The GIS applications in sewer system modeling are developed by using the three application methods (interchange, interface, and integration) described in Chapter 11 (Modeling Applications). These methods facilitate preparation of model-input data and mapping of model output results similar to their application for water system models described in Chapter 12 (Water Models).

Transfer of data between a GIS and a sewer model is handled differently by different software vendors. Some products offer nothing more than a manual cut-and-paste approach for transferring data between a GIS and the model. Others offer a truly integrated package. Obviously, tight integration between the sewer model and the GIS is desirable. However, it should not be assumed that a tightly integrated model is the best modeling tool. For example, the interchange or interface capability of a comprehensive sewer model might be more useful for some users compared with a tightly integrated model having limited modeling capability to simulate complex situations such as surcharged sewers.

SOFTWARE EXAMPLES

Sewer system modeling software is used to compute dry- and wet-weather flow for hydraulic analysis and design of collection systems and wet-weather control facilities such as storage tanks and equalization basins.

Table 13.1 lists representative sewer system modeling packages and their GIS capabilities, vendors, and Web sites. The salient GIS features of some programs are described in the following subsections.

What is common among the recent software developments is a transferability of fundamental database information, also referred to as a decision support system (DSS). Under a DSS framework, neither the GIS nor the model is central to the process. Both perform satellite functions for a central master database. (Heaney et al., 1999).

SWMM

Numerous hydrologic models were created in the U.S. during the 1970s, including the U.S. EPA's legacy computer program SWMM and the U.S. Army Corps of Engineers' Hydrologic Engineering Center's HEC series of models (HEC-1 through 6). Two of the most popular models, HEC-1 and HEC-2, have been updated and renamed HEC-HMS and HEC-RAS.

Collection system hydraulics can be characterized by using an H&H computer model such as SWMM. SWMM is a comprehensive computer model for analysis of quantity and quality problems associated with urban runoff. Both continuous and single-event simulation can be performed on catchments having sanitary

sewers, storm sewers, or combined sewers and natural drainage, for prediction of flows, stages, and pollutant concentrations.

SWMM is one of the most successful models produced by EPA for the wastewater environment. SWMM was developed from 1969 to 1971 as a mainframe computer program and has been continually maintained and updated. Versions 2, 3, and 4 of SWMM were distributed in 1975, 1981, and 1988, respectively. The first batch-mode microcomputer version of SWMM (Version 3.3) was released by EPA in 1983. The first conversational-mode user-friendly PC version of SWMM, known as PCSWMM, was commercially distributed in 1984 by Computational Hydraulics, Inc., of Guelph, Ontario (Computational Hydraulics, 1995). The first PC version of EPA's SWMM was Version 4, which was distributed in 1988 (Huber and Dickinson, 1988; Roesner et al., 1988). An excellent review of SWMM's development history can be found in the book by James (1993).

SWMM is regarded as the most widely used urban H&H model in the U.S. (Heaney et al., 1999). SWMM continues to be widely used throughout the world for analysis of quantity and quality problems related to stormwater runoff, combined sewers, sanitary sewers, and other drainage systems in urban areas, with many applications in nonurban areas as well. From 1988 through 1999, the EPA Center for Exposure Assessment Modeling in Athens, Georgia, distributed approximately 3600 copies of SWMM. The University of Florida distributed roughly 1000 copies of SWMM in the late 1980s. Third-party interfaces for SWMM, such as MIKE-SWMM, PCSWMM, and XP-SWMM, have several thousand users. The number of subscribers to the SWMM Users Group Internet discussion forum (Listserv) on the Internet is nearly 10,000 (EPA, 2002).

The current version (4.3) was released by EPA in May 1994 for the 16-bit MS-DOS operating system. Professor Wayne Huber of Oregon State University, one of the authors of SWMM, has developed several updated versions of SWMM 4. His latest version (4.4H) was updated in March 2002. All of these and previous SWMM versions were written in the FORTRAN programming language. None of them have a user interface or graphical capability. Users must provide ASCII text input and rely on ASCII text output. EPA is currently developing an updated version of SWMM referred to as SWMM 5. Written in the C++ programming language, SWMM 5 will incorporate modern software engineering methods as well as updated computational techniques. The modular, object-oriented computer code of SWMM 5 is designed to simplify its maintenance and updating as new and improved process submodels are developed. The new code will also make it easier for third parties to add GUIs and other enhancements to the SWMM engine. This approach follows the same approach used by the highly successful EPANET model from EPA (described in Chapter 12 [Water Models]), which analyzes hydraulic and water quality behavior in drinking water distribution systems (Rossman, 2000).

SWMM simulates dry- and wet-weather flows on the basis of land use, demographic conditions, hydrologic conditions in the drainage areas, meteorological inputs, and conveyance/treatment characteristics of the sewer system. The modeler can simulate all aspects of the urban hydrologic and quality cycles, including rainfall, snow melt, surface and subsurface runoff, flow routing through drainage

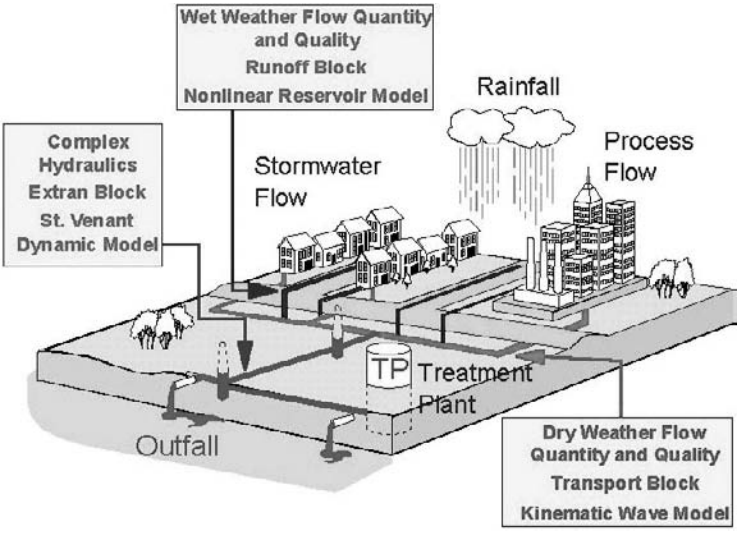

Figure 13.2 SWMM conceptual schematic.

network, storage, and treatment. Statistical analyses can be performed on long-term precipitation data and on output from continuous simulation. Figure 13.2 shows a conceptual schematic of SWMM. This figure shows that SWMM is a complex model capable of modeling various phases of the hydrologic cycle using different blocks (modules) such as RUNOFF, TRANSPORT, and EXTRAN.

SWMM can be used both for planning and design. Planning mode is used for an overall assessment of the urban runoff problem or proposed abatement options. SWMM is commonly used to perform detailed analyses of conveyance system performance under a wide range of dry- and wet-weather flow conditions. These days, SWMM is frequently used in the U.S. for modeling wet-weather overflows including CSO, SSO, and stormwater discharges from collection systems. As such, it is the model of choice for use in many collection-system modeling studies. For example, SWMM can be used to develop a CSO model to accomplish various tasks leading to the development of a CSO Plan of Actions mandated by EPA. These tasks include characterizing overflow events, developing the CSO vs. rainfall correlation, maximizing the collection-system storage, and maximizing the flow to the treatment plant. The CSO model can also be used to develop the EPA-mandated LTCPs to evaluate various CSO control options. Sizing of CSO control facilities such as a wet-weather equalization tank requires CSO volume and peak discharge, both of which can be modeled using SWMM.

The use of SWMM to model wet-weather overflows is particularly advantageous for the following reasons:

- SWMM produces estimates of present and future dry- and wet-weather flow rates. Flow estimates can be prepared based upon present and future land-use

conditions, topography, sewer characteristics, and selected meteorological conditions. The model can be calibrated against measured flow rates.
- SWMM models the performance of the conveyance system under a range of dynamic flow conditions.
- Using SWMM, it is possible to assess hydraulic capacity in response to wet-weather input. This characteristic can be very useful for analyses related to abatement of overflows.

SWMM is flexible enough to allow for different modeling approaches to the same area. An approach that adequately describes the service area and accurately computes and routes the flows at reasonable computing time and effort should be adopted. The following modeling strategy is generally used for modeling wet-weather overflows:

- Delineate sewersheds (the drainage areas tributary to overflows, also referred to as subareas or subbasins).
- Use the TRANSPORT Block to generate sewershed dry-weather flows.
- Use the RUNOFF Block to generate sewershed wet-weather flows.
- Combine dry-weather and wet-weather flows to generate combined sewershed flows.
- Use the EXTRAN Block to route the flows through the collection and interceptor system.

SWMM Graphical User Interface

Most users have now become accustomed to modeling in a point-and-click computing environment that provides a user-friendly graphical user interface (GUI). A GUI is a computer program that acts as an interpreter between users and their computers. It is designed to minimize (but not eliminate) the need for human experts and to guide the modeler through the intricacies of a particular numerical model. A GUI provides a suite of tools to create a decision support system for the numerical model that has been adopted. It also stimulates user interest and facilitates interpretation of model results. A GUI improves productivity by increasing the efficiency of data entry, eliminating data errors through expert-checking, and the use of decision-support graphics and interpretation tools. It replaces difficult-to-remember text commands by interactive computer graphics consisting of menus, dialogue boxes, input and output windows, and icons. The main goal of using GUIs is to develop user-friendly computer applications or to

add user-friendliness to existing command-line-driven applications. For example, Microsoft Internet Explorer is a GUI for user-friendly access to the Internet.

Modern software offer pull-down menus, toolbars, icons, buttons, dialogue boxes, hypertext, context-sensitive online help, etc., which are not available in legacy computer programs including SWMM 4. Many commercial modeling packages now offer on-screen point-and-click drawing and editing of drainage network maps, but unfortunately some legacy programs still rely on ASCII text input and output files. SWMM was developed in an era when input files were created on punched cards. After 30 years, SWMM 4 now runs on personal computers, but it is still a text-based, nongraphical DOS program. It reads ASCII input to produce ASCII output, which is most suitable for mainframe line printers. SWMM's ASCII format output is long, boring, difficult to interpret, and not very useful for nonmodelers. Creating computer models and reviewing the model results is often slowed by our inability to see the system being modeled. It is up to the modeler to review SWMM's voluminous output and construct a mental image of the physical system being modeled. Often, the limitation in understanding the model output has been the modeler's own comprehension of the output, not the model itself. Quite frequently, it is impossible for the modeler to absorb the large amount of information contained in the model output (TenBroek and Roesner, 1993).

A GUI and a GIS can be employed to overcome SWMM's input/output deficiencies. Two types of GUIs can be employed for GIS applications in SWMM modeling (Shamsi, 1997; Shamsi, 1998):

- An input interface (also called a front-end interface or preprocessor) extracts SWMM input from GIS layers and creates SWMM's traditional ASCII text input file. The input GUIs can also provide graphical tools to draw a network model that is subsequently converted to SWMM's ASCII input file. For example, an input interface may extract sewer-segment lengths and manhole coordinates from the sewer and manhole layers.
- An output interface (also called a back-end interface or postprocessor) converts text to graphics. It can convert SWMM's traditional ASCII text output file to graphs, charts, plots, and thematic maps that can be easily understood by everyone.

With the help of these GUI/GIS tools, everybody can understand the model output. These tools help one to see storm-surge progress through the sewer system and pinpoint areas of flooding and surcharging. More than just reams of computer paper, such models become automated system-evaluation tools. Other benefits of GUI/GIS tools are:

- Preparation of network schematics is not essential. Digitized plots of sewers and subarea boundaries can be used to create a drainage network diagram on a computer screen.
- Zoom and pan features make it possible to display even the largest networks conveniently on the screen.
- Connectivity data errors are easily detected and can be edited while still in the program. Instabilities in the model output, often the most difficult errors to find, are also easily located.

- Flow and depth data from SWMM output can be displayed in either plan or profile view, providing an animated display of the HGL during the simulation time steps.
- Flow and HGL time-series plots can be displayed for any conduit or node in the hydraulic network.
- Field-collected flow and depth data can be displayed along with the model output for model calibration and verification.
- Network graphics and modeled hydrographs can be exported to word processors to aid in report preparation.

XP-SWMM and XP-GIS

XP-SWMM by XP Software (Belconnen, Australia and Portland, Oregon) is a full-fledged 32-bit Microsoft Windows application. The program has been enhanced by the addition of a graphics database, and an adaptive dynamic wave solution algorithm that is more stable than the matrix method used in the original SWMM. The program is divided into a stormwater layer, which includes hydrology and water quality; a wastewater layer, which includes storage treatment and water quality routing for BMP analysis; and a hydrodynamic/hydraulics layer for simulation of open or closed conduits (Heaney et al., 1999).

XP-SWMM is also included in Visual SWMM from CaiCE Software Corp. (Tampa, Florida). Basically, XP-SWMM and Visual SWMM are GUI programs for SWMM. The user-friendly GUI is based upon a graphical representation of

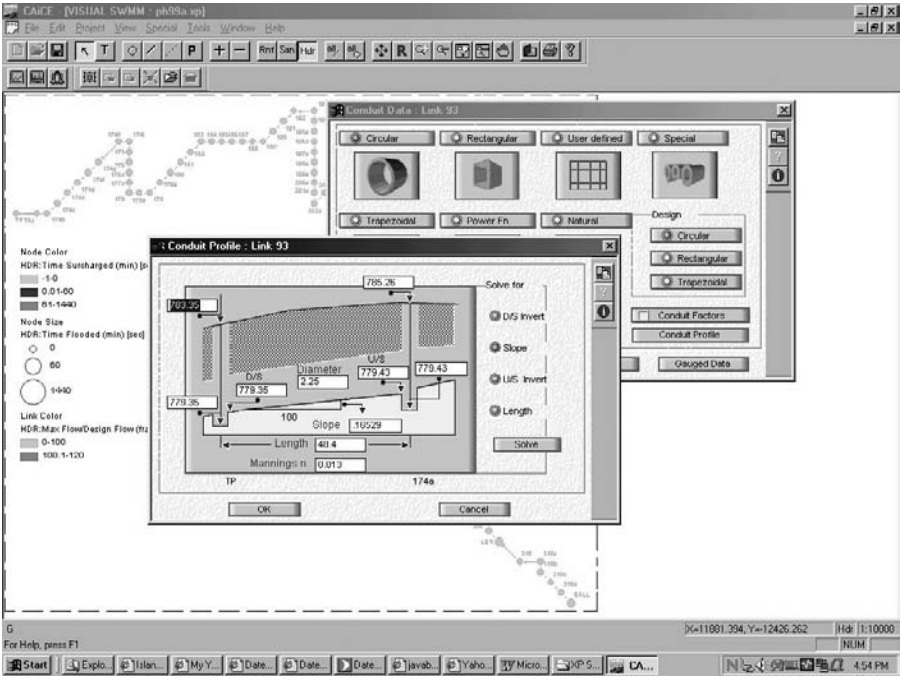

Figure 13.3 Visual SWMM screenshot.

the modeled system using a link-node architecture. It provides a shell that acts as an interpreter between the user and the model. It facilitates on-screen development of a SWMM model in the form of a link-node network. Figure 13.3 shows a Visual SWMM (Version 7) screenshot.

Because the links and nodes are set up on a coordinate-system basis, files can be translated between most CAD and GIS software systems using the interchange method. CAD or GIS files can also be used as a backdrop for the system being modeled. Although XP-SWMM is not linked or integrated to a GIS package, it provides an optional utility called XP-GIS to extract model input data from the existing GIS database tables. XP-GIS is a module for linking XP-SWMM to GIS databases. Its main purpose is to facilitate the import and export of modeling data from GIS and other data sources such as spreadsheets, asset management software, and OLE/ODBC compliant databases. It also allows for the inclusion of Shapefiles as background layers and for data to be viewed and manipulated in an XP-SWMM graphical environment.

GIS Data for SWMM

GIS layers for land use, elevation, slope, soils, and demographics can be processed to extract model parameters for input to various SWMM Blocks and other collection system models. The basic input parameters to be assembled into the RUNOFF Block input files include sewershed area, overland flow slope, overland flow width, percent imperviousness, roughness coefficients, and soil infiltration parameters. Area, slope, and percent imperviousness can be computed from the GIS layers. Table 13.2 shows sample sewershed RUNOFF data extracted from GIS layers using the interchange method for a study area in Pennsylvania.

GIS layers can also be used to estimate inputs for sewershed population, population density, number of houses, average family size, average market value of houses, average family income, and the predominant land-use type for the TRANSPORT Block. Table 13.3 shows sample sewershed TRANSPORT data extracted from GIS layers using the interchange method for a study area in Pennsylvania.

Estimating Green-Ampt Parameters Using STATSGO/SSURGO GIS Files

Based on their resolution, there are three types of U.S. Natural Resources Conservation Service (NRCS) (formerly the U.S. Soil Conservation Service or SCS) soils data that are useful in GIS applications:

- National Soil Geographic (NATSGO)
- State Soil Geographic (STATSGO)
- Soil Survey Geographic (SSURGO)

SSURGO provides the highest resolution soils data at scales ranging from 1:12,000 to 1:63,360. This resolution is appropriate for watersheds a few squares miles in area. STATSGO data are digitized at 1:250,000-scale, which is useful when

analyzing large regional watersheds. NATSGO data describe variations in soil type at the multistate to regional scale, which is not suitable for wastewater and stormwater modeling applications (Moglen, 2000).

The steps for estimating Green-Ampt parameters using STATSGO GIS data are given in the following text:

1. Download the STATSGO database files from the NRCS Web site (www.ftw.nrcs.usda.gov/stat_data.html).
   - comp.dbf — Attribute HYDGRP has Hydrologic Soil Groups (A, B, C, etc.)
   - layer.dbf — Attribute TEXTURE2 has soil texture (S [sand], SIL [silt], etc.)
2. Join the soils layer to the preceding tables using the MUID attribute that provides a common link between the soils layer and the STATSGO database files.

Table 13.4 Sample EXTRAN Input Data

KS Look-Up Table	
HYDGRP	**KS**
A	0.375
B	0.225
C	0.100
D	0.025

MD Look-Up Table		
Soil	**TEXTURE2**	**KS**
Sand	S	0.31
Sandy loam	SL	0.28
Silt loam	IL	0.26
Loam	L	0.23
Sandy clay loam	SCL	0.18
Clay loam	CL	0.16
Clay	C	0.13

SU Look-Up Table		
Soil	**TEXTURE2**	**SU**
Sand	S	4
Sandy loam	SL	8
Silt loam	SIL	12
Loam	L	8
Clay loam	CL	10
Clay	C	7

3. Perform an overlay of soils with subareas layer to estimate:
   - Percentage of HYDGRP in each subarea
   - Percentage of TEXTURE2 in each subarea
4. Calculate the Green-Ampt parameters (saturated hydraulic conductivity KS, initial moisture deficit IMD, and average capillary suction SU) for each subarea using the look-up tables shown in Table 13.4. These look-up tables are based on the data provided in SWMM's users manual (Huber and Dickinson, 1988).

GIS APPLICATIONS FOR SWMM

Representative GIS applications in SWMM modeling are given in the following subsections.

AVSWMM

Shamsi (1997) developed an ArcView GIS interface called AVSWMM for collection-system and wet-weather overflow modeling. Both RUNOFF and EXTRAN Blocks were included. The interface was developed by customizing ArcView 3.2, using Avenue. Avenue is ArcView's native scripting language and is built into ArcView 3.x. Avenue's full integration with ArcView benefits the user in two ways: (1) by eliminating the need to learn a new interface and (2) by letting the user work

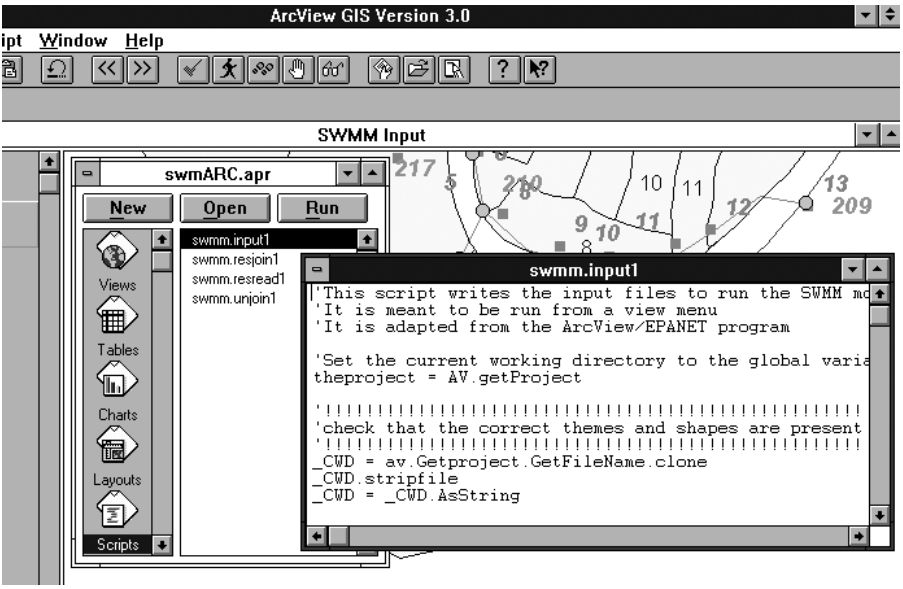

Figure 13.4 ArcView 3.x integrated programming interface for writing avenue scripts.

with Avenue without exiting ArcView (ESRI Educational Services, 1995). Figure 13.4 shows ArcView's integrated programming interface, using Avenue.

The AVSWMM interface was developed as two separate extensions, one each for the RUNOFF and the EXTRAN Blocks of SWMM.

AVSWMM RUNOFF Extension

When the extension is loaded, a menu named SWMM is added to the ArcView interface as shown in Figure 13.5. The SWMM menu has seven calculators and two functions that calculate various RUNOFF Block parameters for subareas (sewersheds). A polygon layer for subareas is required to use this extension. ArcView's Spatial Analyst Extension is required for the analysis of raster data layers. Each calculator prompts the user for the layer containing the subareas and the layer containing the data from which the model parameter is to be extracted. Each calculator adds the calculated input parameters to fields in the subarea layer. The fields are created if they do not exist. Various functions and calculators of this extension are described in the following text:

1. Average Slope Calculator

Function	Assigns average slope to subareas
Input Layers	Subarea polygon layer Slope grid
Output	Adds or updates MEANSLOPE field in subarea layer

2. Census Parameter Calculator

Function	Assigns total population and housing counts to subareas

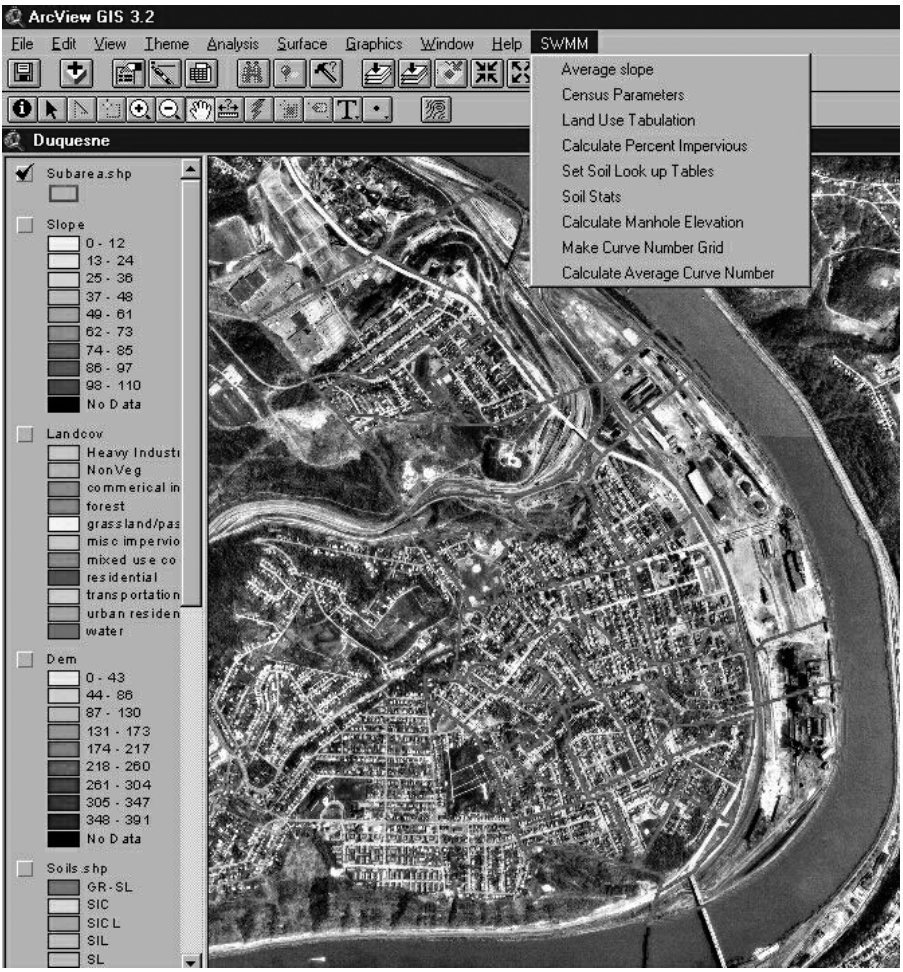

Figure 13.5 AVSWMM RUNOFF Extension.

Input Layers	Census block polygon layer	
	Subarea polygon layer	
Output	Adds or updates total population and housing fields to subareas	
	Pop100	Total Population
	Hu100	Total Households
	PopDens	Population density per acre
	HouseDens	Households density per acre
	MnFamSize	Mean family size

3. Land Use Calculator

Function	Calculates area of each land use class for subareas
Input Layers	Landuse grid layer
	Subarea polygon layer
Output	Adds fields for each land use type to subarea layer
	Calculates area for each land use type

4. Percent Imperviousness Calculator

Function	Assigns percentage of percent imperviousness for each subarea. The calculator will add a percent impervious field to the landuse polygon layer and will prompt for the percent impervious value for each land use type.
Input Layers	Landuse grid layer Subarea polygon layer
Output	Adds or updates field containing percent impervious, PERIMP, to subarea layer

5. Set Soil Look-up Tables Function

Function	Joins the look-up tables for soil infiltration parameters for the Green-Ampt method (Huber and Dickinson, 1988) IMD Initial moisture deficit KS Saturated hydraulic conductivity or permeability SU Capillary suction Additional information is presented below
Input Layers	Soils polygon layer IMD.dbf look-up table KS look-up table SU look-up table
Output	Joins the look-up tables to the soils layer

6. Soil Parameter Calculator

Function	Calculates Green-Ampt infiltration parameters, IMD, KS, and SU for subareas. The user may also select any numerical fields of the Soils layer to average.
InputLayers	Soil polygon layer Subarea polygon layer
Output	Adds or updates average soil parameters to subarea layer MNIMD Mean IMD value MNKS Mean KS value MNSU Mean SU value

7. Manhole Elevation Calculator

Function	Assigns elevation to manholes based from a DEM
Input Layers	DEM grid Manhole point layer
Output	Adds or updates ELEV field containing elevation to Manhole layer

8. Make Curve Number Grid Function

Function	Prepares a grid layer for runoff curve numbers
Input Layers	Land use layer Soil polygon layer Subarea polygon layer
Output	It overlays the land use and soil layers to make a curve number grid. The values of the grid are based on each unique combination of land use and hydrologic soil group.

9. Curve Number Calculator

Function	Calculates subarea runoff curve numbers. Although EPA's SWMM release does not use runoff curve numbers for input, many hydrologic models (e.g., HEC-HMS) and some SWMM GUI programs, such as XP-SWMM (described above) can use this parameter.

Input Layers	Curve number grid Subarea polygon layer
Output	Calculates the average curve number for each subarea. The values are added to the CURVNUM field of the Subarea layer.

AVSWMM EXTRAN Extension

Development of the AVSWMM EXTRAN Extension required the two main tasks described below:

Task 1: Create EXTRAN input file

This task requires that ArcView-compatible GIS layers (themes) exist with attribute fields for all model input parameters. The interface fetches the model input parameters from the GIS layers and exports (copies) them to an ASCII text input file specified by the user. The user should create a header file containing the model control parameters. The control parameters are entered on the A1 line (title) and on B0 to B9 lines (solution and printing instructions). The interface automatically appends this header file to the input file. A simplified example is given in the following text:

Given Data:

1. ArcView GIS layer for manholes
   Manholes layer attributes:
   - ID
   - Bottom elevation
   - Top elevation
   - Inflow rate
2. ArcView GIS layer for sewers
   Sewers layer attributes:
   - ID
   - Upstream manhole
   - Downstream manhole
   - Type (circular, rectangular, etc.)
   - Depth (diameter for circular pipes)
   - Width (not required for circular pipes)
   - Length
   - Material
   - Date installed (material and date installed can be used to automatically calculate Manning's roughness coefficient)
   - Upstream invert elevation
   - Downstream invert elevation

Data To Be Created: An ASCII text input file containing the following parameters:

- Junction (usually manhole) data:
  - Data type (D1 for junctions)
  - Manhole number
  - Top elevation (GR-EL)

  - Bottom elevation (INV-EL)
  - Inflow rate
  - Initial depth (Y0, usually 0.0)
- Conduit (usually sewer pipe) data:
  - Data type (C1 for conduits)
  - Pipe number
  - Upstream junction (FR)
  - Downstream junction (TO)
  - Initial flow (Q0, usually 0.0)
  - Type (1 for circular, 2 for rectangular, etc.)
  - Area (0.0 for circular and rectangular)
  - Depth (DEEP = diameter for Type 1, depth for Type 2)
  - Width (WIDE = width for Type 2)
  - Length (LEN)
  - ZP1 (upstream invert elevation minus upstream node bottom elevation)
  - ZP2 (downstream invert elevation minus downstream node bottom elevation)
  - N (Manning's roughness coefficient, a function of pipe material and age)
  - STHETA and SPHI (usually zero, required for open channels only)

Note that ZP1, ZP2, and N are not part of the given sewer's data, but can be estimated in ArcView from the given data. For example, if the material is concrete and the age of the pipe is less than 10 years (fair condition), then ArcView can use a look-up table to estimate N as 0.015. ZP1 and ZP2 can be similarly estimated from the upstream and downstream manhole data. Sample SWMM input lines for junctions and conduits are shown in Table 13.5.

Table 13.5 Sample EXTRAN Input Data

Task 2: Create SWMM EXTRAN output layers in ArcView GIS

This task creates model output layers in ArcView by reading EXTRAN's ASCII text output file. A database table of the relevant output results is created from the output file. The output database file is then temporarily joined to ArcView layers (usually the pipes layer). The linked output results can then be queried or used to classify a legend. A simplified example is given in the following text:
Given Data: EXTRAN's ASCII text output file. Sample SWMM output lines for junctions and conduits are shown in Table 13.6.
Data to Be Created

- An ArcView layer for manhole SWMM output
- An ArcView layer for pipe SWMM output

As shown in Figure 13.6, the AVSWMM EXTRAN interface adds a SWMM menu to ArcView's main menu. This menu has four functions: Make Input File, Read Output, Join Results, and Unjoin Results. The interface allows a user to create an EXTRAN input file, translate an output result file, join the output result file to the themes, and remove the results joined to the themes. All model runs that have been translated are eligible to be viewed. Model run data are stored in separate folders. AVSWMM EXTRAN functions are described in the following text.
Make Input File: This menu choice creates an EXTRAN input file. As shown in Figure 13.7, the user is prompted for a model input name. The input file is placed in a folder called *name*, which is under the project directory. If the folder does not exist, it is created. The function prompts for a description of the model run. It is a string that is inserted in the input file as a comment line. The function then prompts for an optional header file to attach to the input file. The header files have an extension of .hdr and are created separately by the user in a text editor. The header file contains EXTRAN input file data other than C1 and D1 records, which are already stored in the "name.inp" file.
Read Output: This menu choice translates an EXTRAN output file into GIS database files. The function prompts for an output file to translate. The program assumes the user has run the SWMM model from the input file created previously. The output file should be located in the same folder as the input file. The program translates the Conduit Summary and Junction Summary Statistics tables of the EXTRAN output into GIS databases named condsum.dbf and junctsum.dbf and stores them in the "name" folder. The function also writes a file "name.res" in the project directory. The .res file contains the absolute path to the directory where the model results are stored. This file indicates that a model has been translated. It is used to find all model runs available for linking.
Result Join: This menu choice temporarily joins the translated EXTRAN output to the ArcView attribute tables of manholes and sewers. The tool prompts the user to select a model run to link. The routine temporarily links the result databases to the attribute data. The result data can now be queried, listed, or used to classify a legend. Figure 13.8 shows ArcView database tables showing imported EXTRAN results.

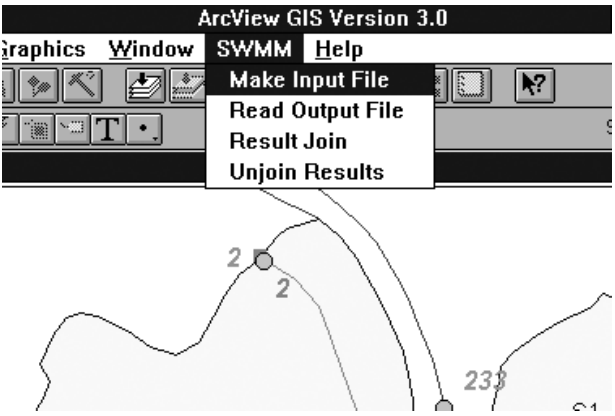

Figure 13.6 AVSWMM EXTRAN Interface.

Figure 13.9 shows a thematic map of maximum sewer flows based on classifying the Q(MAX) output variable from the EXTRAN output.

Unjoin Results: This menu choice reverses (unjoins) the link between the SWMM output and the ArcView attribute tables established by the "Results Join" menu choice. The purpose of this menu choice is to *undo* the last import of SWMM output to ArcView if the user does not like the SWMM results and wants to rerun SWMM and import the output again.

SWMMTools

SWMMTools is an ArcView extension developed by Heineman (2000). Inspired by Shamsi's work described in the preceding subsections, it allows users of SWMM 4.4 to visualize a SWMM model in conjunction with existing GIS data. SWMMTools links SWMM input and output files with ArcView GIS. It allows viewing of model input and output summary data within ArcView. The extension adds a

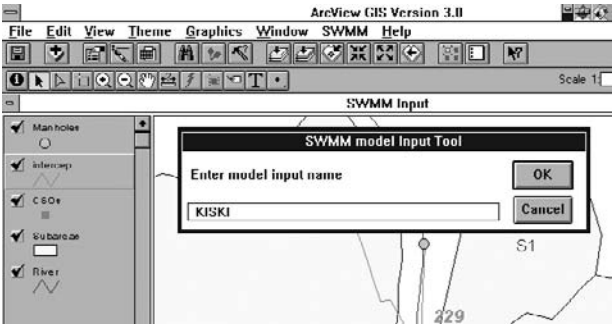

Figure 13.7 AVSWMM EXTRAN: Make Input File feature.

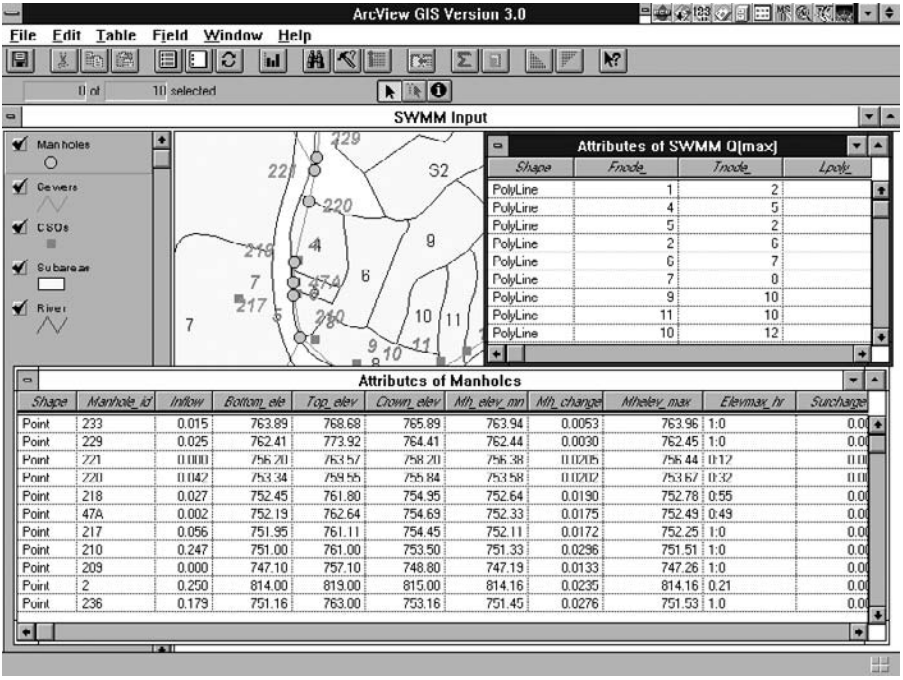

Figure 13.8 EXTRAN results in ArcView.

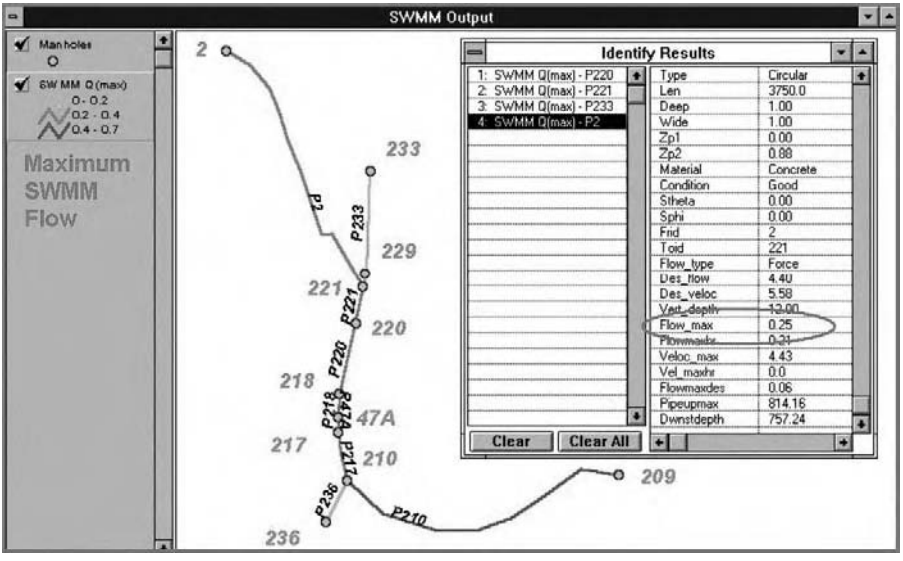

Figure 13.9 Thematic map of maximum sewer flows.

single pull-down menu to ArcView. Three scripts load plan views of RUNOFF, TRANSPORT, or EXTRAN conduit networks. Three scripts link SWMM output with existing RUNOFF, TRANSPORT, and EXTRAN GIS themes respectively. Two scripts work with a stormwater catchment theme to facilitate catchment parameterization. One estimates RUNOFF catchment widths. Another estimates RUNOFF impervious area fractions (parameter DCIA) from GIS land-use data.

AGSWMM

Existing SWMM4-ArcView3 interfaces such as AVSWMM and SWMMTools described in the preceding subsections will continue to work with SWMM4 and ArcView3 Unfortunately, these interfaces cannot work with SWMM5 or ArcView/ArcGIS8 and higher versions because of the following reasons:

1. SWMM4 and SWMM5 input file formats are different
2. SWMM4 and SWMM5 output file formats are different
3. SWMM4 and SWMM5 have different data structures (e.g., three different representations of the same pipe are not required in Runoff, Transport, and Extran Blocks)
4. ArcView3 interfaces are written in Avenue, which is not compatible with ArcView8

To benefit from new features of the new software versions, new interfaces should be developed. Shamsi and Smith (2004) developed a SWMM5-ArcView8 interface called ArcGIS SWMM (AGSWMM). The main features of AGSWMM are listed below:

- AGSWMM links SWMM5 with ArcGIS
- AGSWMM was developed using VBA
- AGSWMM setup installs a DLL file
- AGSWMM adds a new "ArcSWMM" toolbar in ArcGIS
- AGSWMM allows creation of a SWMM5 input file from GIS layers
- AGSWMM allows creation of a SWMM5 backdrop map (.emf file) in ArcGIS
- AGSWMM allows on-screen editing of input parameters in ArcGIS
- AGSWMM allows thematic mapping of SWMM5 output in ArcGIS

Figure 13.10 shows the AGSWMM toolbar. The toolbar consists of two tools: SWMM Input and SWMM Results View. The SWMM Input tool opens the input form shown in Figure 13.10. It allows users to create the SWMM5 input file. The left side of the form is used for creating input data for nodes (e.g., manholes). The right side of the form is used for creating input data for links (or conduits, e.g., pipes). Users can assign the appropriate GIS layer attributes to SWMM5 input parameters using dropdown pick lists. Users can either create a new SWMM5 input file using the "Make SWMM Input File" button at the bottom of the input form, or they can update the input parameters in an existing SWMM5 input file by selecting the "Synchronize SWMM File" button. The synchronization

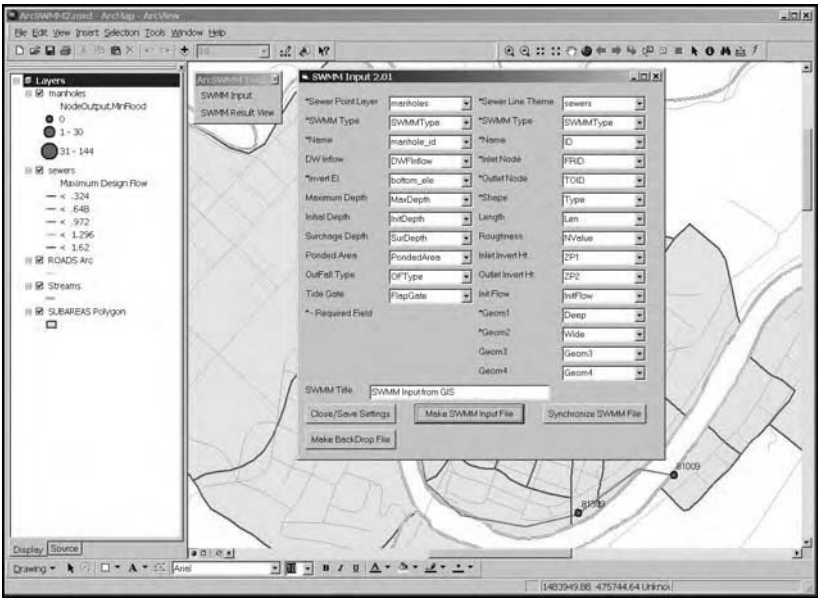

Figure 13.10 AGSWMM toolbar and input form.

capability allows users to edit the input file attributes in ArcGIS (e.g., change a sewer pipe diameter), and the changes are automatically reflected in the SWMM5 input file. This feature keeps the SWMM5 input files current. The "Make Backdrop File" button creates a backdrop map file for SWMM5 in the required .emf file format. This button automatically updates the SWMM5 input file with the appropriate scaling factor and offset distance so that it will properly align with the nodes and links in the SWMM5 map window. Figure 13.11 shows a SWMM5 map screenshot with a backdrop file creating by AGSWMM.

PCSWMM GIS™

PCSWMM GIS (Computational Hydraulics International, Guelph, Canada) is a good example of the model-based integration method described in Chapter 11 (Modeling Applications). PCSWMM GIS is a preprocessor for EPA's SWMM, and it also facilitates output visualization through a variety of plug-in tools. Model input parameters (node, conduit, and subcatchment) are extracted from an ODBC-compliant database such as Microsoft Access using SQL queries. Model input data can also be imported from an underlying dBASE-compatible GIS database. Extracted data are saved in an intermediate database (MS Access) for preprocessing into a useful model. Processed data are exported to a SWMM input file (Runoff, Transport, or Extran). The cost of PCSWMM GIS 2000 is

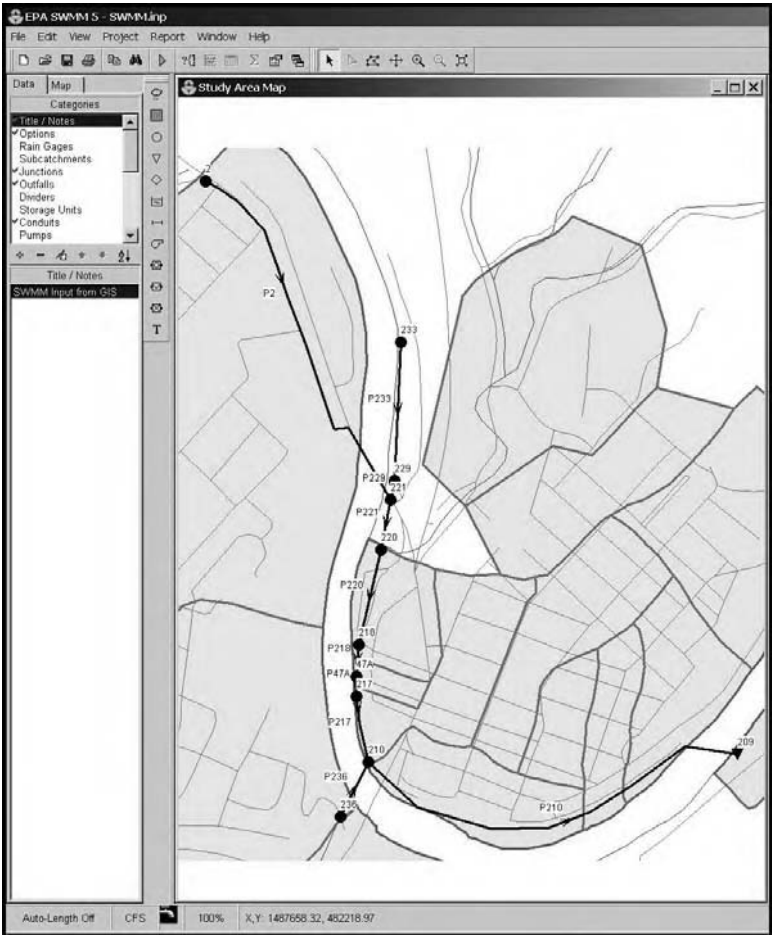

Figure 13.11 SWMM5 map window with a backdrop file created in ArcGIS.

$400. Figure 13.12 shows the PCSWMM GIS interface that has been developed using Visual Basic and resembles the ArcView GIS interface.

SWMM and BASINS

EPA has shown an interest in incorporating SWMM into its BASINS package, which is already integrated with the ArcView GIS software. EPA is now developing a SWMM linkage to its BASINS package. This link would be a valuable tool for urban planners and watershed managers to evaluate the urban pollution load in relation to other loads in the watershed and provide a more holistic view of watershed management. This project is being done through an EPA Office of Administration and Resources Management (OARM) contract with Lockheed

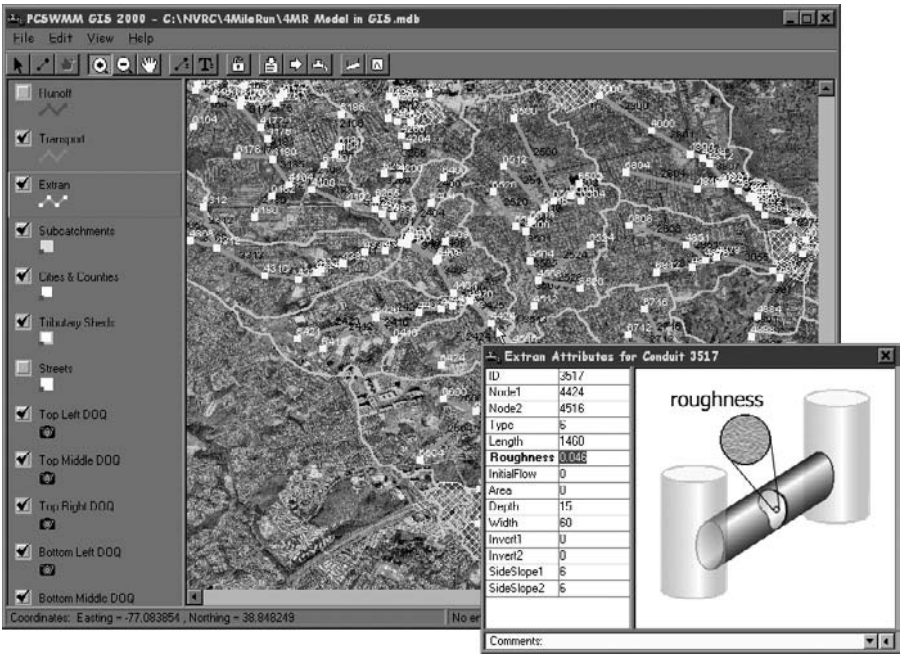

Figure 13.12 PCSWMM GIS: an example of a model-based integration method.

Martin Information Services (LMIS). When completed, this project will bundle SWMM and BASINS together with HSPF, TOXIROUTE, and QUAL2E programs that are currently part of the BASINS modeling environment. It should also allow extraction of SWMM input data from the GIS files that are part of the BASINS CD-ROMs. Detailed BASINS information is presented in Chapter 11 (Modeling Applications).

SWMMDUET

The Delaware Department of Natural Resources and Environmental Control, Division of Soil and Water, developed this program in 1994. SWMMDUET is an example of SWMM and GIS integration. This program integrates SWMM 4.2 (1993) with ArcInfo (ARC/INFO) 6.0. For this reason, it does not function with the latest versions of SWMM and ArcInfo (Schell et al., 1996). It has been written in ArcInfo's native Arc Macro Language (AML). It creates a computing environment that does not require arcane knowledge of SWMM and ArcInfo. SWMMDUET incorporates a preprocessor and a postprocessor, and therefore, provides interfaces both for creating SWMM's input file and for graphing SWMM's output file. SWMMDUET takes advantage of the graphical paradigm around which ArcInfo was constructed and utilizes relational database capabilities to organize data. Beyond data management, the program uses expert-system

logic to assemble data that define the modeling process, prepares SWMM input, executes the SWMM program, and converts the output into meaningful graphical displays. SWMMDUET, therefore, uses the integration method of GIS applications described in Chapter 11 (Modeling Applications). Data-entry sheets and forms eliminate the need for the modeler to know detailed ArcInfo processing techniques. Similarly, feature selection, spatial joins, and processing commands and options of ArcInfo are specified and executed for the user. Hyetographs are related to rain gauges where rainfall data were recorded. The storms are selected simply by a georeference to the gauges. Time-series data are stored as sequential records in the database files. SWMMDUET simplifies the management of vast amounts of hydrologic data, and lets the hydrologist concentrate on hydrologic matters rather than data input and output interpretation. The SWMMDUET software is in the public domain and can be obtained for the cost of distribution (Curtis, 1994).

AVsand™

AVsand from Cedra Corporation (Rochester, New York) is an example of ArcView and SWMM integration. This program offers only limited SWMM modeling capability because not all of the SWMM Blocks and capabilities are available. AVsand can be used for modeling sanitary sewers using a simplified implementation of SWMM's TRANSPORT Block. Storm and combined sewers are not modeled using SWMM; the Rational Method or surface hydrographs are used instead. AVsand accepts user model input via a series of dialogue boxes. AVsand also provides model development and editing tools, such as a Service Area Tool to define service areas, a Node Definition Tool to define nodes, and a Pipe Definition Tool to define pipes between nodes. A Wastewater Loads Tool enables the user to introduce wastewater loads at the selected nodes. A "Query" menu option helps the user to create GIS maps from the model output. It can also create a profile plot of the HGL, which is very effective to help pinpoint the areas of hydraulic overloads.

OTHER SEWER MODELS

The preceding section focused on SWMM models. Other sewer system models with GIS application capabilities are described in the following subsections.

DHI Models

DHI Water and Environment (formerly Danish Hydraulic Institute, Hørsholm, Denmark) and DHI, Inc. (Newton, Pennsylvania), specialize in developing GIS-based H&H computer models. For example, DHI has developed the following sewer system models for the ArcView GIS software package.

MOUSE™

Modeling of Urban SEwers (MOUSE) is a package for the simulation of surface runoff, flow, water quality, and sediment transport in urban catchments and sewer

systems. MOUSE combines complex hydrology, hydraulics, water quality modeling, and sediment transport modeling capabilities in a graphical and easy-to-use interface. MOUSE is a 32-bit Windows application specifically designed to operate within Microsoft Windows and Windows NT operating systems, and is optimized for fast simulations and graphics. Both metric (SI) and imperial units are supported. The MOUSE system is organized in several modules:

- MOUSE Runoff: Surface-runoff models for urban catchment applications
- MOUSE HD: Hydrodynamic network model with some limited RTC capabilities
- MOUSE RDII: Advanced hydrological model for continuous simulation
- MOUSE RTC: Advanced reactive RTC capabilities for MOUSE pipe models
- MOUSE LTS: Long-term hydraulic simulations with statistics
- MOUSE SRQ: Pollutant buildup and transport on catchments surfaces
- MOUSE AD: Pollutant advection-dispersion in drainage networks
- MOUSE WQ: Water quality processes in drainage networks
- MOUSE ST: Sediment transport in drainage networks

Some of these modules are marketed as optional add-on modules to the standard configuration. The various modules together with the user interface part, including the time-series and cross-section editors, advanced graphics both on the input and output sides, and the online HELP system, make the MOUSE system a desirable sewer system modeling package. MOUSE is a sophisticated hydraulic model that is commonly compared to SWMM (Heaney, 1999).

MIKE SWMM™

MIKE SWMM is DHI's implementation of SWMM. Resulting from a collaborative effort between DHI and Camp, Dresser, and McKee (CDM), MIKE SWMM combines the power of SWMM with a user-friendly interface. Data can be digitized and viewed with background images and edited with the same graphical editors that are also part of the MOUSE system. Data can also be entered and edited through database forms, which include scrollable spreadsheet-like sections for efficient editing of tabulated data. These different editors or views of the same information are dynamically linked, so that changes introduced through one editor are automatically and instantly updated in the other views. MIKE SWMM's database tool for storage of network data gives access to a range of query options.

MOUSE GIS™

MOUSE GIS is an application linking the MOUSE numerical sewer modeling system with ArcView. MOUSE GIS is an interface between ArcView and the MOUSE model. The MOUSE GIS interface is used for preprocessing external database information into MOUSE data sets. Once the link to an external database is established, manhole, link, weir, pump, and catchment data can be uploaded. The entire database can be used for the model networks, or a subset can be

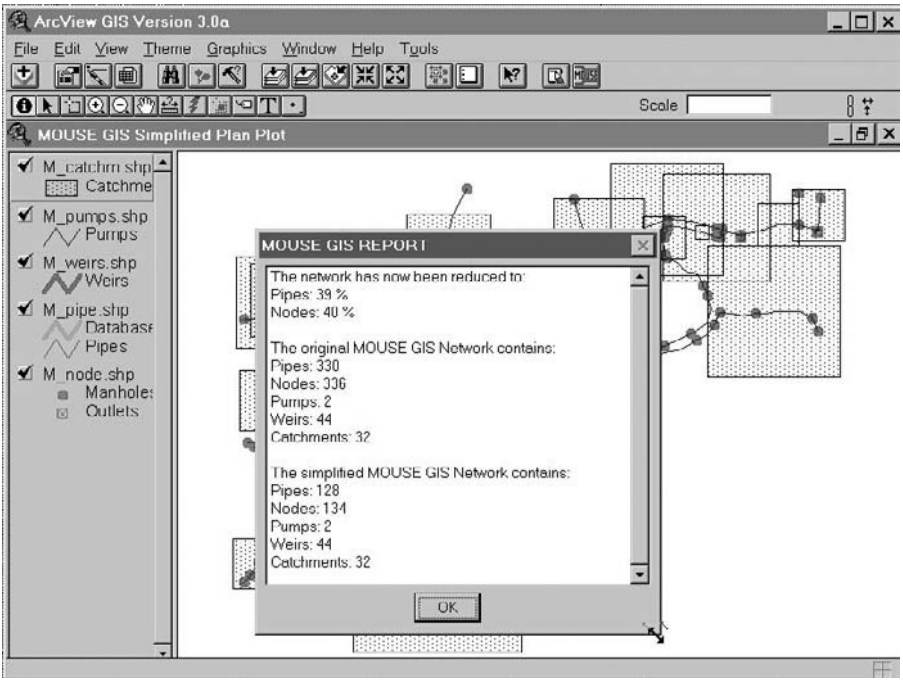

Figure 13.13 MOUSE GIS screenshot showing network skeletonization results.

selected. The selected set can subsequently be simplified (nodes excluded) to reduce the model size. MOUSE GIS also acts as a postprocessor for simulation results. Pipe flow results (maximum flow, velocity, depth and surcharge, flooding, etc.) can be displayed and overlayed with other GIS data. Mouse GIS also provides an interface to MIKE SWMM. Figure 13.13 shows a MOUSE GIS screenshot of the sewer system model for the city of Ljubljana (Slovenia) developed by DHI. The figure also shows the results of network skeletonization performed by MOUSE GIS. The automatic skeletonization has reduced the network size to 40%.

MOUSE GM™

MOUSE GM (in which MOUSE GIS is embedded), an ArcView-based module for MIKE SWMM and MOUSE users, promotes spatial and visual representation of the model and provides a direct link to GIS databases. MOUSE GM includes model-simplification tools that enable the user to create simplified (skeletonized) models from detailed data sets. This productivity tool may save days or weeks of tedious and error-prone work in the early phases of modeling projects. MOUSE GM reads and writes the SWMM file formats. It can be used as the ArcView GIS link and model-simplification tool for all SWMM modeling packages that apply the

standard SWMM data formats. With MOUSE GM, MIKE SWMM users can link to GIS databases and with any asset management system that supports ODBC connectivity.

InfoWorks™

Wallingford Software Ltd. (Wallingford, U.K.) develops and supplies data management, operation, and simulation software for the water industry worldwide. It offers two main software products for sewer system modeling:

- InfoWorks CS (formerly HydroWorks): Integrates asset and business planning with urban drainage network modeling.
- InfoNet: Provides tools, reports, displays, and data management capabilities. It integrates with GIS, desktop office systems, hydraulic modeling systems, maintenance management systems (MMS), field data systems, SCADA, and corporate databases. Data exchange interfaces have been designed not only for import and export purposes but also to connect directly with GIS (ArcView and MapInfo), hydraulic modeling systems (InfoWorks), SCADA, and logger systems. InfoNet has been designed to ensure that data exchange with Microsoft Windows applications and geographic information systems is a seamless operation.

InfoWorks CS is recognized for its fast, efficient, and stable algorithms for wastewater modeling. It models systems containing complex pipe connections, complex ancillary structures and static or variable control devices, open channels and trunk sewers, full backwater effects, and reverse flow. It can be upgraded to include one or more of the following optional modules:

- Water Quality module: Predicts quality components, volume of spillage and floods, and helps develop cost-effective solutions to pollution and sedimentation problems.
- Real Time Control (RTC) module: Allows central management of flow throughout an entire network and local flow control at individual ancillary structures. RTC helps users maximize wastewater system storage, optimize flow routing, optimize operation of ancillary structures, and design cost-effective systems.

InfoWorks products are designed to link H&H models with GIS and information management systems. InfoWorks CS combines a relational database with spatial analysis. It can be used to transfer data to and from third-party applications. One can also import asset data directly from Microsoft Access or .CSV files into the InfoWorks database. For instance, InfoWorks CS allows importing of subcatchment areas, area breakdown, and population data directly from MapInfo Professional, ArcView, or GeoMedia Professional GIS. Figure 13.14 shows the InfoWorks CS output results imported in MapInfo Professional (top) and ArcView (bottom).

In Figure 13.14, nodes are symbolized according to modeled flood volume in cubic meters, which represents the water overflowing from a manhole. Smaller (green) nodes are OK (no overflow), those in light blue and slightly larger are loosing a small amount

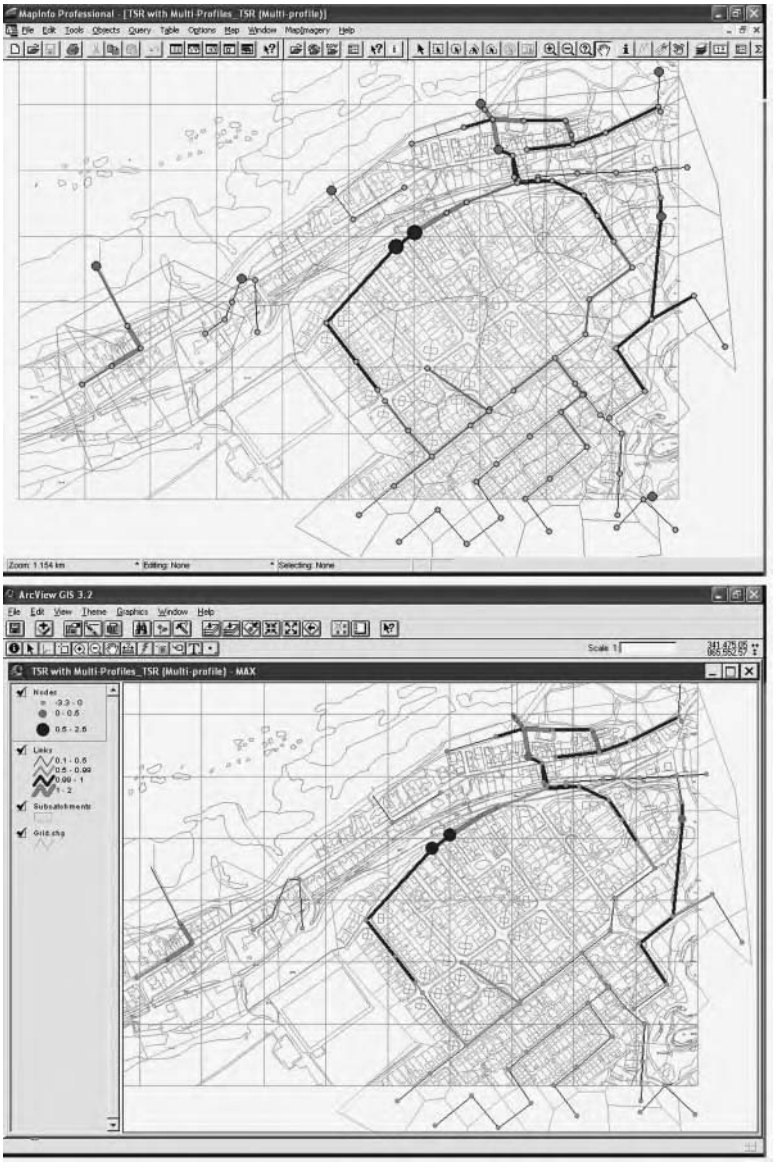

Figure 13.14 InfoWorks CS results in MapInfo Professional (top) and ArcView 3.2 (bottom).

of water, those in dark blue and larger are loosing lots of water. Link theme is showing surcharge depth. This represents 0.1 to 0.5 of pipe height (up to half full), 0.5 to 0.99 of pipe height (between half full and completely full), 1.0 of pipe height, or 100% full, and then 2.0, which is pressurized flow. The associated colors are black, light blue, dark blue and purple.

SewerCAD™ and StormCAD™

Haestad Methods, Inc.* (Waterbury, Connecticut), provides the following sewer system modeling:

- Sanitary sewers
  - SewerCAD Stand-alone
  - SewerCAD for AutoCAD
  - SewerGEMS for ArcGIS
- Storm sewers
  - StormCAD Stand-alone
  - StormCAD for AutoCAD

Stand-alone versions do not require a CAD package to run. The AutoCAD versions run from inside AutoCAD and, therefore, require AutoCAD. An ArcGIS version of SewerCAD called SewerGEMS (Geographic Engineering Modeling System) may be released in 2004.

SewerCAD is a design, analysis, and planning tool that handles both pressurized force mains and gravity hydraulics. SewerCAD performs steady-state analysis using various standard peaking factors, extended-period simulations, and automatic system design. StormCAD provides the same functionality for storm sewer systems.

GIS/database connection modules for these programs are marketed as optional modules that are sold separately. These programs establish a connection between a sewer model and relational and nonrelational database management systems, spreadsheets, and ESRI Shapefiles. For example, the Shapefile Connection Wizard provides import and export capabilities to transfer data between GIS and sewer models.

SEWER MODELING CASE STUDIES

Representative case studies of GIS applications in sewer system modeling are given in the following subsections.

XP-SWMM and ArcInfo Application for CSO Modeling

Application	Hydrodynamic sewer system modeling
Study period	1995–1998
GIS software	ArcInfo
Modeling software	XP-SWMM (sewer system), RMA-2V (river hydraulics and geometry), HEC-RAS (river hydraulics), and WASP5 (river water quality)
Other software	FoxPro and IBM Data Explorer
GIS data	Sewer components, hydrologic soil groups, land use, and curve number
Study area	Fort Wright, Kentucky
Organization	Sanitation District No. 1

* Haestad Methods was acquired by Bentley Systems (Exton, Pennsylvania) in August 2004.

The Sanitation District No. 1 (the District) located in northern Kentucky used GIS, GPS, RDBMS, and computer modeling technologies to simulate virtual flows of sewage through pipes, CSOs, and into and through local rivers (Ohio and Licking Rivers). With the concurrent tasks of updating the GIS and starting up of the facility plan, a common database was developed. The objective of the database was to provide a central location where data could be stored and used for the benefit of both tasks. An XP-SWMM Management System (XMS) was developed within FoxPro, which acts as the translator between different software packages. By including all five data sources (roads and streams, rain-gauge data, XP-SWMM output, CSO loadings, and fecal coliform response of receiving water), a more complete cause–effect relationship was developed. The visualization of the system using IBM Data Explorer provided an overall picture of the system that was not available before. This case study is a good example of GIS being used as an integrator technology or integrating platform (Martin et al., 1998).

AM/FM/GIS and SWMM Integration

Application	Sewer system modeling using the interface method
GIS software	ArcInfo
Modeling software	SWMM
Other software	CASS WORKS (RJN Environmental Associates)
Study area	Boston, Massachusetts, metropolitan area
Organization	Massachusetts Water Resources Authority (MWRA)

MWRA serves the sewerage needs of over two million people in 43 communities in the Boston metropolitan area. It was estimated that nearly half the flow in their system is a direct result of rainfall-induced inflow and infiltration (I/I) due to deteriorated sewers and manholes. In order to evaluate both the short-term and long-term needs of their sanitary sewer interceptor system, MWRA initiated and completed a sewage analysis and management system (SAMS) project, which involved linking of ArcInfo, CASS WORKS, and SWMM using the interface method of model integration. ArcInfo was used to create a link between SWMM data and computerized maps of the MWRA interceptor system and communities served. The maps were used as both a tool to input different planning scenarios into the CASS WORKS system and as a visual medium to geographically show the model results. The integrated AM/FM/GIS system was installed on a multiuser DEC VAX 4000-200. The integrated model allowed the MWRA planners to predict the I/I reduction from elimination of groundwater and rainwater from the interceptor system. Elimination of these flows resulted in significant operational cost savings to the MWRA and its ratepayers (ESRI, 1994).

SWMM and ArcInfo™ Interface

This application was developed as part of a watershed approach to assessing the ecological health of Bayou Chico, which is a subestuary of Pensacola Bay. Bayou Chico is the receiving water body of small, mostly urbanized watersheds located in

southern Escambia County, Florida. A GIS database and the use of remotely sensed satellite images were combined to determine surface characteristics, storm drainage systems, area, and slope of the watershed. These data layers were in turn linked to SWMM, which mathematically represents these physical characteristics and uses this information to determine both runoff and pollutant loading. The SWMM RUNOFF Block was broken into a hydrological component and a pollutant loading component. Both have parameters that may be retrieved from spatially based data. Pollutant loading is partially determined either by land-use class or gutter length. Gutter length can be derived from digitized road layers or are available for some metropolitan areas in the U.S. Census TIGER data files. ArcInfo tools allowed for querying of polygons for areal extent, perimeter, length, width, and other associated attributes. AML programming was used to query ArcInfo layers for SWMM parameter data and to write the information to an ASCII text file in the SWMM input file format (Schell et al., 1996).

Hydra™ and ArcInfo™ Interface

The City of Stockton, California, developed an interface between their ArcInfo GIS and Pizer's HYDRA/HydraGraphics sewer and stormwater modeling software. The GIS contained sanitary sewers and land-use layers, and was utilized as the raw data source for developing a sewer model for master planning purposes. To facilitate this process, a customized GIS data management interface was developed using ArcView GIS as the graphical interface between the City's GIS and the sewer model. This interface included several project-specific Avenue routines to import the City's GIS layers, extract the system model and land-use data, and export the model components to the sewer model (Prins et al., 1998).

CHAPTER SUMMARY

This chapter shows that GIS offers many useful applications in sewer system H&H modeling. GIS applications are developed using the three methods of interchange, interface, and integration as described in Chapter 11 (Modeling Applications). The interface method seems to be the most prevalent method at the present time. The case studies and examples presented in the chapter illustrate that many sewer utilities are successfully using GIS applications for modeling their sewer systems. The software

examples presented in the chapter indicate that many public-domain (e.g., SWMM) and commercial-off-the-shelf software packages (e.g., MOUSE) are available to help users benefit from sewer system modeling applications of GIS.

CHAPTER QUESTIONS

1. Prepare a list of GIS applications for sewer systems.
2. What is a GUI? How does it help modelers?
3. Which sewer system modeling tasks can be performed using GIS?
4. What are the typical input parameters for a sewer system hydraulic model? Which of these parameters can be obtained from a GIS?
5. List the GIS data layers that are useful for sewer system modeling.
6. How does GIS help in presenting the output results of a sewer system model?
7. List the sewer system models you are familiar with. Which of these models use GIS? Which method of GIS linkage (interchange, interface, or integration) do they use?
8. Is a GIS-integrated sewer model always better than a stand-alone model? Provide reasons for your answer.

CHAPTER 14

AM/FM/GIS Applications

At present our water and wastewater infrastructure, especially in the older cities, is in critical stages of deterioration and has started to crumble. AM/FM/GIS technology provides a spatial infrastructure management approach that is very effective in prioritizing your infrastructure improvement and maintenance needs.

Field inspection crews inspecting a combined sewer overflow (CSO) diversion chamber located near Pittsburgh, Pennsylvania.

LEARNING OBJECTIVE

The learning objective of this chapter is to find out how GIS is integrated with automated mapping/facilities management (AM/FM) systems for efficient inspection and maintenance of water industry infrastructure.

MAJOR TOPICS

- Infrastructure maintenance issues
- AM/FM/GIS basics
- AM/FM/GIS software
- AM/FM/GIS application examples

LIST OF CHAPTER ACRONYMS

AM/FM/GIS Automated Mapping/Facilities Management/Geographic Information System
CAD Computer-Aided Drafting/Computer-Aided Design

RBE Rule Base Engine
RDBMS Relational Database Management Systems
SDE Spatial Database Engine

HAMPTON'S WASTEWATER MAINTENANCE MANAGEMENT

GIS software	ArcView, GBA GIS Toolkit Extension for ArcView, MapObjects Internet Map Server (IMS)
Other software	GBA Master Series and WinCan TV system
GIS data	Sewers, manholes, water mains, valves, hydrants, roads, street centerlines, buildings, and digital orthophotos
Study area	City of Hampton, Virginia
Project duration	1998–2001
Organization	Public Works Department, Hampton, Virginia

Hampton, Virginia, has a population of 150,000 and has 12,000 manholes and valves. The City conducted a GPS survey to collect coordinates of more than 8000 manholes located in alleys, buried in yards, or covered with asphalt. The City utilizes more than 35 licenses of ArcView GIS. The City stored attribute data in an external infrastructure database from GBA Master Series and linked it to ArcView GIS. The GBA software performs infrastructure inventory of manholes and pipes, work-order management, and parts inventory management. It can also interface with the City's WinCan system used for CCTV inspection of sewers. The GBA GIS Toolkit, an

extension of ArcView GIS, is used to synchronize data consistency between ESRI Shapefiles, CAD, and the infrastructure management database. This application provides a GIS map linked to a comprehensive inventory, inspection, and maintenance management software program. The system also provides a graphical display of maintenance history and profile plots of user-specified sewer segments (ArcNews, 2001).

Although GIS applications in water, wastewater, and stormwater systems are not new, getting beyond the basic inventory and mapping functions is challenging. After a utility GIS database has been set up, GIS applications must be developed or else the GIS would be nothing but a pretty map. For instance, a GIS-based computerized maintenance management system (CMMS) can be implemented for more efficient maintenance of a utility because it can track problems within the utility network more accurately. The GIS and CMMS integration can facilitate proactive (preventive) maintenance, compliance with regulatory mandates, and systemwide planning activities.

According to the U.S. Government Accounting Standards Board (GASB), an infrastructure asset management system is a requirement for reporting capital asset activity. Electronic asset management systems extend the life of existing infrastructure, thereby optimizing maintenance schedules and deferring major capital expenditures until they become necessary and economically justified. Such systems can also identify risky assets and schedule rehabilitation projects that can save the cost of total replacement (Irrinki, 2000).

INFRASTRUCTURE PROBLEM

A civilization's rise and fall is linked to its ability to feed and shelter its people and defend itself. These capabilities depend on infrastructure — the underlying, often hidden foundation of a society's wealth and quality of life. Infrastructure is a Latin word meaning the structure underneath. According to a 1992 report from the Civil Infrastructure Systems Task Group of the U.S. National Science Foundation, "*A society that neglects its infrastructure loses the ability to transport people and food, provide clean air and water, control disease, and conduct commerce.*" (Tiewater, 2001)

The water, wastewater, and stormwater infrastructure is aging fast throughout the world, including in the U.S. For example, according to the 2001 counts, the U.S. has 54,000 drinking water and 16,000 wastewater systems. America's water and wastewater systems incur an expenditure of $23 billion per year on infrastructure projects. Much of the existing sewerage system in the U.S. was constructed in the 1950s and 1960s — some date back to the early 1900s and late 1800s. According to 2001 estimates, U.S. sewer systems are approaching 100 years in age. Even the newest U.S. water infrastructure systems are over 50 years old. What is worse, because of their material, they are more likely to be deteriorating than some systems dating back to 100 years. Many water systems are structurally obsolete and are now serving two to three times as many people as their design capacity. Many systems have not received the essential maintenance and repairs necessary to keep them

working properly. The American Society of Civil Engineers (ASCE) projects $1.3 trillion in infrastructure needs in the U.S. during 1999 to 2004, of which approximately one third is needed for water and wastewater improvements.

Unfortunately, adequate government funds are not available for this expensive fix. This problem can be partially blamed on the "out-of-sight, out-of-mind" mentality of the decision makers. The lack of funding for the badly needed infrastructure improvements is making people worried. This is evident in the recently conducted public opinion polls. According to a recent Water Environment Federation (WEF) survey, 31% of Americans would not swim in their own rivers. A 1998 ASCE poll showed that more than 75% of the U.S. voters were concerned about the quality of roads, drinking water, and school buildings. In Boston, more voters were concerned about roads, bridges, and drinking water than Social Security and taxes. In New York City, concerns about school buildings and drinking water outscored drug abuse worries (ASCE, 1998). Many indicated that they would vote for a candidate whose election campaign addressed waste disposal (78%), drinking water (73%), and roads and bridges (62%). These surveys indicate that water industry infrastructure is particularly important because it is so closely related to public health and safety.

In the U.S., it has been recently observed that a combination of reduced federal spending and increased federal mandates is taking its toll on the infrastructure of the country. For instance, according to American Water Works Association (AWWA), annual pipe replacement costs will jump to $3 billion by 2020 and $6 billion by 2030. Replacement expenses projected into the future indicate that sewer main replacements are more urgent than water mains and will require more money.

As of 2001, ASCE estimates that the U.S. must invest nearly $277 billion in drinking water and wastewater infrastructure repairs over the next two decades. U.S. water systems have an $11-billion annual investment shortfall and need $151 billion by 2018. U.S. sewer systems have a $12-billion annual shortfall in investment and need $126 billion by 2016. The largest need, $45 billion, is for projects to control combined sewer overflows (CSOs). The second-largest category of needs, at $27 billion, is for new or improved secondary treatment.

In a report "Water Infrastructure Now" published in February 2001, a water conservation organization called Water Infrastructure Network (WIN) estimated a $23-billion per year gap between infrastructure needs and current spending. The report indicated that U.S. water and wastewater systems faced infrastructure funding needs of nearly $1 trillion over the next 20 years and a shortfall of half a trillion dollars. The report called for a 5-year, $57-billion federal investment in water infrastructure to replace aging pipes and upgrade treatment systems. WIN estimates that household water bills must double or triple in most U.S. communities if utilities are forced to absorb the entire infrastructure bill. For instance, the City of Gloucester, Massachusetts, is charging $20,000 per home (to be paid over the next 20 years) to finance the city's conversion from septic to sewer systems (CE News, 2001).

According to a 2001 statement by ASCE President Robert W. Bein, "Something is terribly wrong … America has been seriously underinvesting in its infrastructure."

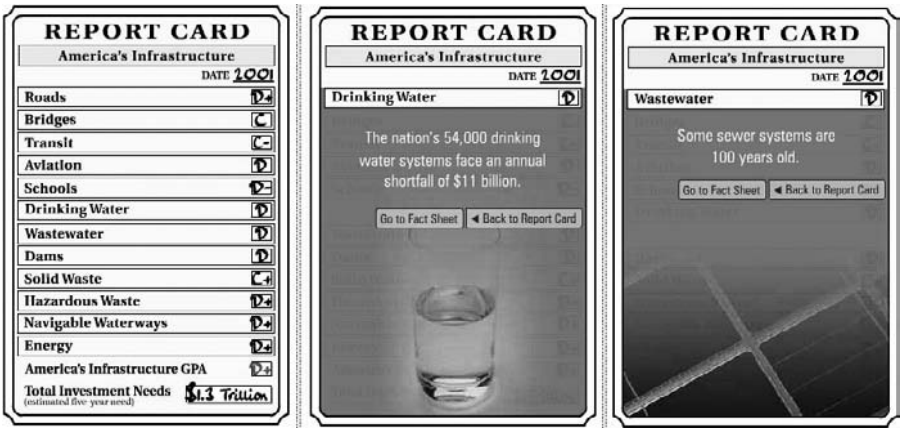

Figure 14.1 ASCE Infrastructure Report Card for the U.S.

In March 2001, ASCE released its 2001 Report Card (Figure 14.1) for America's infrastructure in which the nation's infrastructure received a cumulative grade of D+ for 12 infrastructure areas. Causes for such a dismal grade include: explosive population growth and school enrollment, which outpace the rate and impact of current investment and maintenance efforts; local political opposition and red tape, which outpace the development of effective solutions; and the growing obsolescence of an aging system — evident in the breakdown of California's electrical generation system and the nation's decaying water infrastructure. The 2001 Report Card follows the one released in 1998, at which time the ten infrastructure categories rated were given an average grade of D. The 2001 wastewater grade declined from a D+ to a D, while drinking water remained a D. Solid waste and schools scored the highest and the lowest grades, respectively (ASCE, 2001; EWRI, 2001). Despite the disturbing findings contained in the 2001 Report Card, the nation failed to heed the call to improve its deteriorating infrastructure, according to an update to the assessment released by ASCE in September 2003 (ASCE, 2003).

When the infrastructure condition is bad and funding is scarce, we need infrastructure management tools that can:

- Accurately define (or map) our infrastructure
- Identify the worst portions of the infrastructure
- Determine how to most cost-effectively improve (replace or repair) the worst parts of the infrastructure

AM/FM/GIS products provide an efficient infrastructure management system.

AM/FM/GIS BASICS

Many solutions for managing facilities have spawned from CAD-based architectural applications. Database solutions have evolved from the financial sector to

Table 14.1 Comparison of AM, FM, AM/FM, GIS, and AF/FM/GIS

Feature	AM	FM	AM/FM	GIS	AM/FM/GIS
Layers	Y	N	Y	Y	Y
Topology	N	N	N	Y	Y
Network definition	N	Y/N	Y	Y	Y
Lines	Y	N	Y	Y	Y

Actual locations	Y/N	N	Y	Y	Y
Map intelligence	N	N	N	Y	Y
Facilities management	N	Y	Y	N	Y

Notes: Y = Yes; N = No; and Y/N = Both Yes and No.

include scheduling, inventory, and purchasing functions. Implementation of facility management automation can occur at any scale, from a small spreadsheet recording preventative maintenance items to a full corporate system with CAD capabilities managing the complete maintenance process with integrated contracting, accounting, inventory, asset, and personnel records. CAD-based products have normally been classified as computer-aided facility management (CAFM), whereas the database solutions, dealing with work-order management without a CAD component, have been termed computerized maintenance management systems (CMMS). The FM user community reflects this polarization, because the majority of current implementations are oriented either one way or the other. Computer integrated facility management (CIFM) brings both CMMS and CAFM capabilities into synergy, thereby addressing the implementation of a true facility management automation program. The core consideration is that, in practice, CMMS and CAFM capabilities augment and are essential to each other. For example, maintenance activities keep the data required for planning accurate and up-to-date (GEOTELEC, 2004).

AM/FM/GIS is a combination of four separate systems:

- Automated Mapping (AM)
- Facilities Management (FM)
- Automated Mapping/Facilities Management (AM/FM)
- Geographic Information System (GIS)

The differences between the three systems are summarized in Table 14.1 and illustrated in Figure 14.2.

Automated Mapping (AM)

Automated mapping (AM), also known as computer-aided mapping (CAM), is a CAD application for producing maps. It can be considered an alternative to the traditional manual cartographic maps. Data are organized in layers that are conceptually like registered film overlays. Layers organize data by theme (streams vs. roads) and type (linework vs. text).

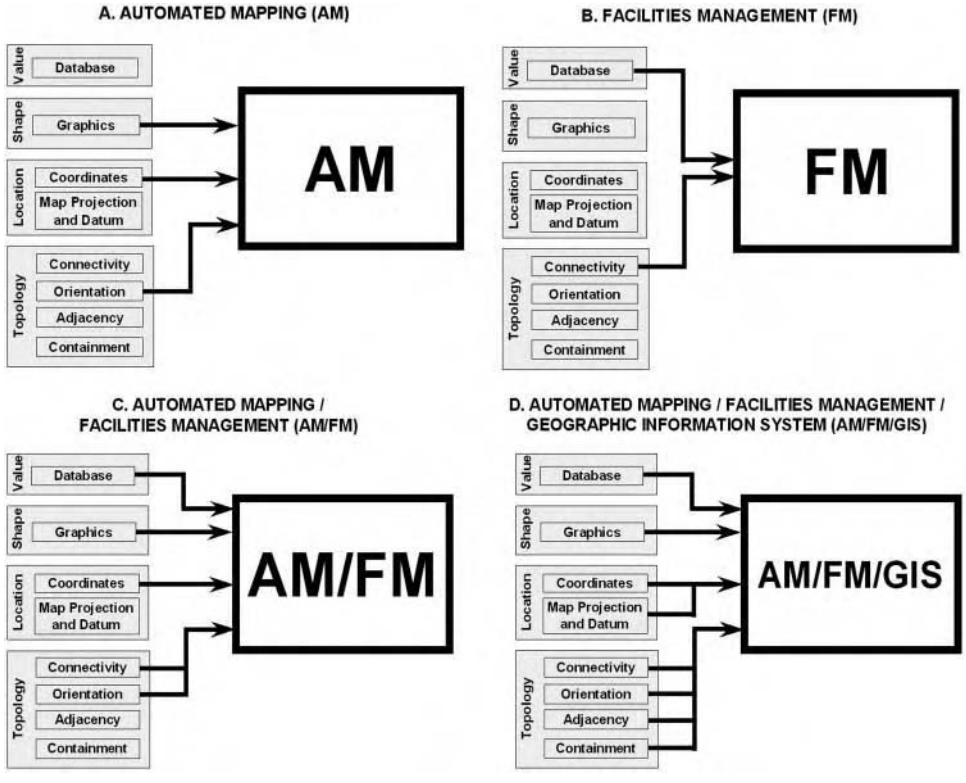

Figure 14.2 Comparison of AM, FM, AM/FM, and AM/FM/GIS.

There are no spatial relations (topology) among data elements except orientation. Figure 14.2(A) shows AM capabilities.

Facilities Management (FM)

Facilities management (FM), also referred to as asset management, is a CAD technology for managing utility system data. FM consists of such activities as inventory, inspection, and maintenance performed by cities, utilities, and government agencies. Organizations incur considerable expenses and resources as these functions are performed on a routine basis. FM includes an infrastructure management database. Compared with AM, there is less emphasis on graphical detail or precision and more emphasis on data storage, analysis, and reporting. Relationships among utility system components are defined as networks. Because FM systems have network definitions, an FM system "knows" the pipes connected upstream or downstream of a given pipe. As shown in Figure 14.2(B), FM systems generally do not have full topology; they offer connectivity and orientation only.

Automated Mapping (AM)/Facilities Management (FM)

AM/FM is a combination of AM and FM technologies. AM/FM software is used to automate maintenance. It allows the integration and automation of maintenance management. AM/FM systems have both orientation and network definitions as shown in Figure 14.2(C). The benefits of AM/FM are improved work-order management, better integrated inventory control, capture of maintenance data and costs, and allocation of costs.

AM/FM/GIS Systems

GIS and AM/FM are different systems but each has its own advantages and applications (Shamsi and Fletcher, 2000). A GIS can help locate the worst pipe. An AM/FM can help users prioritize the work required to bring their worst pipes up to a minimum operating standard. For many years, people have used the GIS and AM/FM systems separately. Developing and maintaining two different systems is expensive and inefficient. Thanks to the latest advances in computer hardware and software, integrated AM/FM and GIS systems called AM/FM/GIS systems are now available. These systems are especially useful for asset inventory, inspection and maintenance, and work management. They are especially popular among visual learners who prefer maps over tables and databases. Visual learners like to click on a manhole in a GIS map to initiate a work order rather than locate it by querying a database. As shown in Figure 14.2(D), AM/FM/GIS systems have more capabilities than AM/FM systems, such as orientation, network, database, and topology.

AM/FM/GIS SOFTWARE

There are currently a variety of computer applications on the market, which were developed for specific components of facility management. In applying automation

Table 14.2 AM/FM/GIS Software Examples

to these diverse functions, vendors have taken approaches that originate from two different technical directions: CAD or relational database management systems (RDBMS) (GEOTELEC, 2004).

GIS-based facilities management requires AM/FM software extensions that can be run from within the GIS software. These add-on programs are also referred to as AM/FM/GIS software. Representative AM/FM/GIS software are listed in Table 14.2. According to this table, there are two types of AM/FM/GIS software:

1. AM focus: These software provide more mapping (AM) capabilities. ArcFM is an example of this type of software.
2. FM focus: These software provide more database (FM) capabilities. Cityworks is an example of this type of software.

Software with an AM focus provide better data editing and mapping capabilities and generally require an FM add-on to provide work-order management functions. Software with an FM focus provide maintenance management functions (e.g., work-order management) but may lack the map maintenance functions. Projects that require both strong AM and FM capabilities may have to use two software products. For example, ArcFM's strong suite of CAD-like map-editing capabilities can be supplemented by Cityworks' work-order management functions.

All the packages listed in Table 14.2 are available for purchase from their respective companies except CASS WORKS, IMS-AV, and IMS-ARC, which are proprietary software programs that are installed by the vendors in their turnkey projects. Figure 14.3 shows Hansen's Infrastructure Management System CCTV-inspection database. Note that each defect has been linked to its location on the sewer pipe and a picture of the defect captured from the inspection videotape.

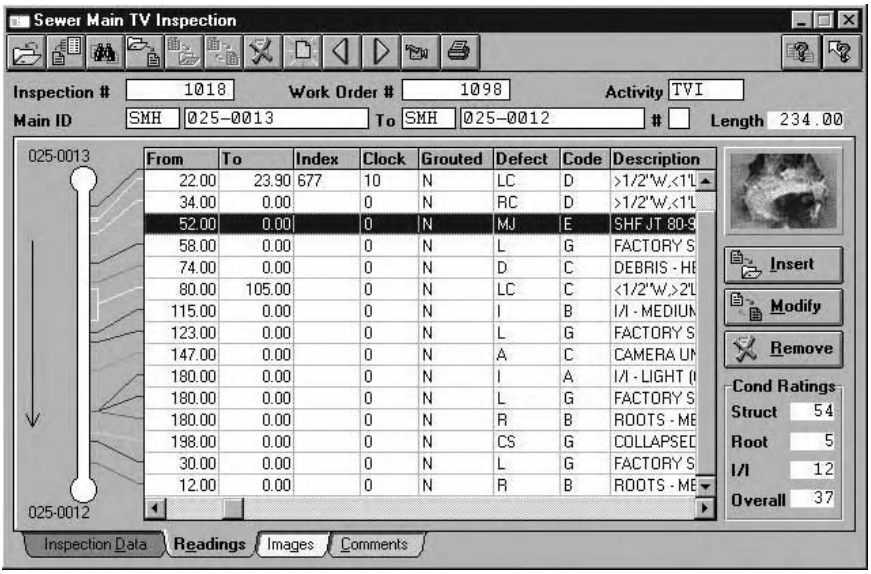

Figure 14.3 Hansen's Infrastructure Management System CCTV-Inspection Database (Photo courtesy of Hansen Information Technologies).

ArcFM

Developed jointly by ESRI and Miner & Miner, ArcFM is an off-the-shelf AM/FM/GIS application for the utility industry and for enterprise implementations. It is designed for editing, maintenance, modeling, and data management of utility information. The first version was written in Visual Basic 5.0 for the Windows NT platform. ArcFM has two components: (1) ArcFM, the main program for creating and editing maps and (2) ArcFM Viewer, the companion program for querying and viewing maps created in ArcFM. ArcFM is suitable for data conversion work by GIS technicians. ArcFM Viewer is a simple program that enables managers to review the finished maps. The relationship between ArcFM and ArcFM Viewer is similar to the relationship between ArcInfo 7.x and ArcView 3.x packages.

In ArcFM, features are modeled as objects with drag-and-drop capabilities. For example, as shown in Figure 14.4, to draw a butterfly valve, users can simply select the valve symbol from the objects library and drag-and-drop it to its correct location. In ArcFM software, GIS tools deal with features that are not simply points and lines, but valves, pipes, manholes, inlets, drainage basins, and more. ArcFM has a rule base engine (RBE) that determines how features are drawn (symbology, placement, rotation, etc.). The RBE can be individualized for different applications. For example, the stormwater RBE may define pipes, their associated features, and the methods that pertain to them. RBE can also validate user-entered data to ensure valid attribute values. With the help of these capabilities, ArcFM can perform routine editing functions, such as adding a new catch basin or service connection or splitting a pipe, with remarkable simplicity.

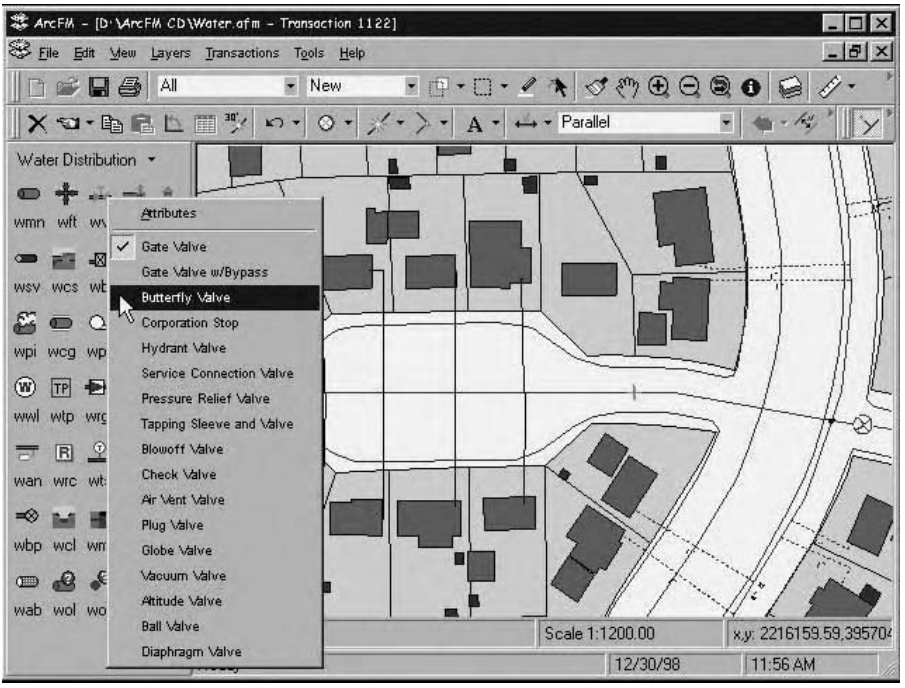

Figure 14.4 ArcFM screenshot showing water objects.

ArcFM has powerful and user-friendly data editing capabilities for routine map maintenance functions, e.g., for adding a new valve or hydrant, splitting pipes, or adding a service connection. ArcFM provides sample data models and business-rule templates for water, wastewater, and stormwater systems. These templates, called *modules,* can be modified for project-specific applications. ArcFM does not have maintenance management capability but it can be integrated with other work management or customer information systems. ArcFM is not a stand-alone program. It requires ArcInfo and Spatial Database Engine (SDE) software and an RDBMS, such as Oracle or Microsoft Access (Shamsi and Fletcher, 2000).

Greenville Utilities was chartered by the North Carolina Assembly in 1905. It is organized as an independent agency of the City of Greenville and operates electric, water, sewer, and gas utilities for the City of Greenville and a portion of Pitt County. Greenville Utilities water operations serve 25,000 customers with 475 mi of main, and sewer operations serve 20,000 customers with 333 mi of main. Greenville Utilities used ArcFM, SDE for its SQL server, and ArcInfo software for implementing an enterprise-wide GIS project for its electric, water, sewer, and gas services. ArcFM Viewer was used by casual users, customer-service representatives, field crews, and others to easily query, plot, and analyze spatial and related attribute data. ArcFM was used as an engineering tool (ESRI, 1999).

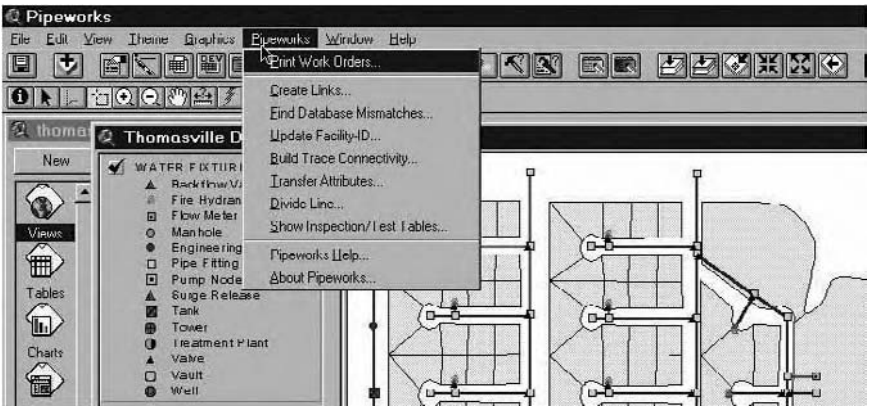

Figure 14.5 Pipeworks menu screenshot.

Cityworks

Cityworks (formerly known as Pipeworks) is available as ArcView 3.x or ArcGIS 8.x and 9.x Extension, helps users integrate their GIS and facilities management. Cityworks' water, wastewater, and stormwater module which for ArcView 3.x costs approximately $4000 per license and works with ESRI coverages and Shapefiles. Cityworks can store project data in any SQL database, such as SQL Anywhere, Oracle, Sybase, etc. Cityworks' capabilities include data inventory, data editing, work-order management, work-order scheduling, network tracing, maintenance histories, inspections, and condition ratings. Cityworks can also be used for managing and recording CCTV inspection programs for sewers. Figure 14.5 shows the Pipeworks menu in ArcView 3.x.

The Cityworks extension provides additional capabilities to make ArcView 3.x or ArcGIS 8.x a complete work-management system. Cityworks work-order modules are used to create and manage work orders, inspections and tests, and detailed inventory for water and sewer systems. The attribute data managed by Cityworks are referred to as extended attributes because these attributes are stored in the extended-coverage database or RDBMS. Examples of extended attributes are inventory data, work orders, work histories, inspections, customer complaints, etc. Cityworks for ArcView 3.x requires that all inventoried features be created and maintained as coverage data types, i.e., line, node, or point feature. The difference between Cityworks and other work-management solutions is its GIS-centric approach. Cityworks does not treat the GIS as subordinate to the work-management system. Instead of integrating the work-management system with GIS, it uses the GIS as a work-management system (Azteca, 1999). General functions of Cityworks are listed below:

- Assign work activity
- Link to service request
- Track tasks
- Track resources: labor, material, and equipment (estimated and actual)
- Link multiple inspections and tests

Table 14.3 Cityworks Inspections and Tests

Water	Wastewater	Storm
Meter inspection	Manhole inspection	Manhole inspection
Hydrant inspection	CCTV inspection	CCTV inspection
Valve inspection	Inlet inspection	Inlet inspection
Hydrant flow test	Dye test	Dye test
Meter changeout	Smoke test	Smoke test
	General test	General test

- Maintenance:
  - Corrective or reactive
  - Preventive or routine
  - Scheduled or cyclical
- Track permits
- Key dates and personnel
- Attach images
- Geocode and geolocate
- Print using Microsoft Word and ArcView templates and automated printing functions
- Search on any combination of work-order ID, work activity, selected map features, feature, type, key dates, key personnel, tasks, status, address, or geographical constraints.

Cityworks' inspections and tests are listed in Table 14.3. Another Azteca product called the Cityworks ArcGIS Interface simplifies the ArcGIS interface by providing a subset of key ArcGIS functionality (presented using large icons) commonly used by maintenance and operations staff. Cityworks Desktop ArcGIS Extension is an extension of the standard ArcGIS interface. It is accessible from a palette of tools that can be positioned anywhere on the map document.

CHAPTER SUMMARY

Deteriorating infrastructure and limited funds require that maximum system improvement be achieved at the lowest possible cost. AM/FM/GIS systems can be used to determine optimal infrastructure improvement strategies to accomplish this goal. Today, AM/FM/GIS systems are helping the water industry with their planning, design, and operational needs. AM/FM/GIS software is engineered to organize asset information, optimize maintenance activities, and prioritize necessary improvements. AM/FM/GIS software offers the integrated strength of AM/FM and GIS programs. AM/FM/GIS software is available in AM-centric and FM-centric flavors. Software selection should be made based on user-specific needs. Applications of AM/FM/GIS technology are presented in the next chapter.

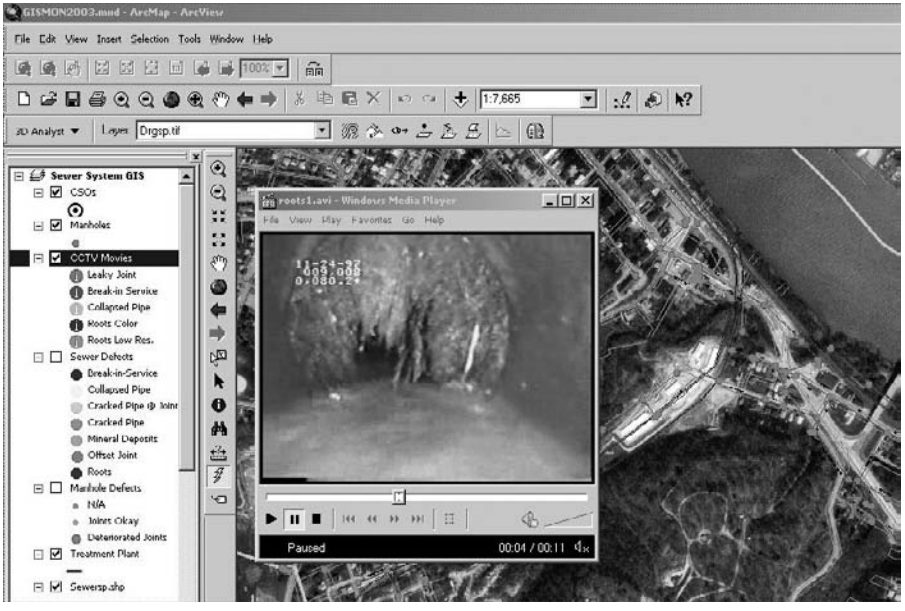
CHAPTER QUESTIONS

1. What is AM/FM/GIS, and how does it differ from AM/FM and GIS?
2. What is work-order management, and how is it done using AM/FM/GIS software?
3. List ten applications of AM/FM/GIS technology.

CHAPTER 15

Maintenance Applications

GIS can be used to prepare inspection or maintenance work orders simply by clicking on a sewer pipe or manhole. This approach simply takes just a few minutes compared to the conventional method of locating and copying maps and typing the work order forms, which usually takes several hours.



Displaying sewer CCTV inspection video in GIS. The movie shows a sewer blocked by heavy root growth.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand GIS applications in inspection and maintenance of water, wastewater, and stormwater systems.

MAJOR TOPICS

- Field inspections
- Asset management
- GASB 34 applications
- Wet-weather overflow management applications
- CCTV inspections
- Video mapping
- Thematic mapping of inspection data
- Work-order management
- Identifying valves to be closed for repairing or replacing broken water mains
- System rehabilitation and repair
- Case studies

LIST OF CHAPTER ACRONYMS

AM/FM/GIS Automated Mapping/Facilities Management/Geographic Information System
AVI Audio Video Interleaved (digital movie format)
CCTV Closed-Circuit Television
CD Compact Disc
CMMS Computerized Maintenance Management System
DVD Digital Versatile Disc
GAAP Generally Accepted Accounting Principles
GASB Government Accounting Standards Board
HTML Hyper Text Markup Language (a file extension)
MPEG Moving Picture Experts Group (digital movievideo format)
O&M Operation and Maintenance
PDA Personal Digital Assistant (electronic handheld information device)
PDF Portable Document Format (Adobe Acrobat)
ROM Read Only Memory
VCR Video Cassette Recorder
VHS Video Home System (video cassette format)

This book focuses on the four main applications of GIS, which are mapping, monitoring, modeling, and maintenance and are referred to as the "4M applications." In this chapter we will learn about the applications of the last *M* (maintenance).

To fully appreciate the benefits of GIS-based inspections, consider the following hypothetical scenario. On March 10, 2004, following a heavy storm event, a sewer

customer calls the Clearwater Sewer Authority to report a minor basement flooding event without any property damage. An Authority operator immediately starts the GIS and enters the customer address. The GIS zooms to the resident property and shows all the sewers and manholes in the area. The operator queries the inspection data for a sewer segment adjacent to the customer property and finds that a mini movie of the closed-circuit television (CCTV) inspection dated July 10, 1998, is available. The operator plays the movie and sees light root growth in the segment. A query of the maintenance history for that segment shows that it has not been cleaned since April 5, 1997. This information indicates that the roots were never cleaned and have probably grown to "heavy" status. The operator highlights the sewer segment, launches the work-order module, and completes a work-order form for CCTV inspection and root removal, if necessary. The export button saves the work-order form and a map of the property and adjacent sewers in a PDF file. The operator immediately sends the PDF file by e-mail to the Authority's sewer cleaning contractor. The entire session from the time the customer called the Authority office took about 30 min. The operator does not forget to call the customer to tell him that a work order has been issued to investigate the problem.

BUNCOMBE COUNTY'S SEWER SYSTEM INSPECTION AND MAINTENANCE

During the 1990s, the Metropolitan Sewerage District (MSD) of Buncombe County (North Carolina) spent more than $111 million rehabilitating the most problematic sewer lines in its system. MSD's aggressive sewer rehabilitation program has successfully implemented numerous rehabilitation technologies. In 1999, MSD began assessing a method of comprehensive basinwide rehabilitation. In this approach, every pipe in a drainage basin was evaluated using CCTV footage and engineering analysis. After evaluating this comprehensive basinwide rehabilitation method for 4 years, MSD determined that it is overly time- and capital-intensive. Seeking a more efficient and quicker method to fix the system, MSD developed and implemented a new GIS-based rehabilitation method called "pipe rating."

The pipe rating method has five main elements: (1) CCTV information, (2) a defect scoring system, (3) GIS database software, (4) sanitary sewer overflow (SSO) history, and (5) engineering analysis. These components are combined to generate specific projects for problem lines. Each structural defect noted in the video inspection is given a defect score, in accordance with MSD's standardized scoring system. For example, a circumferential crack is given a score of 20, and a collapsed pipe is assigned a score of 100. Defects are then embedded within the GIS database, with appropriate scores attached. Upon quantifying all structural defects within a pipe segment, three defect ratings are generated in the GIS: (1) peak defect rating, (2) mean defect rating, and (3) mean pipeline rating. These ratings allow users to visualize the severity of pipe defects using GIS. Figure 15.1 shows an ArcGIS screenshot of mean pipeline ratings. Such maps are used in prioritizing pipe segments for repair work. They are also used to determine when several point repairs should be made to

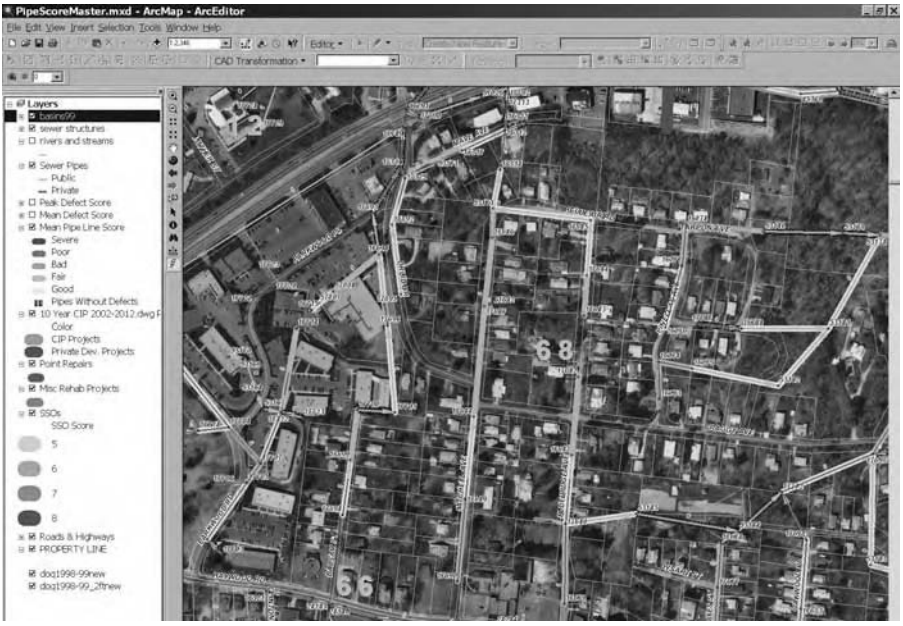


Figure 15.1 ArcGIS screenshot of mean pipeline ratings for the Metropolitan Sewerage District (MSD) of Buncombe County, North Carolina.

a line as apposed to excavating the entire line (Bradford et al., 2004). Additional information about this application is provided in Chapter 17 (Applications Sampler).

ASSET MANAGEMENT

As discussed in Chapter 14 (AM/FM/GIS Applications), at present our water and wastewater infrastructure, especially in the older cities, is in critical stages of deterioration and has started to crumble. Nationally and internationally, aging water and wastewater infrastructure is imposing enormous costs on local communities (Booth and Rogers, 2001). In the U.S., cities and utilities are demanding billions of dollars of government grants and funds for renovating their water infrastructure. Due to an "out-of-sight, out-of-mind" philosophy and the lack of funds to follow a preventive maintenance practice, the replacement is mostly performed on a react-to-crisis basis. A crisis maintenance program only corrects infrastructure problems after they have happened. Notwithstanding the conventional wisdom, this reactive approach may not be the best strategy as substantial expenditure and inconvenience can be avoided by replacing a deteriorated pipeline before it actually breaks. A preventive maintenance program is proactive because it strives to correct a problem before it occurs.

For water and wastewater systems, asset management can be defined as managing infrastructure capital assets to minimize the total cost of owning and operating them while delivering the service levels customers desire (Booth and Rogers, 2001). A typical asset management system has five components (Doyle and Rose, 2001):

1. Facilities inventory: Describes each system element in an asset group. GIS can be very useful in completing this task.
2. Condition assessment: Classifies each asset according to its capability to perform the intended function.
3. Valuation: Assigns a financial value to inventoried assets consistent with Generally Accepted Accounting Principles (GAAP).
4. Operations, maintenance, repair, and replacement management: Arguably the heart of a management system, this component tracks and records data about work orders and customer complaints, issues and tracks preventive and predictive maintenance schedules, and generates crew assignments and work-site maps. GIS has extensive capabilities to fulfill this part.
5. Analysis and evaluation: Considered as the brains of an asset management system, this component prioritizes work effort, analyzes cost-effectiveness, and optimizes asset performance.

An asset management system helps predict the future condition of assets and major rehabilitation costs for planning purposes. An effective asset management system can reduce the cost of system operation and maintenance (O&M). Every successful maintenance program should begin with an accurate system map because it is difficult to maintain a system if the users do not know where the water or sewer lines are. A well-constructed GIS should be used to create the system map. Historical maintenance data should also be linked with the GIS because it is difficult to schedule maintenance when you do not know the last time it was done (Gaines, 2001). A GIS-based asset management system can be used as a decision support system for capital improvement planning (CIP). For example, CH2M HILL (Atlanta, Georgia) used ESRI's MapObjects GIS software to develop an infrastructure capital asset management (ICAM) toolkit that can be used in a Web-based browser/server or stand-alone computing environment (Booth and Rogers, 2001).

In many cases, through more effective planning and management of infrastructure improvements and system operations, organizations can realize annual savings of 20 to 40% (Stern and Kendall, 2001). Boston Water and Sewer Commission (BWSC) has approximately 27,500 catch basins. In 2000, BWSC started enhancing its asset management program for locating, inspecting, and maintaining its catch basins. BWSC improved the productivity and efficiency of its catch basin preventive maintenance program by integrating it with GIS and a computerized maintenance management system (CMMS). In lieu of using global positioning system (GPS), the crews determined the precise location of catch basins by using a measuring wheel to measure distance from known points to the basin's center. BWSC utilized handheld touch-screen computers in the field to collect geographic location information and more than 25 attributes. GIS data in Shapefile format and a GIS interface provided the backbone of this application. The traditional paper-based data collection methods typically averaged 24 catch basin inspections per day, but the GIS-based method boosted this rate to approximately 42 per day.

Boston Water and Sewer Commission's GIS-based field-data-collection approach increased the catch basin mapping productivity by more than 40% compared with traditional, paper-based data collection methods (Lopes et al., 2002).

In the U.S., two key drivers are motivating improved asset management practices in water and wastewater utilities: (1) GASB 34 requirements, and (2) wet-weather overflow requirements.

GASB 34 APPLICATIONS

In 1999, the Government Accounting Standards Board (GASB) issued Rule 34 (known as GASB34) to govern financial reporting requirements of approximately 85,000 state and local governments in the U.S. Considered the most significant change in the history of government financing reporting in the U.S., GASB 34 requires the cities to adequately account for and report their capital asset inventory in a complete, accurate, and detailed manner (Booth and Rogers, 2001). The capital assets include infrastructure networks such as roads, bridges, and water, wastewater, and stormwater systems.

The literature indicates that a GIS-based approach saves time spent in locating, organizing, and confirming the accuracy of field inspection information (Criss, 2000). Industry experts believe that utilities can cut their maintenance costs in half by implementing GIS-based preventive maintenance programs. Thus, integration of GIS and maintenance management software is a natural progression for GIS applications in the water and wastewater industry. For instance, the Wastewater Collection Division of Fairfax County, Virginia, linked the county's sewer maps with the sanitary sewer maintenance management system database, making it easier to access maps during field activities (Fillmore et al., 2001). The City of Denver, Colorado, linked the city's sewer system GIS to an information management system to efficiently track and manage maintenance operations (Gaines, 2001).

WET WEATHER OVERFLOW MANAGEMENT APPLICATIONS

Management of wet weather overflows is a fertile field for GIS technology. By using geographic information in mapping, facilities management, and work order management, a wastewater system manager can develop a detailed capital improvement program or operations and maintenance plan for the collection system.

Broken and damaged sewers, laterals, and manholes usually contribute significant amounts of wet weather inflow and infiltration (I/I) to a wastewater collection system. This contribution often results in combined sewer overflows (CSO) from combined sewer systems and sanitary sewer overflows (SSO) from sanitary sewer systems.

In the U.S., CSO discharges are regulated by U.S. EPA's National CSO Policy. The policy requires a System Inventory and Physical Characterization report. Major portions of this report can be completed using GIS. The CSO policy's Nine Minimum Controls (NMC) mandate proper operation and regular maintenance programs for the sewer system and CSO outfalls that can also benefit from inspection and maintenance applications of GIS. SSO discharges are being regulated by U.S. EPA's SSO rule that requires implementation of a Capacity, Management, Operations, and

Maintenance (CMOM) program. CMOM requires the system owners/operators to identify and prioritize structural deficiencies and rehabilitation actions for each deficiency. CMOM requirements offer a dynamic system management framework that encourages evaluating and prioritizing efforts to identify and correct performance-limiting situations in a wastewater collection system. CMOM is a combination of planning tools and physical activities that help communities optimize the performance of their sewer systems. CMOM requirements mandate that the system owner/operator properly manage, operate, and maintain, at all times, all parts of the collection system. The owner/operator must provide adequate capacity to convey base flows and peak flows for all parts of the collection system. CMOM requirements include "maintaining a map" (Davis and Prelewicz, 2001), which is the simplest application of GIS as described in Chapter 9 (Mapping Applications).

Some wet weather overflow management experts believe that use of GIS is a must for CMOM compliance.

AutoCAD Map GIS Application for CMOM

The Stege Sanitary District (SSD) located near San Francisco Bay serves a population of approximately 40,000 in a 5.5 mi^2 area. The goal of a CMOM program is the ultimate elimination of any type of overflow from the sanitary sewer system. SSD was challenged with the goal of "no overflows" in 1996. To meet this goal, a new maintenance model was implemented for sanitary sewers that used AutoCAD Map GIS and Microsoft Access database software to identify system conditions causing overflows, and prompted immediate action to correct problems via repair or replacement. Those lines showing the greatest damage and whose repair or replacement were within the budget constraints established by the District, would be immediately set right. The ability to make effective and economic decisions regarding the capital replacement needs of the system based on the actual degradation of the system provided a degree of asset management that had not been readily available to the management. The SSD experience indicated that proactive maintenance provides the most cost-effective means of managing the system to achieve the goal of "no overflows."

During 1992 to 1994, SSD created the sewer and manhole layers in AutoCAD format and linked the capacity model output to these layers to identify line segments that were overloaded. Complete GIS capability was added later with the use of AutoCAD Map, an extension of the common AutoCAD drafting program that adds the feature of linking information from external databases. During 1994 to 2001, information was collected in a database on the physical system characteristics, system hydraulic performance under selected flow conditions, system overflows, routine maintenance activities, CCTV inspections, and repairs and replacements. All database information was linked to the mapped line segments, thereby allowing an easy evaluation of problem distribution throughout the system with a textual and graphical response from the database query. The relational database program used

was Microsoft Access, which is compatible with AutoCAD Map. All of the work was completed on a desktop PC (Rugaard, 2001).

CCTV INSPECTION OF SEWERS

Traditionally, municipalities have relied on analog video for internal inspection of sewers. In this technique, remote-controlled and self-propelled cameras move through sewer lines to record the pipe's internal conditions on a video tape. In a parallel operation, technicians create paper logs identifying the location, size, and other key information about the pipe. Referred to as CCTV inspection, this method has been considered to be the most effective and economical method of pinpointing the sources of I/I contribution. For instance, by the late 1990s the City of Boston, Massachusetts, had conducted 12 million ft of CCTV inspection on video tapes. Using an inspection cost of one dollar per foot, the cost of collecting this information could be at least $12 million. CCTV inspection videotapes contain a wealth of useful information about the state of a collection system, yet they have been often treated as single-use items. A lot of money is spent on video inspections, yet inspection data are frequently underutilized mainly because accessing the information from the conventional video tapes and paper inspection log sheets has been difficult and time consuming (Criss, 2000).

GIS can be used as a document management system for CCTV inspection data. For example, users can click on a rehabilitated sewer pipe to see the "before" and "after" movies on their computer screen. This application, however, requires converting VHS video tapes to computer files (digital movies). Once converted and stored on computers, the valuable information once hidden in videotapes can be retrieved with the click of a mouse, eliminating the need for other equipment (TV, VCR, and cables) and office space to house the equipment. CDs take up 70% less shelf space than VHS tapes. As a side benefit, digital movies can be used to create multimedia presentations for utility management when requesting maintenance and rehabilitation funds. After all, a video is worth a thousand pictures. Most video tapes have a short shelf life of approximately 10 years and their video quality and performance are inferior to digital media. Unlike VHS tapes, digital videos do not lose picture quality when copied. Digital technology also allows high-resolution snapshots of defective pipe segments taken from the video. Dynamic segmentation and image integration features allow storage and display of these images with footage reading and a description of the pipe defect. For benefits like these, experts predict that by 2008, approximately 90% of wastewater utilities will be using digital video technology (Bufe, 2003).

As stated in the preceding text, integrating CCTV videos with GIS requires migrating from video tapes to digital movies. Four migration methods are possible:

1. Convert existing video tapes to digital files
2. Digitize existing video tapes
3. Retrofit tape systems with digital systems
4. Record directly in digital format

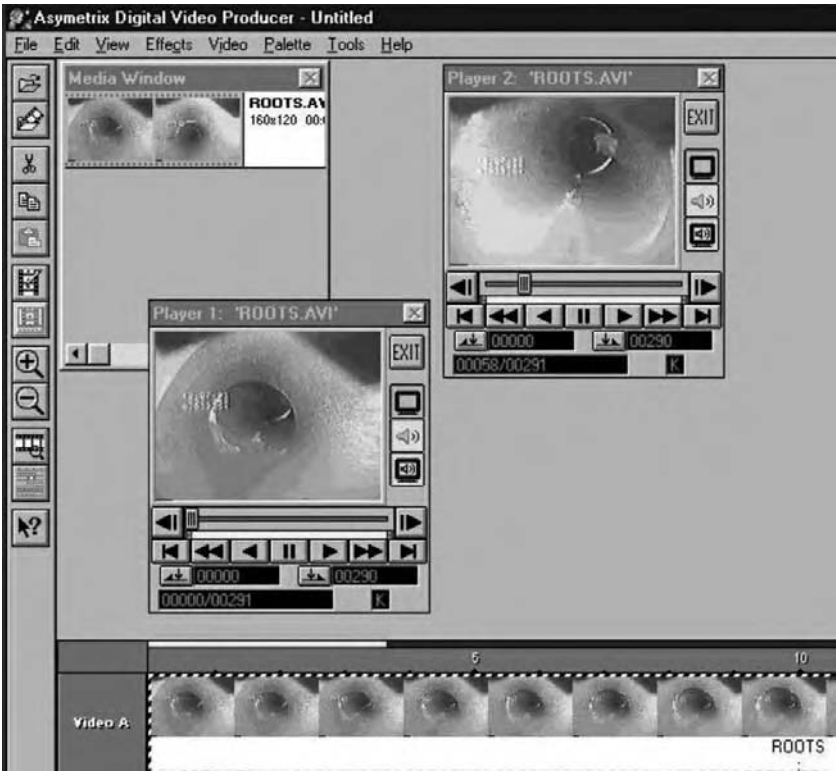

Figure 15.2 Screenshot of Digital Video Producer's video capture capability.

Convert Existing Video Tapes to Digital Files

In this method (which is the simplest), the existing video tapes are converted to multimedia computer files in the AVI or MPEG format. The hardware required for this method includes TV, VCR, multimedia computer, CD or DVD burner, and a video capture card. Video capture cards allow display of TV or VCR output on a computer screen. Some multimedia computers have built-in (internal) video capture cards. If an internal card is not installed, an external card that typically costs a few hundred dollars should be used. A video capture and editing software, which typically comes with the card, is also required. Figure 15.2 shows a screenshot of Digital Video Producer, a video capture software from Asymetrix Corporation.

The TV is connected to the VCR, and the VCR is connected to the video capture card (if external) or the computer (if internal) using AV cables. When a tape is played in the VCR, the user sees the video on the TV and on the computer screen. The video capture software has a VCR-like console with play, stop, and record buttons. When the user clicks on the software's record button, usually at the beginning of a sewer defect (e.g., collapsed pipe, root growth, break-in lateral, etc.), the computer starts to record the video in a computer file, usually in AVI or MPEG format. The

Figure 15.3 Sample mini movie in AVI format showing collapsed sewer pipe.

file recording stops when the STOP button is clicked, usually at the end of the sewer defect. Instead of converting the entire video tape, generally 5 to 30 sec mini movies showing problem areas are captured because the resulting files can be very large. For example, a 5 to 15 sec video segment recorded in color with sound can be 30 to 60 MB in size. Sound can be turned off to reduce the file size. Finally, in order to free up the computer hard disk space, the recorded digital movies are copied to digital media (e.g., CD-ROM or DVD-ROM). Raw video files can be compressed to optimize disk space. A CD cannot store more than 15 to 30 min of uncompressed data. However, in compressed format such as MPEG-1 or MPEG-2, 1 to 1.5 h of video can be stored on a CD and 6 to 12 h on a DVD. Figure 15.3 shows a sample mini movie in AVI format showing a collapsed pipe.

Digitize Existing VHS Tapes

This is basically a more efficient and automatic implementation of the previous method. Special video software is used for compressing and indexing video tapes to digital media. For example, the Tape-to-CD module of flexidata pipe survey reporting software from Pearpoint, Inc. (Thousand Palms, California), uses advanced optical character recognition (OCR) technology to read the footage count displayed on the monitor

screen. This product was designed using skills and expertise gained in the development of automatic recognition of vehicle license plates. It allows the Pearpoint system to provide indexing of sewer records against the footage shown on the original videotape. The resulting CD will not only contain the original real time video but also a report.

WinCan

WinCan from WinCan America, Inc. (Durango, Colorado), is another example of video software that allows the user to capture either videos or pictures. Pictures may be captured in several different formats such as JPG or BMP. Mini movie files can also be created in increments of 5 to 35 sec. Videos may be captured in several different formats, including the most common, MPEG and AVI. WinCan can integrate stored pictures, live video from the camera or VCR, and stored movies in the pipe inspection database. Figure 15.4 shows a screenshot of the WinCan interface. The left window lists the inspected pipes in the WinCan project database. The right windows shows the mini movies for the selected pipes. The bottom window displays the observed defects for the selected pipe. WinCan also allows personal digital assistant (PDA)-based manhole reporting. The PDA (e.g., an iPAQ or PalmPilot) is used in the field to gather data with the user standing above the structure. A customized WinCan software is added to the user's PDA. Pull-down menus and easy fill-in fields make gathering the data as easy as using the full WinCan software. Back in the office, the user HotSyncs the PDA with the computer and the information is simply added to WinCan (WinCan, 2001).

WinCan interacts with GIS packages in two ways: (1) interfaces with the GIS database and (2) updates the GIS database. In the first method, the WinCan database interfaces with the GIS database by using a metadatabase. This metadatabase contains information from WinCan projects, such as unique manhole identifiers, line section numbers, street names, and pipe sizes. When a GIS user attempts to access a particular feature (e.g., a manhole or line segment), the software searches the metadatabase to determine if the feature is available. If an associated WinCan report is available, the software opens the report and highlights the specific item. The user can then display associated pictures, videos, or inspection data. This method requires toggling between WinCan and the GIS software. In the second method, an external utility appends the WinCan data to the GIS database. GIS users can then select the locations in their maps and view WinCan database and associated graphics without starting the WinCan program (Criss, 2000).

Retrofit Tape Systems with Digital Systems

The typical cameras on board the CCTV inspection vehicles are adequate for use in digital applications. Most simply need the addition of a compression unit to convert their analog signals to a digital format. In this method, digital video processing hardware and software are installed in the CCTV inspection vehicle and linked to an existing tape system.

Pearpoint equipment users can interface the Pearpoint hardware directly with WinCan. This eliminates the need for a separate overlay system with encoder.

Figure 15.4 WinCan software screenshot.

According to Pearpoint, the installation is much easier with no hardware integration and wiring/soldering necessary. Camera inclination and other Pearpoint features function instantly with appropriate setup.

Another example of this approach is the PipeTech™ Software Suite from Peninsular Technologies, Inc. (Ada, Michigan). PipeTech is an innovative solution for simplifying sewer inspection projects. It allows collection, editing, analysis, and archiving of all inspection data digitally, eliminating the need for VHS tapes and the stacks of paper attachments that normally accompany an inspection project. PipeTech's Scan product is an on-site solution for video recording and incident reporting. Scan captures and compresses video in real time and facilitates the recording of incident locations. Incidents are entered on an electronic log sheet and are automatically cross-referenced with their occurrences in the video. Scan eliminates the need for a TV, VCR, and VHS tapes in the video vehicle. Videos captured using Scan are clearer than those captured through a VCR (PipeTech, 2000).

Video software such as WinCan and PipeTech also provide an on-screen pipeline or a video viewer for retrieval of stored images and movies. Consisting of a line segment graphic, these utilities allow the user to scroll along a line segment and display observations, photos, or movies by clicking on any desired location. An example is shown in Figure 14.3 for Hansen's Infrastructure Management System. This is possible because the defect location is cross-referenced with the video. In addition to the typical stop, play, and pause controls, video step and loop controls help the user to direct video progression. Seeking to any instant of video is also possible.

Record Directly in Digital Format

In this method, no VHS tapes are involved at all. The sewer inspection video is recorded directly in onboard computers as digital movies, using digital cameras. This method requires installation of appropriate digital recording hardware in the CCTV vehicle. For example, Pearpoint manufactures several video pipeline inspection systems with digital color video cameras.

This system offers complete integration of data and video. It enables a technician to watch the video as it is recorded and flag the video for defects in real time. Users can then jump to the flagged video frames without searching through the entire video (Bufe, 2003).

Linking Digital Movies to GIS

The digital movies created by using one of the preceding methods should be linked to the sewers layer in the GIS database. This will enable users to click on a sewer line in the GIS map to display the digital movie of the sewer defect. The following steps should be performed to accomplish the linkage in ArcView 3.x:

1. Add a new field to the sewer layer table to store the movie filename. Figure 15.5a shows an ArcView 3.2 database table for sanitary sewers containing a field named "Movie" for holding the movie filenames.
2. Enter the video filename for each sewer segment for which a movie is available.

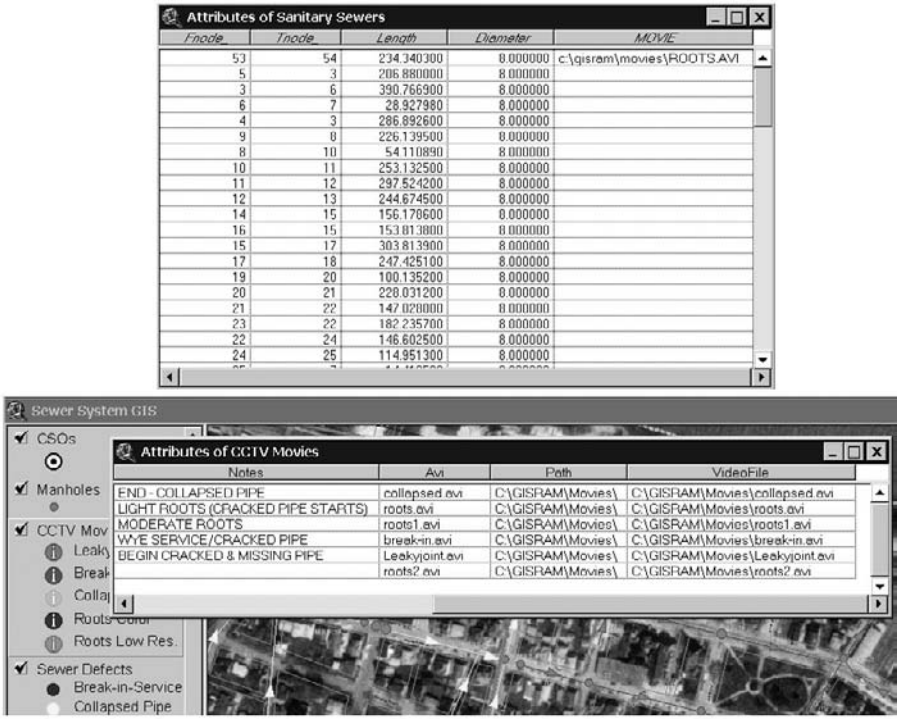

Figure 15.5 Linking digital movies to ArcView GIS. Above (a) linkage to sewers; below (b) linkage to points.

3. Write an Avenue script (shown in Figure 15.6 and described in the following text) for displaying the movie.
4. In the "Theme Properties" dialogue box for the sewers theme, click on the "Hot Link" tab as shown in Figure 15.6. Set "Field" to the field created in Step 1, set "Predefined Action" to "Link to User Script," and set "Script" to the script developed in Step 3.
5. Pick the Hot Link tool (the lightning bolt) shown in Figure 15.6 from the tool bar and click on a pipe with a video file to launch the digital movie.

Figure 15.6 shows a sample script called "Movie&ImageHotLink" for displaying movie files. The code of the script is included in Chapter 1 (GIS Applications, Applications Programming section).

The successful linkage of movies to sewers requires that both the CCTV inspection data and the sewer database table in the GIS have a common ID. This would essentially require planning ahead before conducting CCTV inspections to make sure that the inspection crews use the GIS IDs in their inspection reports. As an alternative to linking videos to sewers, a point layer can be created for video locations. Figure 15.5b shows an ArcView 3.2 point database table for CCTV movie locations. It has three fields for entering movie filenames. The users can enter the video filename and path separately in the AVI and Path fields. Or, an absolute pathname can be

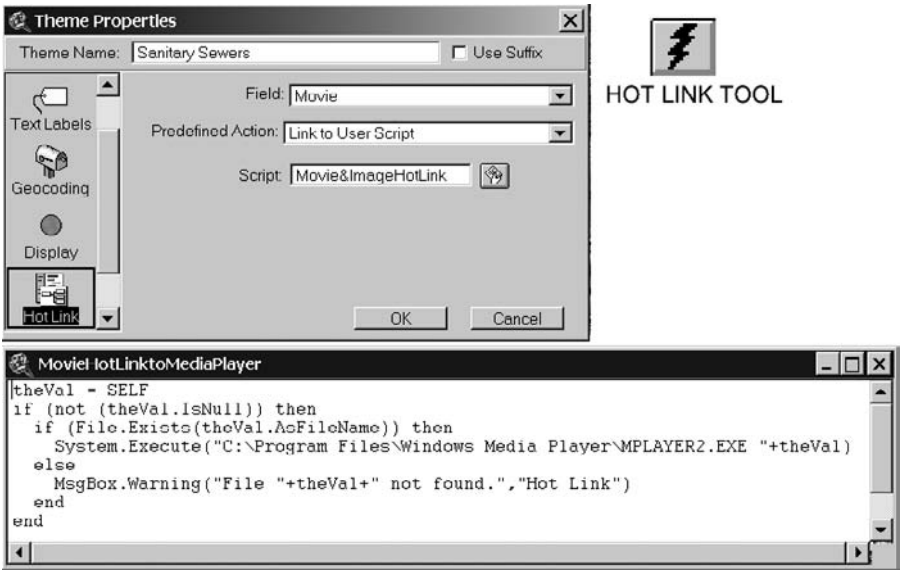

Figure 15.6 ArcView GIS Hot Link Tool for linking sewer movies to sewer pipes.

entered in the VideoFile field. The disadvantage of absolute pathnames is that the application will not work if the pathname becomes invalid when video files are moved to another location (e.g., a CD or network drive). Here the users can click on a video point to see the digital movie.

In ArcGIS, the video files can be displayed without a script using the Hyperlink tool, which also looks like a lightning bolt. As in ArcView 3.x, the movie filename is entered in a database field. When the end of the bolt is near a defective sewer, the hyperlinked filename is displayed if the file exists. Clicking on the sewer will launch the movie. The hyperlinking is configured by right-clicking on the sewer layer, selecting properties, and then the display tab. The figure on the first page of this chapter shows a digital movie being played in ArcGIS 8.2.

VIDEO MAPPING

Today, GIS map features can be linked to any kind of file to document inspection of a location through pictures, field notes, audio, streaming video, etc. When digital video, GPS, and GIS maps are combined, the possibilities are limited only by the user's imagination.

Traditionally, GIS users have employed a low-tech and cumbersome approach to associate an inspection picture (e.g., inside of a sewer manhole) or video with its location. This method involves taking pictures (or recording video), writing the pictures' (or video's) description and frame numbers, scanning the pictures (or converting the video from analog to digital format), collecting GPS coordinates of picture locations, and entering all this information in the GIS database. In today's

information age, this method is error prone and inefficient. The high-tech alternative known as video mapping (or media mapping) refers to georeferencing video footage by associating GPS data with video (Pfister et al., 2001). A GIS software can then read the GPS locations referenced to video time codes into its database. A map of video locations is created that can be clicked by the users to access the desired video footage. Video mapping technology can be applied to document sewer inspections and smoke-testing in GIS maps (Murphy, 2000).

Video mapping integrates GPS data and GIS maps to create interactive multimedia maps without manual scanning of photos or data entry into a computer.

Multimedia Mapping System (MMS) and Video Mapping System (VMS) software programs from Red Hen Systems, Inc. (Fort Collins, Colorado), are typical examples of video mapping products. VMS is a self-contained GPS encoder that records all data types — video, audio, and GPS — on a single tape. Users collect video, location, and audio information at the same time. It contains an integrated GPS receiver that receives location coordinates from satellites and then converts them to an audio signal for storage on video tape (Morrison and Ruiz, 2001). The user attaches the product to a video camera and records the field inspections. VMS sends GPS data from its internal receiver to the camera's microphone input. After recording the video, the user connects the system to a computer with Red Hen's MediaMapper software installed. VMS then sends the data to the computer to create a video map in TAB, SHP, or HTML format. These maps allow the users to click and view still images or video clips, play audio files, or display documents or data sets. MMS integrates the VMS unit and its built-in GPS receiver with a GPS antenna, headphone, and microphone.

MediaMapper software provides basic GIS functions and enables users to link georeference audio and video clips to GIS features. This functionality is essentially similar to ArcView's Hot Link tool described in the previous section but it is enabled by MediaMapper automatically. Software extensions are available for accessing MediaMapper data in MapInfo and ArcView GIS packages.

THEMATIC MAPPING OF INSPECTION DATA

Some applications use information from several different databases or tables. For example, a smoke-testing application might require information from the manhole and customer account databases. It is inefficient and cumbersome to enter the data from different tables in one table. Relational database tables allow accessing information from different tables without physically joining them.

A relational database stores information in records (rows) and fields (columns) and conducts searches by using data in specified fields of one table to find additional data in another field. This capability allows linking two tables that have a common field. The common field can be used to link the GIS feature tables to virtually any external database table. This linkage capability allows the GIS to make effective use of existing databases without requiring additional data entry in the GIS database.

Once the GIS and external database tables have been linked, the external data can be queried or mapped from within the GIS.

Typical manhole inspection reports have valuable attributes, such as:

- Structure number
- Street name
- Inspection date
- Offset from curb
- Structure type
- Cover or grate diameter
- Number of holes in the cover
- Frame adjustment type
- Corbel type
- Manhole wall type
- Manhole area
- Depth of structure
- Bricks missing (Yes/No)
- Ladder rungs (Yes/No)
- Ladder rungs condition
- Apron leaking (Yes/No)
- Pipe seals leaking (Yes/No)
- Manhole wall leaking (Yes/No)
- Catch basin connected (Yes/No)
- Root intrusion (Yes/No)
- Joint deterioration (Yes/No)

A manhole theme table can be linked to a manhole inspection table to create thematic maps of manhole conditions, which are excellent decision support tools for scheduling maintenance and inspection activities. The linkage can be created easily as long as both the inspection reports and the GIS database use the same manhole IDs.

Figure 15.7 shows the linkage of a manhole theme table in ArcView with the external manhole inspection table. The linkage is accomplished using the fields "Mhid" of the manhole theme table and "Mh_id" of the manhole inspection table. When the manhole "MH9-2" is selected in the GIS theme table, corresponding records in the manhole inspection table are also selected. Figure 15.8 shows a thematic map of manhole joint defects based on the "Joint Deterioration" attribute of the manhole inspection report created by using the table-linkage approach.

Similarly, typical CCTV inspection logs also have valuable attributes, such as:

- Date televised
- Type of pipe
- Begin and end manhole
- Total footage televised
- Overall pipe condition
- Manhole condition
- Joint spacing
- Joint alignment
- Number of houses
- Remarks

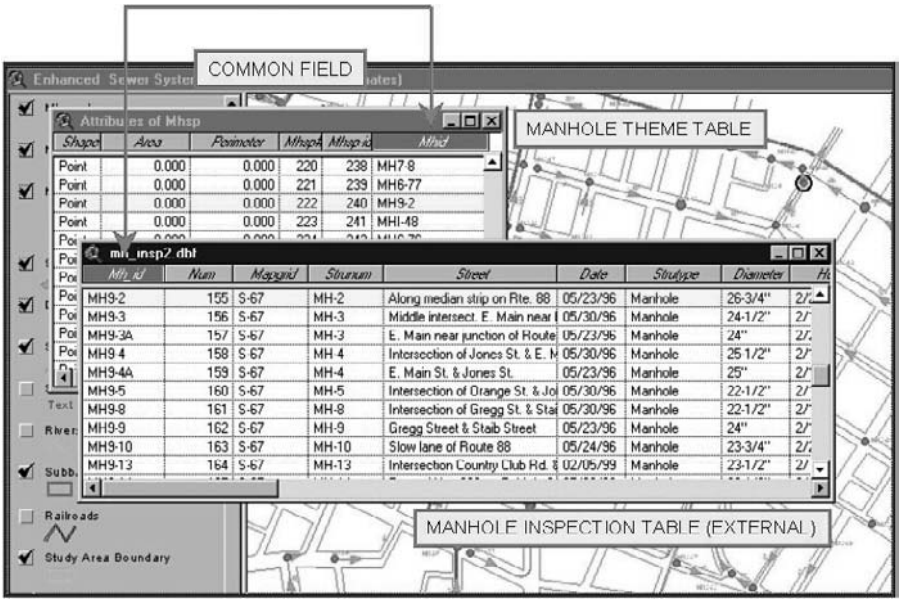

Figure 15.7 Linking manhole theme table and external manhole inspection table in ArcView.

Using the method described in the preceding text, the CCTV inspection logs can be integrated with the GIS database. This allows creation of thematic maps of sewer conditions. As described earlier, the successful linking of GIS features and inspection data requires that both the GIS database and the inspection data have a common ID.

Figure 15.8 Thematic map of manhole joint defects.

Figure 15.9 Thematic map of pipe defects.

Figure 15.9 shows a thematic map of pipe defects based on the "Remarks" attribute of the CCTV inspection logs, which contained information about sewer defects such as root growth, collapsed pipes, leaks, break-in service, etc.

WORK ORDER MANAGEMENT

Although this section focuses on wastewater system work orders, the methodology is equally applicable to water and stormwater systems.

Conventional work order management requires searching and printing the appropriate sewer system maps and manual completion of paper forms. GIS can be used to prepare work orders simply by clicking on the desired sewer or manhole in the GIS map. When the user clicks on an object, a work order inspection form is displayed that the user can fill by entering work information or by selecting predefined actions from drop-down lists. The completed work-order form and

corresponding map area can be printed for the inspection and maintenance crews. The entire process takes just a few minutes compared to the conventional method of locating and copying maps and typing the work order forms, which usually takes several hours.

GIS-based work-order management requires automated mapping/facilities management (AM/FM) software extensions that can be run from within the GIS software. These add-on programs, referred to as AM/FM/GIS software, are described in Chapter 14 (AM/FM/GIS Applications). AM/FM/GIS systems are especially useful for asset inventory, inspection and maintenance, and work management (Shamsi and Fletcher, 2000). The Cityworks (formerly Pipeworks, Azteca Systems, Sandy, Utah) AM/FM/GIS software suite includes ArcView and ArcGIS extensions, which help users integrate their GIS and work management. Its Wastewater Module can be used for inspection and maintenance of sewer systems and for managing and recording a CCTV inspection program for sewers. Cityworks Work Order modules are used to create and manage work orders for inspections and tests, and for detailed inventory for water and sewer systems. The Cityworks work management solutions are based on a GIS-centric approach. Cityworks does not treat the GIS as subordinate to the work management system. Instead of integrating the work management system with the GIS, it uses the GIS as a work management system (Azteca, 1999). Figure 15.10 shows the Cityworks work order management screen for CCTV inspection of sewers.

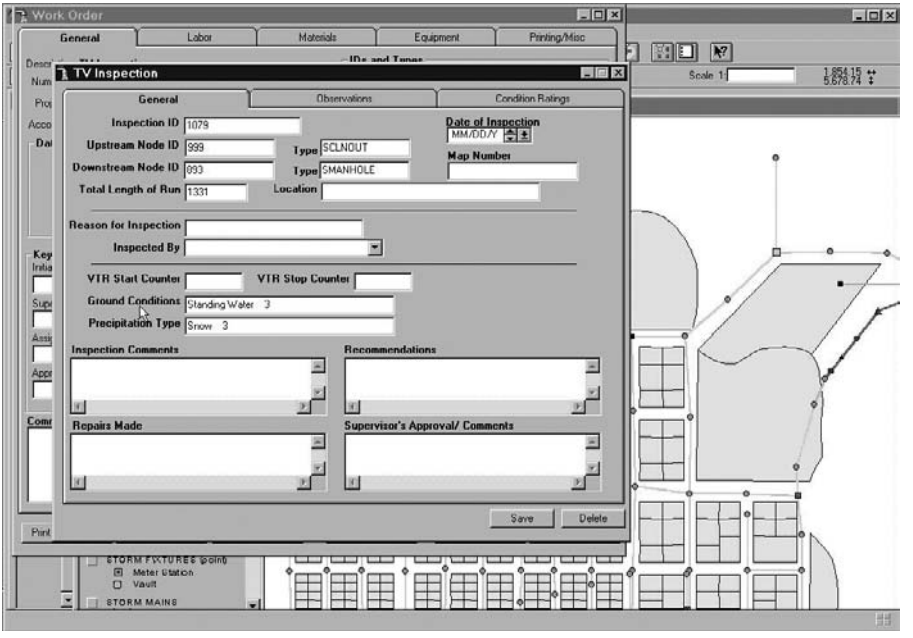

Figure 15.10 Cityworks work order management screen for CCTV inspections.

WATER MAIN ISOLATION TRACE

In many cases, the labor and material costs for fixing a broken water main are smaller than the hidden costs resulting from the pipe break. The hidden costs might be incurred due to human injury, property damage, litigation, customer inconvenience, traffic delays, police and emergency services, lost economic opportunities, and diminished fire-fighting capacity in other parts of the system. GIS offers many applications in the inspection and maintenance of water distribution systems. Water main isolation trace is one such application.

When a water main breaks, it should be isolated from the rest of the water distribution network for repairing the break or replacing the pipe. Water main isolation trace is defined as identifying those water distribution system valves that must be closed to repair or replace a broken water main. A water distribution system network layer that "knows" which links are connected to which nodes (i.e., has topology) can be used to traverse networks (Haestad et al., 2003) for solving the water main isolation problem. In addition to valve identification, GIS also allows an advance analysis of various water main shutdown scenarios, such as:

- Refining the valve search based on inoperable valves
- Identifying dry pipes (i.e., pipes without water)
- Identifying the affected customers served by dry pipes
- Identifying critical water service customers (e.g., hospitals), who need uninterrupted service
- Determining the extent of a service interruption to avoid unintentional shutdowns
- Capturing leak history data that are useful in pipeline replacement modeling

A GIS must have *topology* to benefit from the isolation trace application. Topology is defined as the spatial relationship between features. Spatial relationships between connecting or adjacent features, such as the pipes connected to a hydrant, which are so obvious to the human eye, must be explicitly defined to make the digitized maps "intelligent." For example, our eyes can instantly identify the pipe serving a house just by looking at a paper map. A GIS, on the other hand, must mathematically compare the pipe and parcel layers to complete this task. Topology is, therefore, defined as a mathematical procedure for explicitly defining spatial relationships between features. The subject of topology is so sophisticated that it is considered a branch of mathematics (Shamsi, 2002). The GIS layers that have topology can be used to trace transportation or utility networks. A water distribution system network layer that knows which links are connected to which nodes can be used to traverse networks (Haestad et al., 2003).

ESRI's ArcMap software provides many network analysis functions. ArcMap's standard interface can be customized to add network analysis functions such as network tracing. For example, a sample toolbar called the Utility Network Analyst (UNA) was developed by ESRI to help ArcGIS users develop custom applications (ESRI, 2002c). The UNA consists of a toolbar, a pull-down menu for saving and loading flags and barriers and setting options, a set of tools for specifying flags and barriers, and a combo box containing the list of available trace tasks. The UNA toolbar has a set of trace tasks (Find Connected, Trace Upstream, etc.) that can be used to solve

many problems. The Isolation Trace Task of the UNA toolbar takes a single specified edge flag and determines the valves that would need to be turned off to isolate the area. The UNA toolbar can be downloaded from http://arcobjectsonline.esri.com. The steps required to use the Isolation Trace Task are:

1. Register the trace task with Categories.exe as an ESRI Utility Network Task.
2. Close and restart ArcMap.
3. Add your network to ArcMap. Use the Add Edge Flag Tool on the Utility Network Analyst toolbar to place an edge flag at the location you wish to isolate.
4. Choose "Isolation Trace" from the list of available trace tasks and perform the trace. The result will be a display of the isolated area and a selection set of the valves to turn off.

CASE STUDIES

Representative case studies of GIS applications in maintenance are given in the following subsections.

Isolation Trace Case Studies

Figure 15.11 shows an isolation trace example from the PipeWorks example data. Pipeworks (now known as CityWorks) is an AM/FM/GIS software package from Azteca Systems (Sandy, Utah, www.azteca.com), that runs as an ArcView Extension. The trace is conducted by selecting the broken water main (midway on the pipe in the center of the map) and clicking on the "Isolation Trace" button. The top screenshot shows that four valves must be closed to isolate the broken water main for repair or replacement. Next, it was assumed that one of these four valves located at the bottom of the screen is "open inoperable," which would prevent this valve from being closed down. This scenario was modeled by changing the valve status from "open operable" to "open inoperable." The actual valve status can be made available in the GIS database if field inspections data are integrated with it. The bottom screenshot shows that due to the inoperable status of one of the valves, two additional (i.e., a total of six) valves must be closed.

In 2001, San Jose Water Company, which services the City of San Jose, California, created an ArcView 8.1 application called "Main Break" to accomplish the preceding functions using Visual Basic and ArcObjects running against a personal geodatabase. The application was installed at SJWC's main office and on seven laptop computers. The laptop computers empowered the field personnel with a mobile GIS that allowed on-site identification of the valves to be closed (Coates, 2003).

Sewer System Inspections in Washington County

A sewer system inspection GIS was implemented for a small community located in the Washington County of Pennsylvania with a population of 4900 people and a

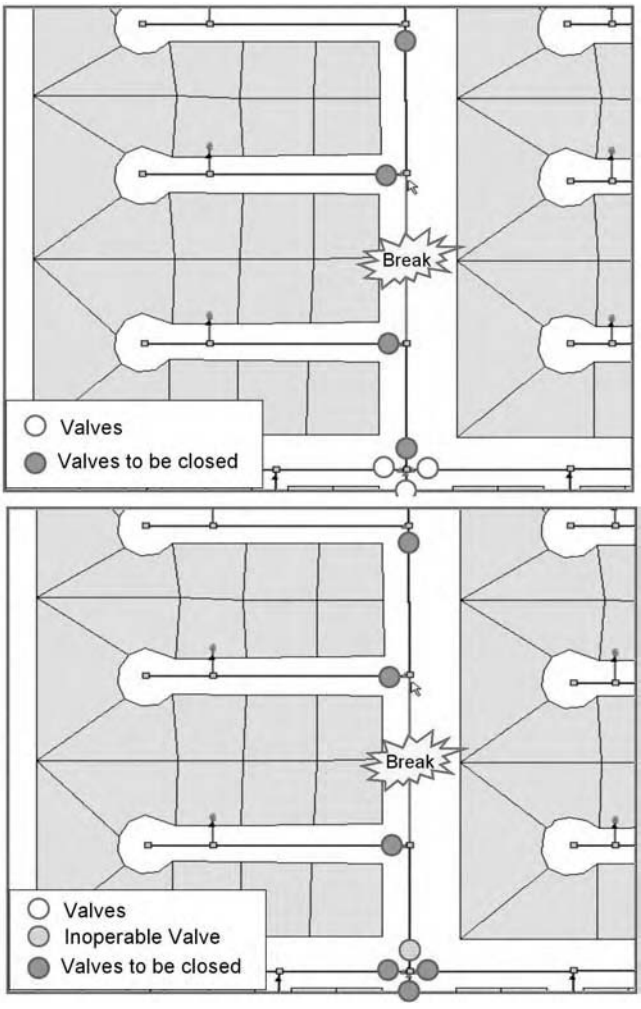

Figure 15.11 Isolation trace example. Above: all valves operable; below: one valve inoperable.

1.5 MGD (million gallons per day) sewage treatment plant. This GIS project consisted of the following tasks:

1. Develop manhole and sewer line coverages
2. Add manhole attributes from corrective action plan (CAP) manhole inspection reports
3. Add sewer attributes from CCTV inspection logs
4. Develop service laterals coverage from CCTV inspection logs
5. Develop video coverage from CCTV inspection tapes
6. Add street names to the existing roads coverage
7. Align image and feature themes
8. Package the information for delivery

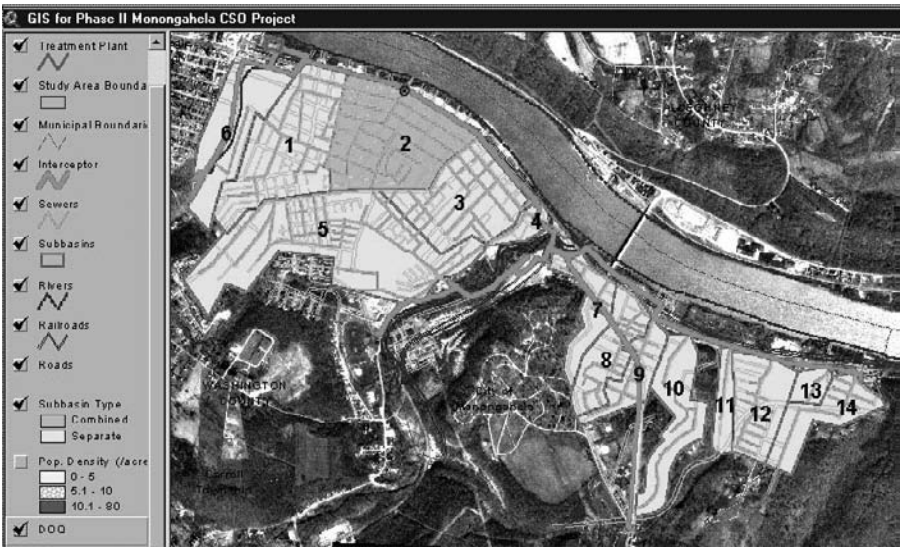

Figure 15.12 ArcView layers created from sewer system inspections data.

The project was completed in 2000 in 6 months for a cost of $15,000. Various free public-domain GIS data were used to keep the project cost low. These data included USGS digital orthophoto quarter quadrangles (DOQQ), digital raster graphics (DRG), and digital elevation models (DEM). Tasks 3, 4, and 5 were accomplished using the various techniques described in this chapter. Fifty mini movies were created from the existing VHS tapes and stored on five CD-ROMs. The movie files consisted of uncompressed AVI files of 40 to 60 MB size and resulted in approximately 3 GB of digital data.

Figure 15.12 shows various ArcView GIS themes of the project overlayed on the DOQQ image. The figure on the first page of this chapter shows an ArcView project screen displaying a mini movie of root growth for a user-specified location. Figure 15.8 and Figure 15.9 presented earlier show thematic maps of manhole and sewer defects, respectively.

Sewer Rehabilitation in Baldwin

Facing stringent regulatory requirements at the turn of the century, many communities in the Allegheny County (Pennsylvania) started undertaking comprehensive sewer rehabilitation projects to reduce systemwide inflow and infiltration. Rehabilitation activities included internal televising, pipe lining, pipe bursting, pipe replacement, manhole repair, and manhole replacement.

Baldwin Borough, a 5.5 mi^2 municipality located in the Greater Pittsburgh area with a population of 22,000, undertook a similar project. Baldwin's consultant,

(Chester Engineers, Pittsburgh, Pennsylvania) developed a sewer rehabilitation data management system (SRDMS) to assist in the planning and design phases of Baldwin's sewer rehabilitation projects. Initially, the system was successfully tested in the bidding phase for internal inspection of over 200,000 ft of sanitary sewers and 3,000 manholes. The system utilized digital map data compiled during a sewer-mapping effort initiated in 1996. The project team field-verified the sewer network data based on CCTV inspections conducted during a 3-month period in 2001. Concurrent with this effort, a Microsoft Access™ database was developed to capture conditional information for each surveyed sewer feature, apply unit costs for all necessary repair work, and generate a variety of reports for use in bid document submittals. Subsequent rehabilitation projects proved the effectiveness of SRDMS, leading to its implementation in several Allegheny County communities.

SRDMS is a GIS-based system because it reads and writes the information in a GIS database. It utilizes a relational database (e.g., Microsoft Access) to manage disparate data related to rehabilitation work, including manhole inspections, televised sewer line inspections, and flow data. This relational database is linked with the GIS database to facilitate mapping of the extent and severity of system damage and the recommended remedial activities. The required GIS layers can be created from a variety of sources, such as ArcInfo™ coverages, ArcView™ Shapefiles, and CAD files (e.g., Integraph™ or AutoCAD™). Preprocessing of CAD data to ensure the connectivity of sewer features may be necessary as the system requires that connectivity be established between all lines and manholes. SRDMS can use field inspection data from the conventional paper forms or the latest digital data collectors (e.g., PDAs, or tablet PCs). The GIS interface was initially developed as an ArcView 3.2 Extension. An ArcGIS version was created subsequently. SRDMS links inspection and repair information contained in the Access database to the corresponding GIS features. Applications of this system have resulted in a 20 to 30% reduction in project management labor effort over traditional methods. SRDMS provides the end user with the following functionalities:

- Provides the ability to visualize the overall condition of the sewage collection system using thematic maps of problematic areas.
- Identifies the precise locations of specific rehabilitation activities based upon an engineering interpretation of CCTV and manhole inspection results.
- Develops budgetary pricing for system repairs and rehabilitation work. It generates cost estimates for manhole rehabilitation and line repair work by applying multipliers to unit repair costs. Unit costs are entered by the project manager. The unit cost estimates may be modified at any time. The system will automatically update all aggregate costs based on the updated figures.
- Provides a series of reports detailing system damage, recommended remedial action, and cost estimates for the repair of damaged structures.
- Develops plans for distribution to prospective contractors during the bidding process.
- Provides a mechanism for tracking and reporting the progress of the rehabilitation activities.

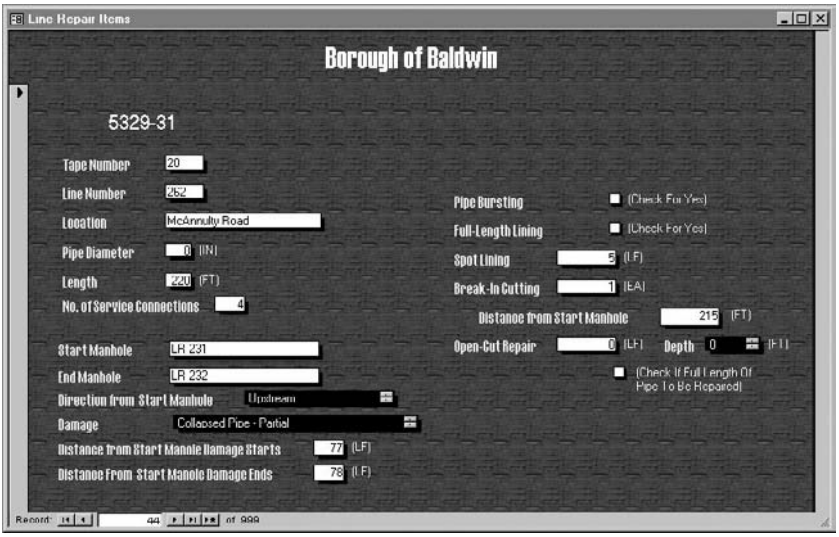

Figure 15.13 SRDMS line defect and repair entry form.

- Expands the content of the original GIS to include the location of service lateral connections identified during the televising process.
- Corrects inaccuracies in the original GIS based upon information obtained during the televising process.

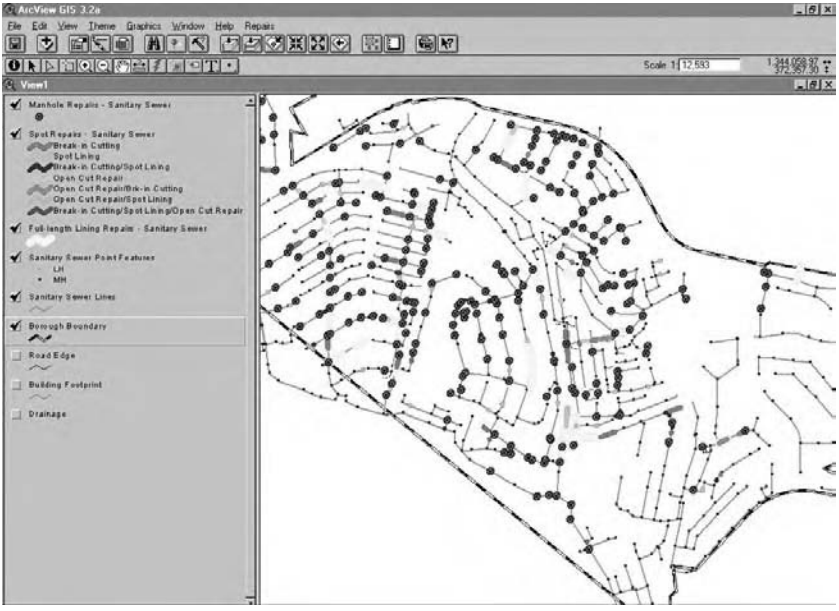

Figure 15.14 SRDMS line and manhole repair map.

Figure 15.13 shows the SRDMS line defect and repair entry form. The left side of this form receives input from the CCTV inspections database and automatically updates the GIS layer for pipes. The right side of the form, which recommends appropriate repairs, is completed by the project engineer or manager based on individual judgment and experience. Manhole and line repairs recommended by the user are added to the GIS as new layers. Figure 15.14 shows an ArcView screenshot of the line and manhole repair map. All the manholes targeted for repairs are clearly shown as large dots. All the sewers targeted for spot repairs or full-length lining repairs are shown in different colors.

CHAPTER SUMMARY

This chapter provided an overview of GIS applications for the fourth *M* of the "4M approach" in the inspection and maintenance of water, wastewater, and stormwater systems. These applications include asset management and field inspections required by regulations such as GASB 34 and wet-weather overflow policies in the U.S. GIS also allows integrating work-order management and video inspections (e.g., CCTV inspections of sewers) with maps, which results in workflow efficiency improvement and cost savings for water and wastewater utilities. GIS can be used as a project management tool for system rehabilitation and repair work. Last but not least, GIS allows thematic mapping of inspection data to enable effective communication with decision makers and stakeholders. Real-world examples and case studies presented in this chapter show that GIS can be used for more efficient inspection and maintenance of water, wastewater, and stormwater systems.

CHAPTER QUESTIONS

1. What is the "infrastructure problem," and how can GIS help to solve this problem?
2. What is asset management, and how can GIS help in asset management of water, wastewater, and stormwater systems?
3. Describe two examples of GIS applications in regulatory compliance for water, wastewater, or stormwater systems.
4. What is water main isolation trace? How will you implement it on a mobile device?

CHAPTER 16

Security Planning and Vulnerability Assessment

Although water and wastewater systems are generally well prepared to deal with natural disasters and accidents, many utilities prior to September 11, 2001 had given little consideration to defending themselves against acts of terrorism. Read this chapter to see how GIS can help in safeguarding your water and sewer systems against the acts of terrorism.

Water distribution systems are especially vulnerable to acts of terror.

LEARNING OBJECTIVE

The learning objective of this chapter is to understand GIS applications in security planning and vulnerability assessment of water and sewer systems.

MAJOR TOPICS

- GIS applications in planning
- Security planning
- Vulnerability assessment
- Security modeling software

GIS APPLICATIONS IN PLANNING

GIS technologies have enabled planning professionals to make better and faster planning decisions. New software advances have revolutionized the preparation and use of master plans for water and sewer systems. GIS technologies provide various planning tools such as:

1. Remote-sensing data (described in Chapter 3)
2. Land-use/land-cover data (described in Chapter 3, Chapter 11, and Chapter 12)
3. Intelligent maps (described in Chapter 8 and Chapter 9)
4. Hydrologic and hydraulic models (described in Chapter 11 to Chapter 13)

With the help of case studies and examples, this chapter will focus on how to apply these tools for security planning purposes.

CITY OF ALBUQUERQUE'S WASTEWATER MASTER PLAN

In 1990, the City of Albuquerque, New Mexico, began a multiphase planning effort to evaluate its existing wastewater conveyance and treatment facilities, project future growth and flows, create programs for monitoring and rehabilitating existing infrastructure, and develop an organized approach to ensuring that future facilities keep pace with development. The City used GIS technology to develop a 40-year master plan for its wastewater collection and treatment system. The master plan was created by integrating the City's GIS data with a number of other computer applications including demographic modeling,

land-use mapping, hydraulic analysis, and infrastructure rehabilitation planning. The GIS approach enabled the City to create a master plan that could be easily updated in future as new development takes place (American City & County, 1991).

SECURITY PLANNING

Water, wastewater, and stormwater systems face both natural (floods, droughts, earthquakes, fires, etc.) and man-made (terrorism, vandalism, sabotage, arson, cyber attacks, etc.) threats. Although water industry utilities have learned from natural disasters, their experience with human-caused threats is small (Grigg, 2002). The basic form of protection against attacks or threats of attacks is a security system. Security planning methods include hazard assessment, vulnerability assessment, mitigation, response planning, and crisis communications (Burns et al., 2001). Vulnerability assessment is an important step in disaster preparedness. In the U.S., many utilities are performing mandatory vulnerability assessments.

When terrorists attacked the World Trade Center complex in New York and the Pentagon building in Washington, D.C., on September 11, 2001, the U.S. witnessed one of the worst days of its 225-year history. The unfortunate event also witnessed the best of the American spirit as people everywhere, including the GIS community, rushed to help. GIS supported response efforts at the World Trade Center and the Pentagon by coordinating the search for survivors and identifying hazardous areas. Planning for collection of airborne imagery over Ground Zero began within hours of the terrorist attack. Only 3 hours after the attack, France's SPOT 4 satellite captured 20-m resolution infrared images of the fires blazing in Manhattan. On September 12, Space Imaging's IKONOS satellite acquired 1-m imagery of both the World Trade Center area and the Pentagon (Barnes, 2001b). LIDAR* images collected on September 19, 2001, at 5000 ft were used to create 3D depictions of the terrain and buildings of the World Trade Center complex (Logan, 2002). The media, to cover the stories related to the terrorist attack, frequently used these 3D renderings.

Since September 11, 2001, concerns over intentional contamination have resulted in new federal legislation in the U.S. requiring community water systems to develop Emergency Response Plans (ERPs) (Haestad Methods, 2003a). In the Public Health Security and Bioterrorism Preparedness and Response Act of 2002, U.S. Congress recognized the need for drinking water system utilities to undertake a more comprehensive view of water safety and security. It amended the Safe Drinking Water Act and specified actions that community water system utilities and the U.S. Environmental Protection Agency (EPA) must take to improve the security of the nation's drinking water infrastructure. In 2002, EPA issued $90-million grant monies to help U.S. water and wastewater utilities assess their security needs. In January 2003, the U.S. Government launched the Department of Homeland Security for coordinating the work of America's security and intelligence agencies.

Although water and wastewater systems are generally well prepared to deal with natural disasters and accidents, many utilities — prior to September 11 — had given

* For additional information on LIDAR data, please refer to Chapter 3 (Remote-Sensing Applications).

little consideration to defending themselves against acts of terrorism. Immediately after the September 11 terrorist attacks, many water and wastewater utilities in the U.S. quickly adopted or expanded security measures (Landers, 2002).

Vulnerability of Water Systems

Drinking water utilities today find themselves facing new responsibilities. Although their mission has always been to deliver a dependable and safe supply of water to their customers, the challenges inherent in achieving that mission have expanded to include security and counterterrorism. Water distribution systems are especially vulnerable to acts of terror. Water systems can be contaminated by injection of poisonous substances such as cyanide. Water system operators, therefore, should be able to monitor contaminant levels and to predict contaminant movement throughout the system. These are complex tasks that require real-time monitoring and distribution-system water quality modeling. Real-time monitoring of every contaminant that could be deliberately introduced in a water system is not practical. However, a change in indicator parameters can signal the possibility of intentional contamination. The operators should be equipped with the most effective means of interpreting the monitoring data, communicating the results to decision makers and the general public, and implementing the control measures quickly (Schreppel, 2003). At the present time, most applications are focusing on the security analysis of drinking water distribution systems.

Vulnerability of Sewer Systems

Sewer systems can be used to contaminate receiving waters that are used for drinking-water supply intakes. Terrorists can pour volatile matter in the sewer system to create fire hazards. Large combined and storm sewers can also be used to gain access to restricted areas that have been blocked for security reasons. Although much of the attention regarding the security of water infrastructure has focused on the drinking water side, wastewater professionals have been quick to acknowledge and attempt to address their vulnerabilities. For example, the Metropolitan Sewer District (MSD) of Greater Cincinnati, Ohio, turned its attention to its sewage collection system, analyzing the likelihood that its sewers — particularly some of its large combined sewers — might be used as conduits in a terrorist attack. MSD used a GIS to compare maps of its collection system with the maps of Cincinnati to conclude that there were no major targets of opportunity in close proximity to any of its large sewers (Landers, 2002). Analysis of using a sewer system to attack a wastewater treatment plant or pumping station still requires some research.

GIS APPLICATIONS IN VULNERABILITY ASSESSMENT

Water and wastewater utilities must remain vigilant and develop comprehensive engineering and management measures to protect against future threats (Grigg, 2003). Implementing homeland security necessitates understanding the systems,

infrastructure, organizations, and vital interactions necessary for the well-being of communities. GIS is critical to this effort because it integrates all types of information and relates that information spatially. GIS can help in the areas of risk assessment, security planning, mitigation of the effects of attacks, preparedness activities, response measures, and recovery efforts.

GIS applications for community protection include modeling chemical releases in water and air, tracking and accessing information about hazardous storage sites, and managing hospital information. GIS applications can also reveal additional problems caused by proximity to hazards such as chemical storage. The modeling capabilities of GIS can simulate the effects of many types of attacks on critical resources, infrastructure, and populations. After identifying the hazards, assessing the risks, and prioritizing the values (i.e., assets of greatest value), both strategic and tactical plans can be formulated. GIS enhances response to acts of terror by helping managers to quickly assess the extent of damage and by speeding the decision-making process (ESRI, 2002d).

There is no one-size-fits-all security approach that will work for all water or sewer systems. Because each utility's situation is unique, security measures must be tailored to each system. In general, however, there are two basic requirements for the vulnerability assessment of water and sewer systems:

1. Network connectivity: This requirement pertains to what system components are connected to what and what is upstream (or downstream) of what. This capability would determine, for example, the area that would be impacted by a contaminated water storage tank. A GIS must have topology information to determine network connectivity. Network topology is inherent in many GIS packages and can easily provide this information. Network-tracing (described in Chapter 9 [Mapping Applications]) and isolation-tracing (described in Chapter 12 [Water Models]) functions are good examples of the network topological capabilities of GIS.
2. Contamination analysis: This requirement pertains to the strength and extent of the contaminants. GIS alone cannot provide this information. Hydraulic models capable of simulating both the quantity and the quality of water must be used in conjunction with a GIS.

GIS and hydraulic modeling can be used for infrastructure protection, vulnerability assessment, consequence management, and security planning to safeguard water, wastewater, and stormwater systems against potential sabotage activities and terrorist attacks. Lindley and Buchberger (2002) outlined a holistic approach that combined GIS and hydraulic modeling to integrate multiple risk factors so as to identify locations that may be vulnerable to contaminant intrusions. Intrusions were defined as the introduction (either accidental or deliberate) of an undesirable agent into the potable water distribution system. An intrusion pathway was defined as the connectivity route between the potable supply and the contaminant source. EPANET* software was used for hydraulic modeling. GIS was used for layering of the locations having adverse pressure, intrusion pathway, and source concerns.

* Additional information about EPANET is provided in Chapter 12 (Water Models).

SECURITY MODELING SOFTWARE

Sample security modeling software products are described in the following subsections.

H_2OMAP^{TM} Protector

H_2OMAP Protector from MWH Soft, Inc. (Pasadena, California), is an add-on module for the H_2OMAP suite* that can be used for water security planning, infrastructure protection, and vulnerability assessment. Designed with the latest geospatial modeling technology, Protector uses a geodatabase for modeling various security scenarios. It can be used for estimating the consequences of a terrorist attack or a crisis event on a drinking-water supply infrastructure as well as formulating and evaluating sound emergency response, recovery, remediation and operations plans, and security upgrades. The program can be used to identify viable solutions before an incident or disaster occurs, or to assist in responding should it occur.

Protector allows users to model the propagation and concentration of naturally disseminated, accidentally released, or intentionally introduced contaminants and chemical constituents throughout water distribution systems; assess the effects of water treatment on the contaminant; and evaluate the potential impact of unforeseen facility breakdown (e.g., significant structural damage or operational disruption or both). It enables users to locate areas affected by contamination, calculate population at risk and report customer notification information, and identify the appropriate valves to close to isolate a contamination event. Finally, it helps users track contaminants to the originating supply sources, compute required purging water volume, develop efficient flushing strategies, determine the resulting impact on fire-fighting capabilities, and prepare data for eventual prosecution.

Figure 16.1 shows a Protector screenshot showing isolation analysis. It depicts affected and closed facilities color-coded according to their vulnerability (risk factors).

WaterSAFE™

WaterSAFE from Haestad Methods, Inc. (Waterbury, Connecticut), is an add-on component for WaterCAD and WaterGEMS** software products. WaterSAFE is designed to manage and safeguard water distribution systems. It is a water system security and emergency planning tool specifically created to study infrastructure vulnerability to terrorist attacks and natural events.

Harnessing the powers of ArcGIS, WaterSAFE enables water utilities to analyze the movement of multiple constituents and track multiple sources for a given period of time. With this information, water utilities can assess the impact in real time and swiftly relay the results to customers in contaminated areas to take the necessary precautions. These water quality analysis features can enable utilities to better respond, strategize, and implement a fast and effective recovery plan in the event of

* Additional information about H_2OMAP suit is provided in Chapter 12 (Water Models)
** Additional information about WaterCAD and WaterGEMS is provided in Chapter 12 (Water Models).

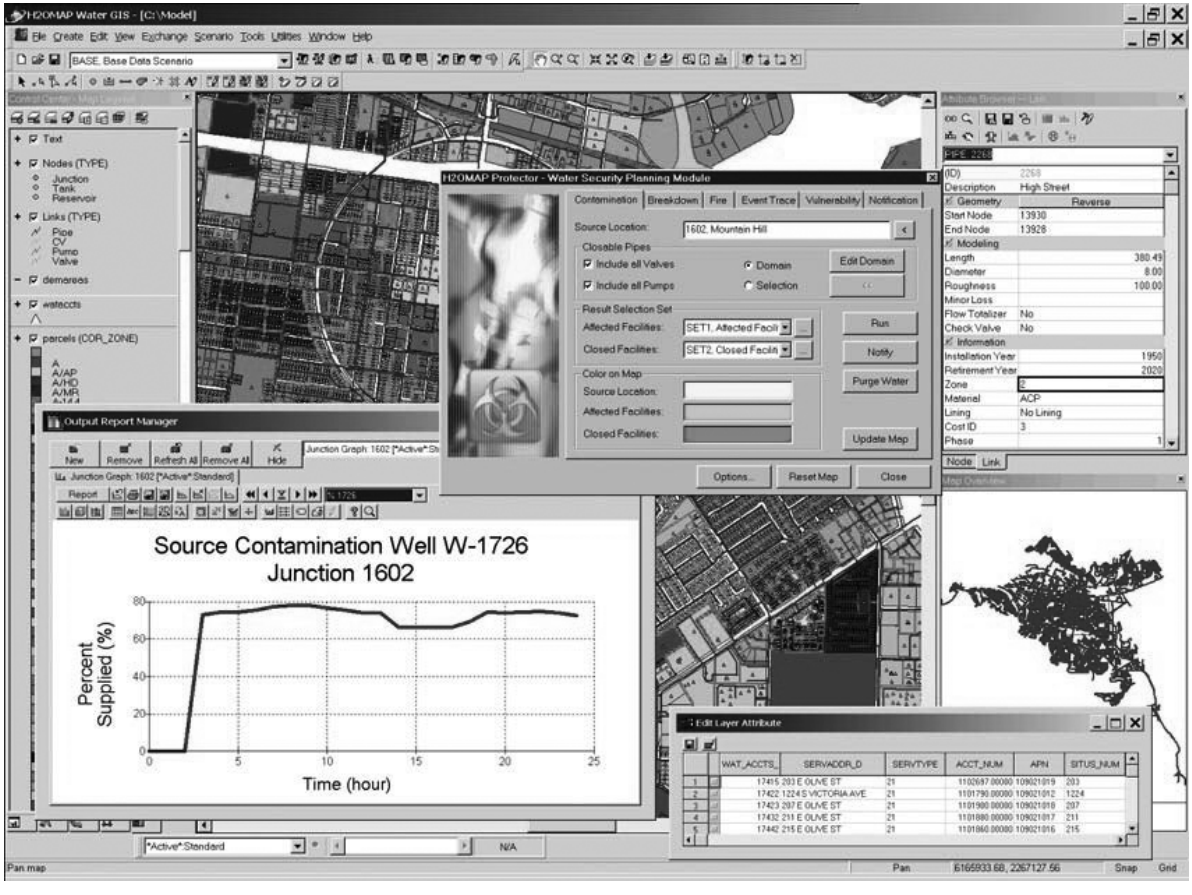

Figure 16.1 Protector screenshot showing isolation analysis.

a contamination emergency. WaterSAFE's extended water quality analysis features can also assist in conducting statistical analysis of water quality and evaluating contamination effects on a water treatment plant.

In 2003, a WaterCAD model was used to prepare an example ERP. Two scenarios were modeled: a rehearsed drill before a terrorist attack and a real-time solution. It was assumed that a contaminant was introduced into the tank of a typical midsized system and that complete mixing occurred in this tank. The vulnerability of the water system was assessed by monitoring the effects of injection location, the nature of the contaminant, the amount of contaminant added, and the period over which the contaminant was added. The modelers were able to reduce the spread of the contaminant, monitor the impact of flushing on the environment, and more quickly bring the system back to normal operation (Haestad Methods, 2003a).

VSAT™

Association of Metropolitan Sewerage Agency (AMSA) Washington, D.C., in cooperation with EPA, released a new water and wastewater system security analysis software in 2002. Known as Vulnerability Self Assessment Tool (VSAT), the software is available free of charge. Three versions, VSATWater, VSATWastewater, and VSATWater/Wastewater, are available for water, wastewater, and both water and wastewater systems, respectively. The VSAT products provide a structured, cost-effective approach for utilities to assess their vulnerabilities and to establish a risk-based approach to taking desired actions. The software allows utilities to assess the vulnerability of the complete range of utility assets including people (utility staff), physical plant, knowledge base, information-technology platform, and customers.

VSAT does not use GIS or hydraulic modeling. However, the information obtained from GIS and modeling can be used to run the VSAT program. For example, the first VSAT task is asset categorization and identification, which requires utility managers to conduct an inventory of utility assets. A GIS can be used to conduct an asset inventory for input to the VSAT program.

SECURITY PLANNING DATA ISSUES

The number of GIS data formats has increased exponentially with the growth in the GIS industry (Goodchild, 2002). According to some estimates, there might be more than 80 proprietary geographic data formats (Lowe, 2002b). Why are there so many geographic data formats? One reason is that a single format is not appropriate for all applications. For example, a single format cannot support both fast rendering in a command and control system and sophisticated topological analysis in a natural resource information system. Different data formats have evolved in response to diverse user requirements.

Users must possess considerable expertise to overlay, combine, or analyze different map layers or images. Converting from one format or type of data to another is cumbersome, time consuming, and error prone. Therefore, different GIS data formats or models used by different government organizations can lead to compatibility

problems that can hamper data sharing needs during an emergency situation such as a terrorist attack. This can be avoided by adopting compatible data models and interoperable data formats throughout a city or county. Efforts are currently underway in the GIS industry to standardize data formats and database-management systems by promoting open platforms, data, and database management systems. For example, the Open GIS Consortium (OGC) has been created with the vision of "the complete integration of geospatial data and geoprocessing resources into mainstream computing." OGC was formed in 1994 to facilitate access to and geoprocessing of data held in systems or networks. It defines an open GIS as "open and interoperable geoprocessing" or "the ability to share heterogeneous geodata and geoprocessing resources transparently in a networked environment."

CHAPTER SUMMARY

Water, wastewater, and stormwater systems can be vulnerable to acts of terrorism and sabotage. This chapter shows that GIS offers many useful applications in security planning and vulnerability assessment of these systems. GIS maps and hydraulic models can be used as effective security planning tools to evaluate the system vulnerability to natural and man-made disasters, and recommend solutions. For example, GIS and hydraulic models can be used to determine the areas of a water distribution system that can be affected by a contaminated water supply source. At the present time, most applications are focusing on the security analysis of drinking water distribution systems.

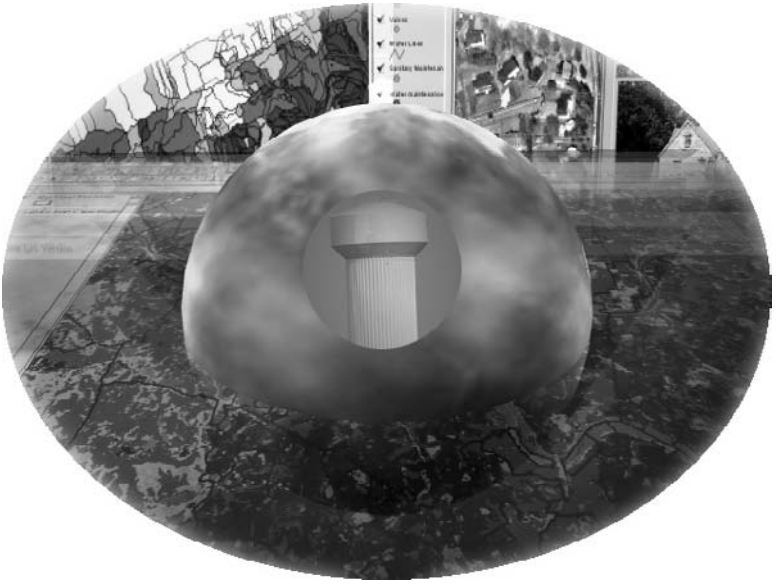
CHAPTER QUESTIONS

1. How are water and sewer systems vulnerable to acts of terrorism?
2. What can be done to protect water and sewer systems from acts of terrorism?
3. How can GIS applications help in security planning and vulnerability assessment of water and sewer systems?

CHAPTER 17

Applications Sampler

The use of GIS applications is growing throughout the world. This chapter shows how people around the world are applying GIS in their water, wastewater, and stormwater projects.



This chapter presents the latest examples of GIS applications in the water industry.

LEARNING OBJECTIVE

The learning objective of this chapter is to document GIS application projects around the world for water, wastewater, and stormwater systems.

MAJOR TOPICS

- Water system modeling
- Sewer system modeling
- Collection system rehabilitation and asset management
- Resource planning and capital improvement project (CIP) allocation
- Water quality management
- Water master planning

This chapter presents a collection of recent case studies on GIS applications for water, wastewater, and stormwater systems. These case studies were written specially for publication in this book by 18 GIS and water professionals from 6 countries (Belgium, Bulgaria, Czech Republic, Denmark, Spain, and the U.S.). For the names and organizational affiliations of the case studies' authors, please see the Acknowledgments section. The case studies were submitted in response to the author's "Call for Case Studies" distributed to various Internet discussion forums.

DRAINAGE AREA PLANNING IN SOFIA

Application	Sewer system modeling
Author(s)	Milan Suchanek, Tomas Metelka
Project status	Completed in March 2003
Hardware	1000 MHz Pentium III personal computers
GIS software	Arc View 3.3
Other software	MOUSE 2002; MOUSE GM; MOUSE Gandalf; MOUSE LTS; AquaBase
GIS data	Subcatchment polygons, conduit lines, node points, CSO points, land use, population, property boundaries, buildings
Study area	City of Sofia, the capitol capital of Bulgaria, watershed area of about 400 km^2
Project duration	November 2001 to March 2003
Project budget	$460,000
Organization	Sofiyska Voda A.D.

The city of Sofia's sewerage system is a very complex combined drainage system dating back to early 1900. The drainage area is made up of about 400 km^2 of watershed area, draining wastewater from 1.2 million people. At the same time, the hydrological conditions of the city, which is located on the foothills of the Vitosha mountains, promote heavy rainfall, mainly during late spring.

By the end of March 2003, the first simulation model for the sewer drainage system was developed in Bulgaria. The skeletal planning model was built for the city of Sofia, having about 5000 manholes, 5000 pipes, 3000 catchments, and 140 CSO or diversion chambers. The study area was subdivided into seven main subcatchments and their main trunk sewers. The respective submodels were built up and calibrated based on 6 weeks of flow survey at some 75 flow and 25 raingauge sites. Finally all seven submodels were merged into one combined model covering the whole drainage area.

The local GIS system, supported by comprehensive manhole and ancillary surveys, supplied the model with the system structural data. The overall data migration process was an important task in the project execution.

The Sofia drainage area planning project brings a new experience to the general view of project management. The management project was based on British standards, and the WaPuG *Code of Practice* handbook was followed. At the same time, Danish technology was applied, along with Czech and Bulgarian know-how. Figure 17.1 shows a screenshot of the Sofia model in MOUSE (Suchanek and Metelka, 2004).

PIPE RATING PROGRAM IN BUNCOMBE COUNTY

Application	Collection system rehabilitation and asset management
Authors	Ed Bradford, Roger Watson, Eric Mann, Jenny Konwinski
Project status	Implemented in 2004 and is being used to generate rehabilitation projects
Hardware	Standard desktop PCs (connected to network)
GIS software	ArcGIS 8.x
Other software	Microsoft Access XP, Windows Media Player, Microsoft Excel, Microsoft Word, etc., as necessary to generate reports
GIS data	Sewer line polylines, sewer structure points, 6-in., 1-ft, and 2-ft resolution DOQs, county parcel polygons, drainage basin polygons, digital video hyperlinks, CCTV inspection and defect-coded Microsoft Access tables, river and stream polylines, and road centerline polylines
Study area	Entire MSD service area (180 mi^2, 920 mi of sewer)
Project duration	Began in 2001. No end date scheduled
Project budget	No defined budget *per se* for the program itself. Construction projects have generated $700,000 in actual cost so far, which could increase in future
Organization	Metropolitan Sewerage District (MSD) of Buncombe County, North Carolina
Web site	www.msdbc.org

MSD's Pipe Rating Program is a new method of generating and prioritizing sewer rehabilitation projects. The typical approach of *reactive* planning is to define, develop, and complete a rehabilitation project after problems such as sanitary sewer overflows (SSO) or structural failures occur (Bradford et al., 2004a). Pipe Rating is a *proactive* tool that utilizes CCTV information, a GIS database, and real-world maintenance history to view, score, and rate pipe segments based on a number of

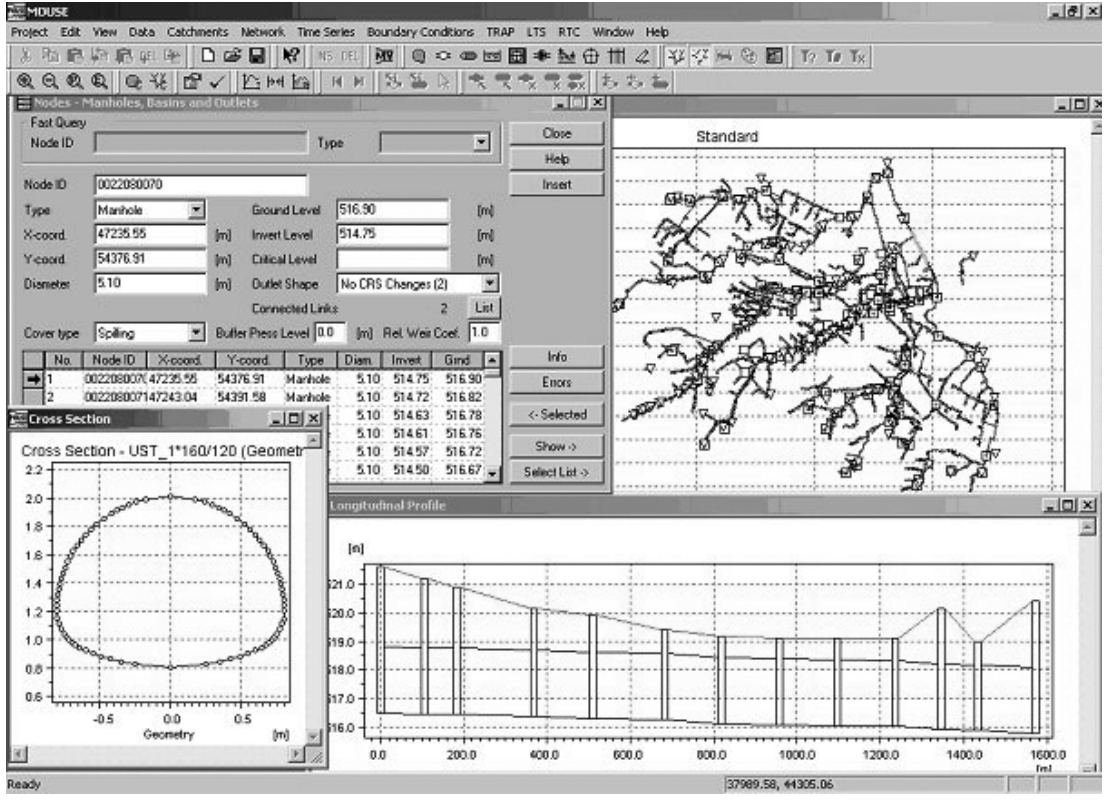

Figure 17.1 Screenshot of Sofia's MOUSE sewer system model.

factors. These factors, for any given manhole-to-manhole segment, include the number and severity of structural defects and the history of overflows on that segment. These are all combined to yield a rating, which may then flag a particular line segment for further investigation.

The data are gathered from a number of sources and incorporated into this program, which runs on the standard ArcGIS platform. CCTV video is captured by cameras traversing the pipes, and recorded on VCR tapes or in digital format (CD or DVD). First, each video is linked to its respective pipe segment within the District's GIS system so that it is immediately available to engineers and field responders. Second, a database is also created from the field data to record various features about the pipe, such as defect and structural information. This is accomplished by assigning to each defect a value pursuant to the standardized defect-rating manual developed by the District for this purpose. CCTV data are collected and embedded in a standard Microsoft Access database. When the technician identifies a defect along the segment, it is keyed in with the corresponding defect code. Each defect, and its corresponding severity score, is assigned to its pipe segment and used for future analysis performed in the GIS. Table 17.1 shows the defect structural scores used by MSD. These scores are based on MSD's standardized Sewer Condition Classification Manual. Scores are weighted according to MSD priorities.

Finally, all the information is used to calculate three pipe scores for each pipe: mean pipeline, mean defect, and peak defect scores. These scores allow users to visualize the severity in three categories for prioritization within the rehabilitation program. Once this has been accomplished, engineers can retrieve the videos from the GIS for confirmation and to evaluate them for rehabilitation procedures. Figure 15.1 shows an ArcGIS screenshot of mean pipeline ratings. Figure 17.2 and Figure 17.3

Table 17.1 Sewer Pipe Structural Defect Scores

Code	Description	Score
CC	Circumferential crack	20
CL	Longitudinal crack	20
CM	Multiple cracks	30
COH	Corrosion heavy	50
COL	Corrosion light	20
COM	Corrosion medium	30
D	Deformed sewer	65
FC	Circumferential fracture	40
FL	Longitudinal fracture	40
FM	Multiple fractures	60
HL	Hole large	50
HP	Hole patched	5
HS	Hole small	25
JDL	Joint displaced large	30
JDM	Joint displaced medium	5
OJL	Open joint large	30
OJM	Open joint medium	10
X	Collapsed pipe	100

show maps of mean defect and peak defect pipe ratings, respectively (Bradford et al., 2004a).

WATER SYSTEM MODELING IN TUCSON

Application	Resource planning and capital improvement project (CIP) allocation
Author	Dean Trammel
Project status	GIS and hydraulic modeling effort completed in 2003
Hardware	Dell personal computers (1495 MHz, 384 MB RAM) with Windows 2000 Professional
GIS software	ArcMap and ArcInfo
Other software	Haestad Methods' WaterGEMS, WaterCAD for AutoCAD, Microsoft Access, Microsoft Excel
GIS data	U.S. census–disaggregated population projection data in the form of polygon Shapefiles, with associated population projections for each year from 2000 through 2050
Study area	Tucson, Arizona
Project duration	Resource planning effort: March 2002 to early 2004, GIS and hydraulic modeling: about 9 months
Project budget	CIP-budgeted planning effort, part of regular business
Organization	Tucson Water, Tucson, Arizona

Tucson Water's potable system supplies over 180,000 services, maintains over 4,000 mi of pipe, and installs over 500 new meters per month. Tucson Water also serves reclaimed water to over 550 reclaimed services, maintains over 100 mi of reclaimed pipe, and installs between 75 and 100 new reclaimed meters per year. In addition to the GIS data listed above, the following data were also used:

- The Pima Association of Government (PAG) took U.S. census tracts for the year 2030 and broke them up further into smaller disaggregated population-projection polygons, or traffic analysis zones (TAZ).
- Engineers, planners, and administrators made up a Resource Planning Committee that determined a boundary for the water service provided by Tucson Water, which was a modified version of a boundary used for previous planning efforts.
- Polygon Shapefiles that describe pressure zones and water services areas (WSA) for the entire service area, based on a parcel base of Tucson Water's customers.
- Ten hydraulic models of the central water system called local area models and five smaller models that represent isolated systems outside the central system.
- Shapefiles of the proposed master plans. These files were used as a backdrop to compare population projections with prospective new developments planned for the near future, and to make sure that these areas were correctly represented in the 2030 and 2050 model.
- SCADA, billing, production records.
- Cost estimates.
- Hydrology supply scenarios.

Traffic and census tract population projections were analyzed using ArcGIS to estimate future potable water demands. The estimated demands were applied to Tucson Water's current hydraulic model using Haestad Methods' WaterGEMS software. The model was then used to determine what facility and piping modifications would be

required to meet growth within current service areas and future development in outlying areas. Using capital and energy cost estimation tools within the hydraulic modeling software, different planning scenarios can be compared as to their overall costs.

First, the WaterGEMS skeletonization tool, Skelebrator, was used to reduce the existing local area models down to a point where they could be combined into a complete system model. Second, within WaterCAD for AutoCAD, the import/export submodel tool was used to combine the ten local area models and the isolated system models into a complete water system model. Third, the new model was balanced and checked for calibration to peak-day conditions. Fourth, demands were allocated to the model using processed data to predict demands for years 2030 and 2050. The WaterGEMS demand allocation tool, LoadBuilder, was used to distribute this demand correctly to the model. Lastly, scenarios for new additions to the system were made using WaterGEMS and WaterCAD for AutoCAD, and the functionality, capital cost, energy costs, and operations and maintenance costs associated with these scenarios were evaluated using built-in tools in the hydraulic modeling software. Figure 17.4 shows a screenshot of WaterGEMS model layers in ArcMap (Trammel, 2004).

WATER SYSTEM MODELING IN THE CITY OF TRUTH OR CONSEQUENCES

Application	Development of a water distribution model in MIKE NET from GIS data
Authors	Eric Fontenot
Hardware	Standard Desktop PC, 128 MB RAM, 850 MHz Pentium III processor
GIS software	ArcView 3.2
Other software	AutoCAD, MIKE NET, Microsoft Access
GIS data	Water distribution pipes, network demands
Study area	Truth or Consequences, New Mexico
Project duration	4 months
Project budget	$42,000
Organization	DHI, Inc., Newton, Pennsylvania, and Hørsholm, Denmark
Web site	www.dhigroup.com

The City of Truth or Consequences' water supply system was strained due to population increase and real estate development. The City had concerns about the system's ability to deliver fire suppression flow to certain parts of the city at peak demand. The City, therefore, engaged in strategic planning to evaluate possible improvements.

A model of the existing water distribution system was created by DHI, Inc., from several data sources. The detailed, topologically oriented model of the water distribution network was created primarily from GIS data and updated from hardcopy maps of the water system. Water demands were determined and distributed, based on production and billing information contained in a customer information system (CIS).

The comprehensive modeling evaluated the current system, as well as those alternatives identified in a preliminary engineering report. The placement of two

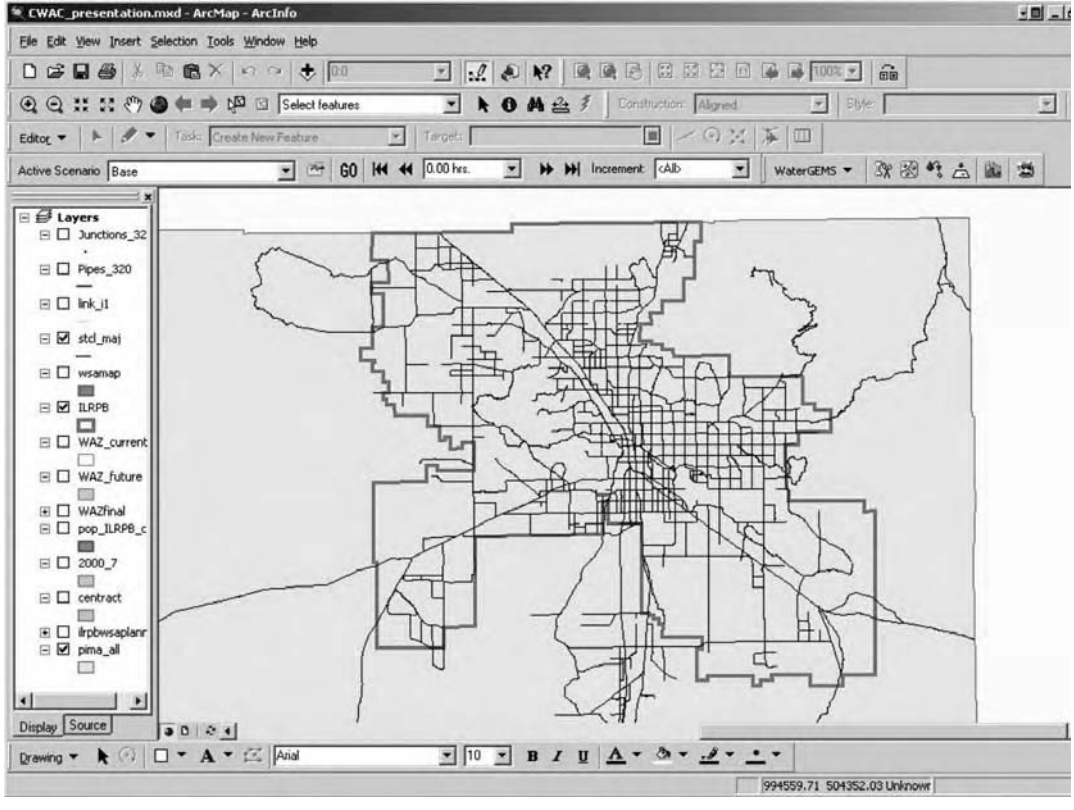

Figure 17.4 Screenshot of WaterGEMS model layers in ArcMap.

new storage tanks was evaluated, and recommendations were determined based on model results.

Background

Truth or Consequences is located east of Interstate 25 between Albuquerque and Las Cruces, adjacent to Elephant Butte Lake. The water system serves a combined population of approximately 7300 in Truth or Consequences and Williamsburg. There were 2820 residential and commercial connections, 268 of which were located in Williamsburg. The water system had 5 groundwater wells that fed a 200,000-gal clearwell, a 1,000,000-gal tank serving a low-pressure zone, a 3,000,000-gal tank serving a high-pressure zone, and 2 booster pump stations. Disinfection via chlorination was provided prior to the clearwell.

The five groundwater wells, ranging in age from 2 to 50 years, pumped into a 200,000-gal tank. Water was pumped from the 200,000-gal tank to the 1,000,000-gal storage tank, which supplied the low-pressure zone. Some of the piping in the low-pressure zone was quite old, dating back to the 1940s when the water system was originally constructed. Around 1970, the water system was divided into high- and low-pressure zones with the construction of the 3,000,000-gal tank. Water from the low-pressure zone was pumped into a storage tank to supply the high-pressure zone.

Due to increased demands and an aging system, the City was planning on constructing two additional tanks, one in each pressure zone. The current system did not maintain adequate pressure at peak demand, and the City had some concerns about the system's ability to deliver fire suppression flow to certain parts of the city. The 1,000,000-gal tank needed to be drained and rehabilitated, which could be done only after the construction of additional storage. The 3,000,000-gal tank also needed maintenance. Because it was the only tank in the high-pressure zone, an additional tank or booster station capable of providing adequate fire suppression flow was required to permit the draining and painting of the tank.

Building the MIKE NET Model from Various Data Sources

The City provided GIS data for the water distribution system, historical SCADA information for water tanks and booster pumps, billing information from the City's CIS, fire suppression flow data, and a hard copy of the water distribution system map. The GIS information included the network geometry, pipe diameter, and pipe material.

The GIS information supplied by the City was a mixture of AutoCAD files (DWG extension) and ArcView Shapefiles (SHP extension). The pipe locations and diameters were all contained in one AutoCAD drawing file. It was determined that modeling pipes 4 in. and larger would be adequate to represent the water distribution system and determine the locations of the problem areas in the system, and evaluate the proposed alternatives.

The drawing file was separated by layer and exported to the DXF format, so that it could be imported to MIKE NET. Each exported layer contained network

geometry as well as pipe material and pipe diameter information. The following nine DXF files were created and imported into separate MIKE NET project files:

- 4-, 8-, and 12-in. PVC pipes
- 4-, 8-, and 12-in. AC pipes
- 4-, 8-, and 12 in. CI pipes

These files were checked for connectivity errors and merged together to form the City's water distribution network in MIKE NET. Figure 17.5 shows the network model built from GIS data in MIKE NET.

The GIS data, water system drawings, fire suppression flow data, billing data, and SCADA data were used for preliminary model building. The GIS data were used to build the network topology and connectivity. The GIS data was found to be about 85% accurate. Errors in the GIS data included incorrect network connectivity, missing pipes, omissions in separation between the high- and low-pressure zones, incorrect pipe material labels, and incorrect pipe diameters. The network connectivity was checked against the water system drawings and updated to match the drawings in which differences occurred.

Street names, from an ArcView Shapefile, were geocoded to each pipe in the model. The billing data supplied by the city were summed by street name, and the demand for that street was distributed to those pipes in MIKE NET bearing that street name.

Elevation data were supplied in 2-ft contour intervals in the City's GIS data. These data were extracted to an X, Y, Z triplet text file using a DHI-developed ArcView extension, and the node elevations were assigned by using the Generate Node Elevation tool in MIKE NET.

Tank and pump data were added manually from the water system drawings and information obtained during interviews. Upon completion of the model, these data were exported from MIKE NET to ArcView Shapefiles and supplied to the City as an updated GIS coverage of their water distribution assets (Fontenot, 2004).

ARCGIS AND ARCFM INTEGRATION IN BELGIUM

Application	ArcGIS/ArcFM 8 for water distribution network management
Authors	Reynaert et al. (2003)
Project status	In use since January 2002
Hardware	Citrix application servers & standard Dell desktop PCs
GIS software	ArcInfo/ArcView 8 , ArcSDE 8, ArcIMS 4, ArcFM 8
Other software	SQL Server 2000, Citrix Metaframe XP
GIS data	Water distribution network data and topographic data
Study area	Antwerp province, Belgium
Project duration	1998 to 2002
Organization	Pidpa
Web site	www.pidpa.be

Pidpa is a European company that produces and distributes drinking water to more than 1.1 million people throughout Antwerp province in Belgium (Flanders).

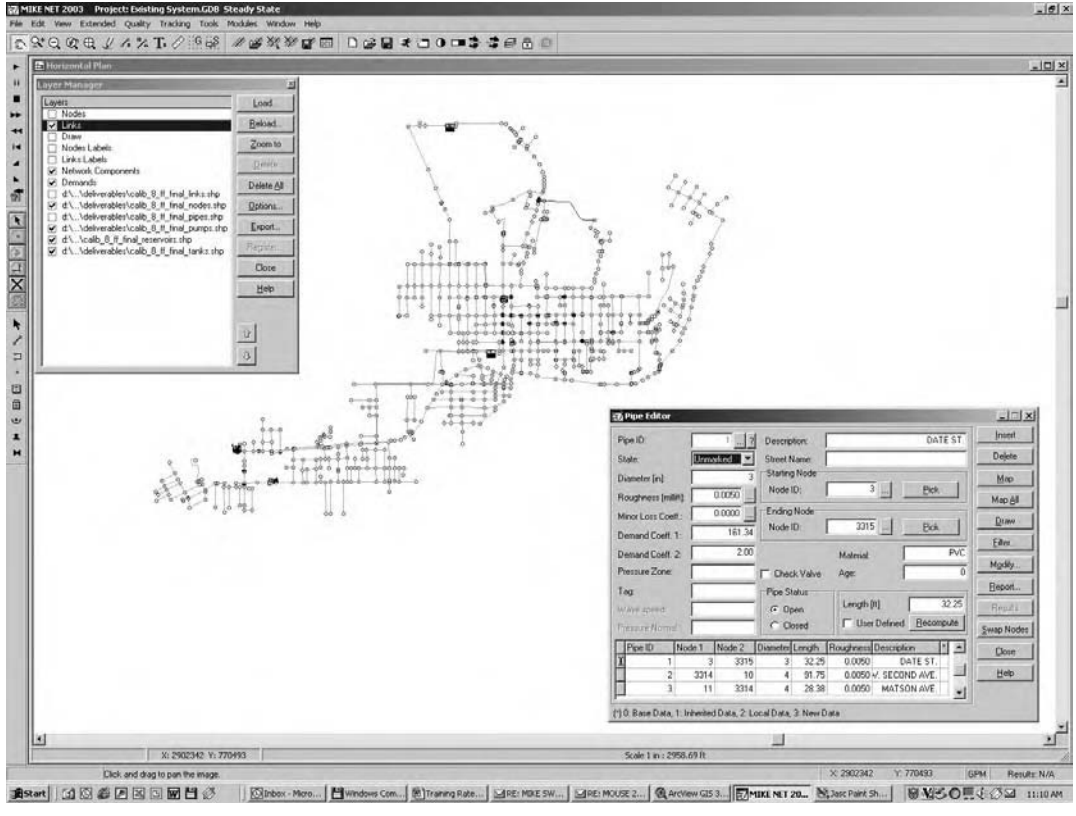

Figure 17.5 The city of Truth or Consequences' MIKE NET model developed from GIS.

Pidpa used ESRI's ArcGIS 8.2 software and Miner & Miner's ArcFM 8.1.3 software to develop a data-centric GIS solution for the management of its drinking water network, including functions for water main isolation trace and pressure zone trace (Horemans and Reynaert, 2003).

Pidpa selected ESRI as the strategic partner to implement an open and generic GIS solution for the management of its drinking water network data. The ArcGIS 8/ArcFM 8 implementation is based on a centrally located SQL Server 2000 database (with ArcSDE 8 on top) containing newly entered and converted vector data as well as large amounts of raster data at scales 1:1000 and 1:5000. All data are combined into a seamless hybrid map that is used in ArcInfo, ArcView, and ArcIMS on a daily basis by about 15 editors and a large group of viewers. Figure 17.6 shows a screenshot of ArcInfo 8 and ArcFM 8 being used on a seamless hybrid map with raster and vector data.

One of the major project goals was to create a strong generic water distribution data model that could be shared and further enriched with input from other European drinking water companies. Together with the choice for commercial off-the-shelf (COTS) software, this approach ensures a feasible future evolution of the implemented GIS and can create a large user base.

Pidpa was well aware of the fact that much of the data used throughout the company has a geographical element. With this in mind, Pidpa started integrating the GIS with many other information systems for use in the office as well as in the field. At the time of this writing, the main operational links were to CIS and to a library of 90,000 synoptic drawings. A first set of interfaces to SAP was operational, and a link to the SCADA system and hydraulic modeling software was under development. It was anticipated that by sharing data between these environments and optimizing workflow over the boundaries, users would be able to get required data in a user-friendly fashion (Reynaert et al., 2004).

WATER SYSTEM MASTER PLANNING IN PRAGUE

Application	Conceptual hydraulic modeling of water supply system
Authors	Peter Ingeduld, Zdenek Svitak, Josef Drbohlav
Project status	Conceptual model complete
Hardware	Standard Pentium III and IV desktop computers
GIS software	ArcView, LIDS (MicroStation and ORACLE based)
Other software	MIKE NET, Microsoft Access
GIS data	Water supply objects layer of Prague's water supply system
Study area	Prague, Czech Republic
Project duration	January 2001 to June 2002 (conceptual model)
Project budget	$165,000
Organization	Pražská vodohospodářská spole čnost a.s. (Prague stockholding company)

Hydraulic modeling of water supply and water distribution networks was used for planning and linking consumers to the network, evaluating the remaining capacity of the network, and planning for network breakdown. Modeling was also used to simulate various loading scenarios, such as fire suppression flow analysis and its impact on the water supply system, reconstruction of existing pipes and planning for new pipes,

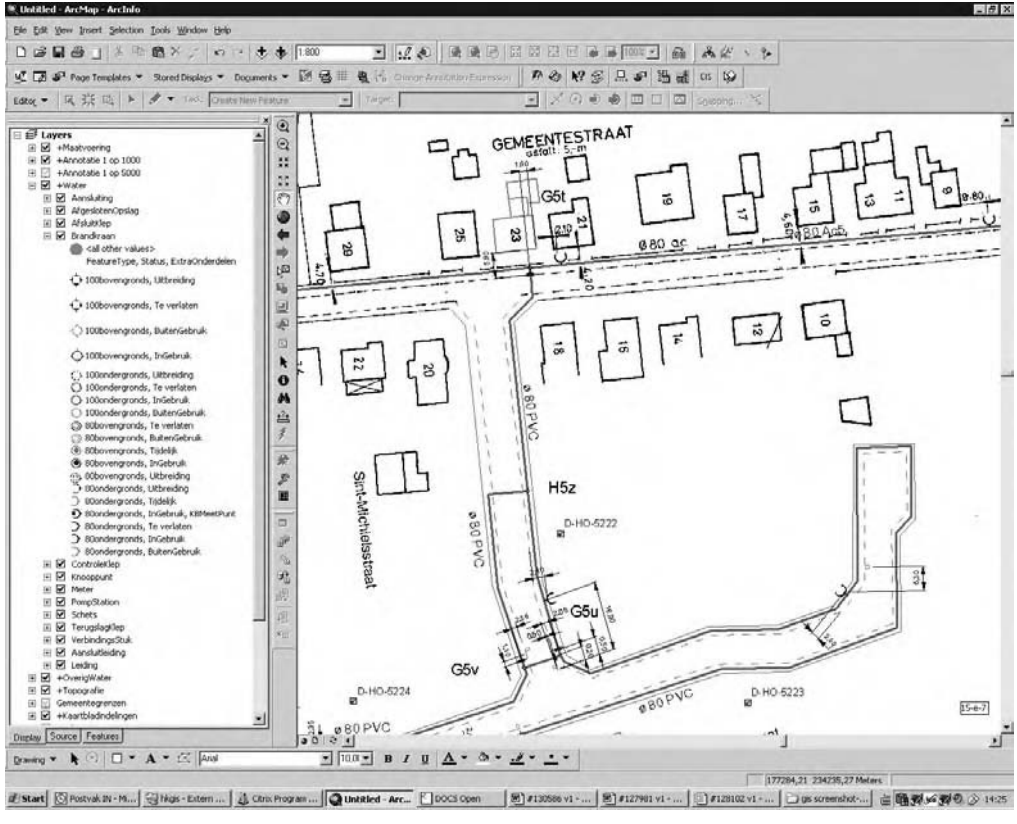

Figure 17.6 Screenshot of ArcInfo 8 and ArcFM 8.

pressure zone evaluation, and for comparing measured and simulated data. A conceptual model with all important water tanks, pumping stations, and water sources was developed for the whole Prague water supply system. This model will greatly assist in formulating and answering questions regarding supply strategies and in providing high system reliability. Hydraulic modeling was done using DHI's MIKE NET software. Figure 17.7 shows a screenshot of MIKE NET for the Prague model (Ingeduld et al., 2004).

WATER QUALITY MANAGEMENT IN MECKLENBURG COUNTY

Application	Water quality management planning
Authors	Carl W. Chen and Curtis Loeb
Project status	Completed in August 2003
Hardware	Personal computers
GIS software	Included in Watershed Analysis Risk Management Framework (WARMF)
Other software	SWAT
GIS data	10-m DEM, land-use Shapefiles for existing and future conditions
Study area	The Palisades golf course community, Mecklenburg County, North Carolina, at the eastern shore of Lake Wylie; 5.7 mi^2 for The Palisades and 1137 mi^2 of watershed surrounding Lake Wylie
Project duration	2002 to 2003 (12 months)
Project budget	$145,000
Organization	Systech Engineering, Inc., San Ramon, California

Rhein Interests, LLC, and Crescent Resources, LLC (North Carolina), proposed to develop The Palisades as a new community comprising homes, a golf course, open spaces, an equestrian center, offices, and stores. The Mecklenburg County required the project to be designed with best management practices (BMP) to meet the water quality criteria of total suspended sediment, total phosphorus, total nitrogen and algae (chlorophyll a) in the eight coves of Lake Wylie. The County approved the use of two GIS-based watershed models, SWAT and WARMF, for the project. SWAT simulated the nonpoint loads of pollutants from The Palisades, which were converted to point source loads for input to WARMF. WARMF simulated nonpoint source loads of pollutants from other areas and the water quality responses in the coves that not only receive the nonpoint source loads from The Palisades but also exchange water with the main body of Lake Wylie. Two levels of resolution were used to delineate the watershed; the finer resolution of The Palisades was nested with the coarser resolution of other subwatersheds. The lake was divided into 29 stratified sections, including coves. As a part of the project planning and design, a monitoring program was established to collect meteorology data at four stations, stream flow and water quality data at four stream stations, and water quality data at eight coves during the spring and summer months of 2002. The data were used to calibrate the models. The calibrated models were used to determine the BMP train necessary to meet the water quality criteria for coves. The water quality management plan for The Palisades was approved by the County. Figure 17.8 shows a screenshot of the WARMF application for The Palisades golf course community (Chen and Loeb, 2004).

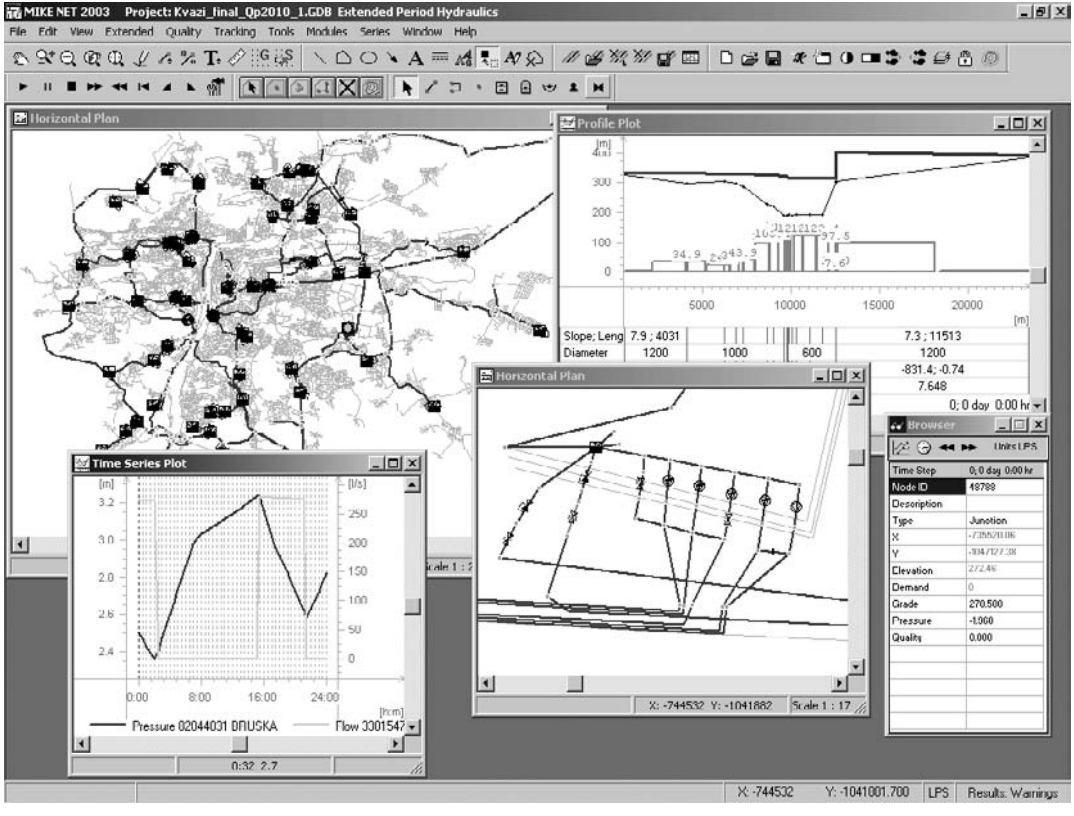

Figure 17.7 Screenshot of Prague's MIKE NET water system model.

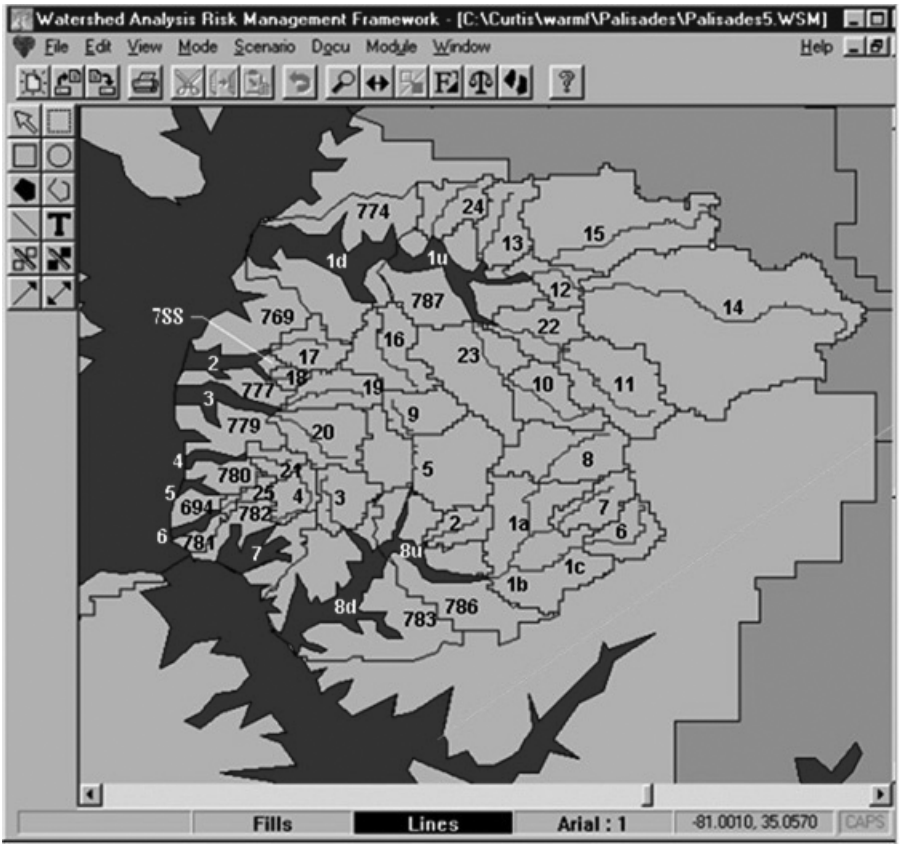

Figure 17.8 Screenshot of the WARMF application for The Palisades golf course community.

WATER MASTER PLANNING IN SUECA, SPAIN

Application	Quantity and quality modeling of water distribution systems
Authors	Hugo Bartolin and Fernando Martinez
Project status	Completed
Hardware	Standard desktop PC (Intel Pentium IV)
GIS software	ArcView GIS 3.2a, Spatial Analyst (Optional)
Other software	EPANET 2
GIS data	Three AutoCAD files with cartographic information (pipe polylines, valves, water sources, street segments, building blocks, future zones of development)
Study area	Town of Sueca (about 26,000 inhabitants) and its tourist beach area (about 30,000 in summer), both supplied by independent networks. The town is located in Valencia on the east coast of Spain.
Project duration	3 months (December 2002 to February 2003)
Project budget	$6000 (consultancy)
Organization	Polytechnic University of Valencia. Grupo REDHISP — IIAMA (Institute of Water and Environmental Engineering)
Web site	www.redhisp.upv.es www.redhisp.upv.es/software/gisred/gisred_eng.htm

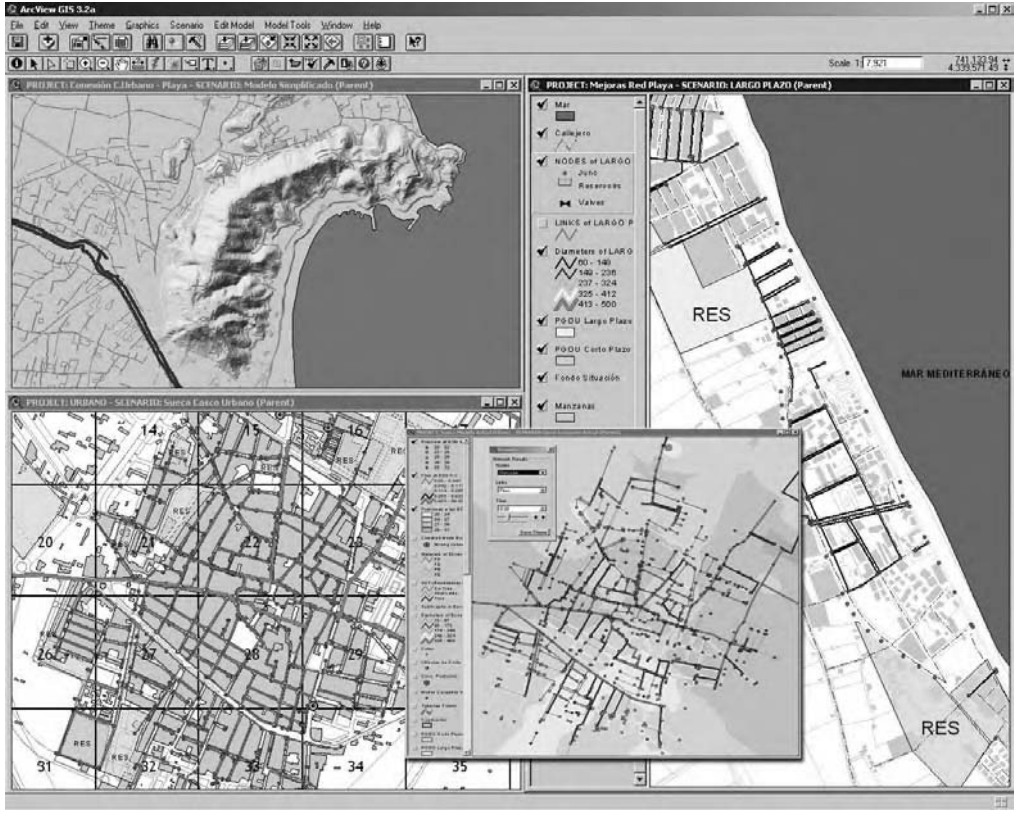

Figure 17.9 Screenshot of GISRed extension for Sueca master plan.

GISRed is a customized extension of ArcView GIS 3.2 software for modeling and calibration of water distribution networks. It basically integrates hydraulic modeling tools, the widely used hydraulic simulation software EPANET (Version 2), and a hydraulic calibration module based on genetic algorithms.

The extension is essentially a tool to assist technicians in the task of modeling water distribution networks and supporting decision-making issues based on the model, all within a GIS environment. It is useful for performing complex tasks such as importing a whole or partial network from an external data source, creating a hydraulic network model, and automatically calibrating it.

One of the tasks GISRed can assist in is master planning issues. In the Sueca master plan project, a general procedure using the GISRed extension was carried out. The main idea was to define a scenario for both independent network models and give a diagnosis of the performance of each real system. Based upon this, new short- and long-term scenarios were proposed, taking into account the variation of the population, the new growing areas, and, therefore, the future demand projection. Finally, network system improvements were planned and simulated to check the feasibility of each alternative and support all the action strategies. In addition to that, the models were connected by two mains in order to enhance the quality of service and prevent emergencies. Figure 17.9 shows a screenshot of GISRed extension for Sueca master plan (Bartolin and Martinez, 2004).

CHAPTER SUMMARY

This chapter presented eight case studies on GIS applications for water, wastewater, and stormwater systems in Belgium, Bulgaria, Czech Republic, Denmark, Spain, and the U.S. The case studies indicate that GIS is being used in all aspects of water, wastewater, and stormwater management, from planning and H&H modeling to mapping and asset management.

CHAPTER QUESTIONS

1. On the basis of the case studies presented in this chapter, which GIS application appears to be the most common?
2. On the basis of the case studies presented in this chapter, which GIS software appears to be the most commonly used?
3. Using the case study presentation format used in this chapter, write a case study summary of a GIS project completed in your organization. Optionally, submit this case study to the author (info@GISapplications.com) for potential publication at GISapplications.com Web site.

Conversion Factors

Conversion Factors from Customary U.S. Units to Système International (SI) Units

To Covert	To	Multiply by
Acres	Square meters (m^2)	4047
Acres	Hectares (ha)	0.4047
Cubic feet	Liters (l)	28.32
Cubic feet per second (cfs)	Cubic meters per second	0.02832
Cubic yards	Cubic meters (m^3)	0.7646
Feet (ft)	Meters (m)	0.3048
U.S. gallons (water)	Liters (l)	3.7843
U.S. gallons (water)	Cubic centimeters (cm^3)	3785
U.S. gallons (water)	Milliliters (ml)	3785
U.S. gallons (water)	Grams (g)	3785
U.S. gallons (water)	Cubic meters (m^3)	0.0038
Gallons per minute (GPM)	Liters per second	0.0631
Gallons per minute (GPM)	Liters per minute	63.08
Inches (in.)	Centimeters (mm)	2.54
Inches (in.)	Millimeters (mm)	25.4
Miles (mi)	Kilometer (km)	1.6093
Millions gallons per day (MGD)	Cubic meters per day	3785
Millions gallons per day (MGD)	Cubic meters per second	0.044
Pounds (lb)	Kilograms (kg)	0.4536
Square feet (ft^2)	Square meters (m^2)	0.0929
Square miles (mi^2)	Square kilometers (km^2)	2.5921
Yards	Meters (m)	0.9144
Square miles (mi^2)	Square kilometers (km^2)	2.5899

Index 261

Preface

The field of geographic information systems (GISs) is emerging as one of today's most exciting and progressive technical areas. GIS technology has evolved during the past four decades and is only now starting to penetrate major industry and service hubs. With such a wide array of new users, there exists not only considerable interest in GIS but also a fair amount of uncertainty and misunderstanding surrounding the discipline.

Like other technical fields, there have been various methods employed to convey the fundamentals, implementation, and importance within the industry. My personal approach within this book is to encourage the highest quality understanding of GIS fundamentals before suggesting the reader study through application. In taking this route, this book attempts to disband user uncertainty and misgivings through guiding discussions about GIS rudiments and technical theory. With this in mind, I want to clarify the book's distinct structure, level of technical information, and somewhat hands-off approach.

The book is structured into three distinct parts:

- Part I: What Is a Geographic Information System?
- Part II: Geodesy, Earth Models, and Coordinate Systems
- Part III: GIS Applications and Environments

Although the specific content of each division is summarized in the Introduction, I want to offer some insight into each part's overall intent and degree of technical detail. On the surface, the technical level varies among the parts, but with very good reason. Let me briefly explain.

Part I presents the preliminary background of what a GIS is, why it exists, how it works, and what forms of data it uses. Within this first division, my primary focus is to get readers up to speed on GIS's composition and I take an explicitly less technical path to achieving this. A more technical approach to this background information would leave the reader swathed in tangential theory and would needlessly add further complexity to an already intricate subject. The topics in Part I are supportive in nature and are approached as such with distinct technical brevity.

Part II is the true "nuts and bolts" of GIS and, as such, is approached with a much greater technical treatment. My approach to Part II is to comprehensively explain the theory behind GIS's core components, such as the reference model of the Earth, the coordinate systems, and the map projection. As you will notice, Part II is dramatically more complex in nature than Part I and this is done for a specific reason: Most GIS uncertainty, misgivings, and misuse extend from a limited understanding of these core components. I believe a comprehensive understanding of these topics is essential for effective, proper, and creative GIS use.

Part III takes a step beyond the theoretical to provide an overview of geographic data presentation, real-world applications, and inexpensive (practice) systems and data. To this end, Part III is technically less complex than the previous part for the sole reason of conveying a clearer vision of how GISs are actually used, rather than overwhelming the reader with a thorough discussion on each element.

I want to highlight one other feature—a benefit—to my approach: It is theory based rather than hands-on based. I call it a benefit because true hands-on approaches lead the reader to focus primarily on the use of a GIS (typically on a specific system) rather than on understanding a GIS. Presented too early, this hands-on method, I feel, becomes an impediment to comprehension. A quality theoretical understanding is the key ingredient to effective and insightful real-world use. A hands-on approach restrictively focuses on a particular system, while a theory-based approach lets the user (reader) freely experiment and choose the system on which to learn. This is not to say a hands-on approach to GIS is a wrong learning method; I am simply stating that for the best use of a GIS and to gain the greatest amount of user perspective, the theory-based approach proves beneficial and leaves the reader at the doorstep of hands-on practice.

I hope you enjoy this book and gain a deep appreciation and excitement for geographic information systems.

Acknowledgments

Many people provided their support, guidance, and encouragement during the research and writing of this book. I wish to express my thanks to the following:

Dr. Tyler S. Pruett, for his significant input in the book's overall structure and his help with the writing and technical review of some important chapters, particularly Chapters 1, 3, 9, and 12. I am grateful for his early guidance and support of this book.

Dr. Paul Aplin at the University of Nottingham, United Kingdom, for his comprehensive technical review and keen eye for my many errors. His superior technical and structural suggestions have enabled me undoubtedly to write a much better book.

René Essiembre, for his assistance and support during the writing of some seriously technical chapters. I am grateful he let me "pick" his GIS-brain.

I have also benefited from the help and support of John R. Kubasek from John R. Kubasek & Associates, Inc.; John Pavek and Glenn Small, PE from T&M Associates, Inc.; and Van Bowersox from the National Atmospheric Deposition Program (NADP).

I wish to express my tremendous gratitude to Mark Walsh and Barbara Lovenvirth from Artech House. Mark's support of this project has remained steadfast from the very beginning and throughout the thick and thin of the book's development. Barbara has been equally committed to this project throughout its development and has shown me remarkable support and guidance. I thank them wholeheartedly for believing in this project.

My heartfelt thanks go to my beloved family—my wife Janet, my youngest son Jacob, and my adoring triplets, Zachary, Nicholas, and Sarah. My family has inspired me to continue writing "the book" and has shown me much needed enthusiasm when mine was waning. Their support and love is endless as is my love for them.

Finally, and most importantly, I want to thank God for giving me the fortitude to complete this book.

Introduction

The 2004 U.S. presidential elections marked a milestone in how information is used and portrayed. For the first time ever, analysts used geographic information systems (GISs) to generate election maps that showed which presidential candidate was leading in each county in every state throughout the country. This information was well received by political analysts and home viewers alike, though few understood the *thing* called GIS. To most, the highly visual election results were the products of some "black box" that offered amazing analysis tools. Understanding how the "black box" worked was not their concern.

The perception of GIS in the business world goes much the same way. Many engineers, environmentalists, and business professionals who use GIS do not necessarily know how it works. This is not unfounded since groundbreaking technology typically evokes initial skepticism and uneasiness. Do you remember the initial unease associated with the "smart machine" in the early 1980s? Back then, personal computers were new and quickly embedding into the worldwide society. This "smart machine" apprehension resulted in the typical person using computers only for word processing and merely tapping a small percentage of the computer's true capability.

GIS is not secluded from these issues of technology fear. Actually, modern GIS environments are almost 100% dependent on the "black box." Without software technology, GIS as we know it would cease. Consequently, the GIS community experiences the same uneasiness among its users. Many GIS novices, and even some intermediates, use but a fraction of the functional capability of GIS software systems, minimizing the system's ability to that of limited queries and static mapmaking. Others politely refrain from using GIS at all, believing it will be complicated, overly technical, or a waste of time altogether.

The rapid growth of GISs worldwide, particularly in the 1990s, has challenged users with the void of GIS standards and software market saturation. Company after company has injected GIS software products into the open market, transforming the flux of GIS capitalism into a sequence of software start-ups and reinventions. Sadly, this has left users, both novice and advanced, apprehensive about what is the right software environment for their time and money investments. Only recently has this lack of standards become an evolving topic in the GIS community, to which the ultimate resolution will be a homogeneous GIS user interface.

Pushing beyond the apprehension to learn GIS requires not only graphical consistency in the GIS platform and environment but also the recognition that GIS is an iterative discipline. *Learn by doing* is a caveat to any valid GIS approach, although to get the most out of a GIS, the user must not only use the system but also understand its potential. Even a rudimentary understanding, such as a basic grasp of fundamental concepts, can intrinsically help with the conveyance, analysis, and final usage of geographic information. With understanding, these modern-day pioneers have at their disposal a powerful analysis tool that will open new avenues of data analysis in their applications. The success of GIS for the 2004 elections only proved that a basic understanding could provide amazing tools for analysis and real-time information conveyance.

GIS has been around for nearly four decades but has gained a true user backing only within the past 10 years. With technical and industry professionals becoming aware of GIS's capability and benefits, the dedicated following of developers and users is now growing. The next 10 years will mark new milestones in geographic information, while everyday life will continue to embed with GIS applications.

A Definition of Geographic Information Systems

So what is a GIS? A *geographic information system,* as defined in the Environmental Systems Research Institute's (ESRI's) *Dictionary of GIS Terminology*, is a collection of computer hardware, software, and geographic data for capturing, storing, updating, manipulating, analyzing, and displaying all forms of geographically referenced information. This is a very general description for such a complex and wide ranging set of tools. GIS is, in essence, a central repository of and analytical tool for geographic data collected from various sources. The developer can overlay the information from these various sources by means of themes and layers, perform comprehensive analysis of the data, and portray it graphically for the user.

In the case of the 2004 elections, a layer discerning counties overlaid a base map of the United States. County demographics were developed into the GIS

prior to election day and integrated other geographic data sets such as candidate information. These data sets for county demographics are readily available.

Throughout election day, real-time data from each reporting precinct in every county fed into the GIS and was cross-referenced with the existing data. The result was three-dimensional mapping that illustrated not only candidate leaders and preelection poll accuracy in each county but also voter turnout by socioeconomic status and party affiliation.

GISs hold a wide range of functionality and analytical capability that with the right developer can provide a collection of useful data and maps. Although the method of presenting geographic information has transformed throughout the ages, the individual uses have only expanded. In fact, such yesteryear applications as farming, sailing, cartography, and warfare still use geographic information.

Poincaré's Maps and the Move Toward GIS

Jules-Henri Poincaré can be considered one of the first bridges between the old technology of cartography and the first traces of GISs. Poincaré was one of France's most innovative thinkers of the late nineteenth and early twentieth centuries. His work covered the landscapes of mathematics, time, physics, relativity, and geodesy. He used his geometric visualization methods, which portrayed non-Euclidean geometry through "visually" representative maps, to fill in the blanks on the world map.

Poincaré began his prestigious career examining coal mines throughout France. While working as a mining engineer, Poincaré was instrumental in determining the root cause for a deadly explosion of a mine pit in Magny. He conducted a meticulous and logical investigation of the events while maintaining consideration of the mine's structure, geology, worker locations, and reason. Poincaré drew highly detailed maps of the mine that indicated the flow direction of air through the mine shaft. This gathering of information on a single diagram assisted Poincaré in determining that an accidental puncture of a Davy "safety" lamp caused the ignition of the mine's resident methane gas. He also provided the exact location of the ignition and exact lamp punctured (lamp 476). After the Magny incident, Poincaré became reputed for his visualization techniques.

In 1889, Poincaré's notoriety spread with the presentation and acceptance of his visual mapping method. He plotted the habits of a small asteroid repetitively orbiting around Jupiter and the Sun (known as a three-body problem). He intentionally neglected the examination of the entire orbital path and, ingeniously, focused on the orbit's impact points within a single plane in space. The result was a stroboscopic diagram identifying a complex series of plotted impact points. This plotted diagram caused a stir in the scientific community because it

identified chaos, or instability, within the natural process of the universe. The mapping method, now known as Poincaré's Map, intertwined geography, location, visualization, data, and analysis.

In the following years, Poincaré gained access to France's bureaucracy, acting in various high-level, high-visibility positions. As the Bureau of Longitude's scientific secretary, Poincaré became heavily involved with the escalating and competitive telegraphic longitude work. France had not made any important impacts as had other worldwide entities, such as the United States and Britain. France and Poincaré wanted to establish telegraphic simultaneity, a primitive methodology compared to today's global positioning system (GPS) technology. At the same time, the International Geodetic Association desperately needed an accurate length measurement of a meridial arc to remeasure the shape of the Earth. France jumped at the chance.

In 1900, Poincaré headed a mission to help France's Bureau of Longitude accurately plot the region of Quito, Ecuador. Although his expedition teams in Ecuador met misfortune every step of the way in the difficult, obstacle-filled terrain, Poincaré was successful. After 7 years, Poincaré completed the mission and created a network of latitude and longitude measurements that later were connected by telegraphic cable and linked to the world telegraph network. Poincaré, once again, used his visual geometrical methods to help detail the measurement data and cable pathways upon a geographic map.

Through his many exploits, Poincaré used mathematics and ingenuity to expand the parameters of map visualization, physics, geodesy, and scientific concept. In doing so, he revolutionized methods of using geodetic information to widen the realm of analysis. Undoubtedly, Poincaré left his mark as an early pioneer to modern-day information systems, such as GIS and GPS, and his Poincaré Map was a predecessor to present-day chaos theory.

Old Technology, New Platform

As seen through the work of Poincaré, the concept of a GIS is rather old. Ancient cartographers used observation, field informants, celestial positions, and measuring tools (such as the sextant) as inputs to calculate distances and determine land formations. Hand-drawn maps then depicted this information. Maps indicating demographics, such as the layout of crops throughout the nation or population, were based upon field information and generalization and were not completely accurate. Usually informed generalization and estimation helped develop the maps.

As technology increased, so did the precision of maps. Graphic landforms more accurately portrayed reality, while maps better portrayed demographics. Color palettes, symbol sets, and attribute tables depicted data.

Today, geographic information is at its most precise. As the new platform for real-time data, GIS utilizes high-resolution satellite imagery, light intensity detection and ranging (LIDAR), GPS data, computer-aided design (CAD) files, and enterprise database management systems for complex analysis. Users can cross-reference these geographic data sources in a GIS and create impressive geographic displays catered to an area of interest and to individual or specific applications. Users now have the opportunity to customize their maps not only to show the information they want but also how they want it. For instance, an engineering firm widening a section of interstate roadway not only can use a GIS to mark a satellite map of the roadway section with bridge locations, exit and on ramps, and elevations but can also map soil boring points with hyperlinked data, traffic data, surrounding vegetation types, and roadway drainage.

GIS is appearing in almost every industry, forging its place as the new platform for geographic information. GIS is now used for education, land management, natural resource management, environmental, and aeronautical applications, just to name a few. GIS even crosses every industrial and humanitarian threshold with software and data development efforts. The only limits to GIS are the user's fundamental knowledge of the system and overcoming the stigma of creative GIS use.

The GIS Mystique

Whether it is the result of users' anxiety, disinterest, or uncreative whim, GIS bears a cross of a subtle mystery. This GIS mystique, as I call it, is the ultimate result of misconception and limited knowledge. Let me explain.

GIS holds a preconception that is grossly different from reality. For instance, GIS is sometimes solely viewed as mapmaking software. This is simply not true. GIS has found its way into everyday life, from the internal management of utility companies that deliver electricity and water to mapping distant planets, such as the European and U.S. expeditions on and around Mars and Venus. The reality of GIS, as this book details, is that it can do so much more than make a map.

Similarly, GIS is sometimes wrongly linked on a one-to-one basis with GPS technology, found in handheld receivers, E911 systems, and cellular phones. This user misconception "dumbs down" GIS technology to the point that it severely limits the ultimate capability and potential of a properly structured system. GPS data is but a small portion of the information a GIS manages and, in all honesty, is not needed for every user's application.

To overcome this communicable mystique, we must first understand that there is still not enough hands-on work with GIS by all levels of users. The users

are only interested in information at their fingertips from the "black box," while management rarely understands the levels of visualization in GIS or how it can be successfully implemented. Consequently, many GIS development efforts are underfunded and prematurely abandoned.

A properly structured GIS requires time, and many users are either not willing to invest this time and money or not afforded the opportunity to design a system that maximizes capability. As competition increases, more users hastily implement a GIS to stay in line with their market and, subsequently, promote the fact they use GIS technology. If truth were told, many industry people want the term "GIS" on their laurel list, though they have little intention of using the software. Many systems suffer from this lack of use and grow stagnant. Competition, along with users' indolence, dilutes GIS structure and scientific implementations.

About This Book

Geographic Information Systems Demystified is written to give readers a digestible approach to understanding what a GIS is and how it can be used, while revealing the falsehoods of the GIS mystique. This book is not all encompassing but rather focuses on GIS theory. It presents the important elements of GIS to get anyone started and ready to work with certainty, and provides candid insight into this often unfamiliar technology science.

While many GIS learning sources are software product biased, the book offers an unbiased approach to the fundamentals of learning GIS, helping readers become functional and knowledgeable users. This guidebook also presents an original, comprehensive, and innovative treatment of spatial coordinate systems, a topic rarely covered at all in most popular GIS learning titles. The book examines and explains critical GIS concepts in a consistent structure, demystifying an often misunderstood discipline.

The structured topics first lay down the basics of GIS and then build upon this knowledge foundation with more specific information. The book is laid out in three parts:

- Part I: What Is a Geographic Information System?
- Part II: Geodesy, Earth Models, and Coordinate Systems
- Part III: GIS Applications and Environments

Part I focuses upon what a GIS is, why is it needed, the structure of geographic data, and the importance of metadata. It offers an understanding of how geographic data transforms into geographic information through a succinct

presentation of geographic information basics and solidifies the knowledge foundation for the entailing topics found in Part II.

In Part II, the discussions tackle the more complex elements of GIS applications and, quite different from Part I, are much more technical and comprehensive. Core topics, such as map scale, Earth models, and map projections, are scrupulously defined and add to the host of GIS skills designed to give the user creative control over the analysis, portrayal, and use of data. The most common GIS tools are discussed in technical detail geared to get anyone quickly up and running with their own GIS applications.

Part III highlights some of the creative tools and techniques presently available within the discipline of GIS, as well as how GIS is used today in various industries. It details how geographic data can be uniquely used for analysis and presentation. Topics such as thematic mapping and real-world examples offer the user ways to creatively depict their geographic data and widen the spectrum of possible GIS applications. Also addressed are places to get free GIS environments, component software, and geographic data.

This book includes useful appendices and a glossary that may be used in tandem with the text. This information offers handy standards for ellipsoid parameters and datum transformation tables to use. This information was useful in the writing of this book and I felt it would be equally useful to the readers. The glossary defines words and phrases used throughout the book but should not be viewed as a comprehensive glossary of GIS terminology. If you wish for a more thorough glossary, check out some of the resources in the bibliography.

The Book's Approach to GIS Concepts

With GIS's realistic business and engineering models offering attractive cost savings and efficiency, geospatial systems can sometimes transcend practical concerns. The technology injects a touch of creativity into the veins of global infrastructure and serves decision makers on all levels of business and financial permanence. Important new GIS concepts are born every day, and industry trends fluctuate so frequently that a tempered approach to introducing GIS concepts hardly seems fitting. This book attempts to show GIS science and industry as they are, providing a literal roadmap through the industry's landscape.

We must remember that GIS is still brand new to the overwhelming majority of desktop computing users, as well as the technical and business fields. The importance of understanding fundamental GIS concepts is clearly underestimated in the industry today. This book addresses the most important concepts in earnest and details methods for using and developing geospatial systems. Every critical concept is discussed in a clear, consistent voice that is intended to raze any false preconceptions the reader may have.

Since GIS is an international infrastructure organization tool, the book takes a worldwide approach to the technology. GIS is booming throughout the world, especially in Europe, the Americas, India, Japan, and Australia. Topics are designed to further the overall understanding of GIS as it relates to worldwide applications.

The Goal to Demystify GISs

This book's main goal is to take the fear of the "smart machine" out of the user and expose the inherent mystery of GIS. Geared to the beginner and intermediate user, this book intends to forge a paced, seemingly trolling, pathway to productive understanding and unveil the wide range of user choice and creativity.

GIS is being used in almost every industry and affects some portion of every person's daily life, usually without awareness. Whether you realize it or not, your life is affected on some level by GIS technology. GIS is currently being used in almost every conceivable industry. Major GIS software companies boast more than a million daily application users. In fact, if you have ever used MapQuest, you have explored geographic data and performed analysis using GISs.

Geographic Information Systems Demystified intends to herald the broad availability of worldwide geographic information, diminish apprehension of the GIS unknowns, and widen the user's eyes to the great possibilities that can be achieved using GIS. In essence, this book aims to rip open the top of the "black box" and reveal the wonderful things that lie hidden inside.

Part I:
What Is a Geographic Information System?

From Geographic Data to Geographic Information

1

How Does a GIS Work?

In a geographic information system (GIS), geographic data are transformed into geographic information. This simple transformation, however, involves a complex series of functions and processes. In a nutshell, geographic data begins as raw positional feature data holding attributes. These data are then overlaid with complementary and/or contrasting data sets, which form coincident relationships. Data and relationships are analyzed, geoprocessed, and then presented as geographic information products. These geographic information products are often interactive software applications used to help people make decisions.

GISs are accessible to an array of users, from the expert GIS software developer to the GIS novice project manager, and, subsequently, offer visualization to users throughout the spectrum of skill levels. This diversity becomes a unique benefit of GIS and explains how quickly it can become visible within an organization, as well as offering project visibility to the public.

To fully understand the power of a GIS, we must first take a closer look at how raw geographic data becomes usable geographic information. The following sections depict the movement and manipulation of geographic data sets, as well as the areas where user ability is vital to usable output. The core geographic data transformation involves the following fundamental flow of information.

The Fundamental Flow of Information

Geographic data originate from actual locations and physical characteristics of features on or near the surface of the Earth (or other celestial bodies such as Mars or the Moon). These raw, positional data are the start points for every GIS by providing the basic geographic information needed for attribution, dataset

modeling, relationships, and analysis. Refer to Figure 1.1. Raw data can come from a range of sources, such as aerial photographs, previously digitized maps, and global positioning systems. These types of digital and nondigital geographic resources are readily available and, in many cases, are plentiful, well designed, and comprehensive. Additionally, many digital sources are free. Other more labor intensive sources are field data and measurements collected from site visits, and transformed maps, whereby old hardcopy maps are first scanned into a computer and then digitized.

In the most fundamental sense, raw data are either geographic data or are transformed into geographic data through a GIS, and are in turn used to produce geographic information products. Geographic information products are user-conceived information results created through a GIS and a user's ability to relate, manipulate, and present overlaid geographic data. These products are used to analyze data for a specific application.

The overall work of transforming data in a GIS can be summarized through its three distinct procedures:

- *A GIS leverages the flexibility of geographic data.* Raw data are static (nonchanging) and offer only a limited amount of flexibility on real-world applications. When raw data are transformed to geographic data through a GIS, the capability for enhanced data use and analysis (i.e., data flexibility) significantly increases. At a minimum, overlaying two geographic data sources provides sufficient new information, better analytical means, and additional flexibility to not only help someone visualize the real world but also help them make an informed decision.

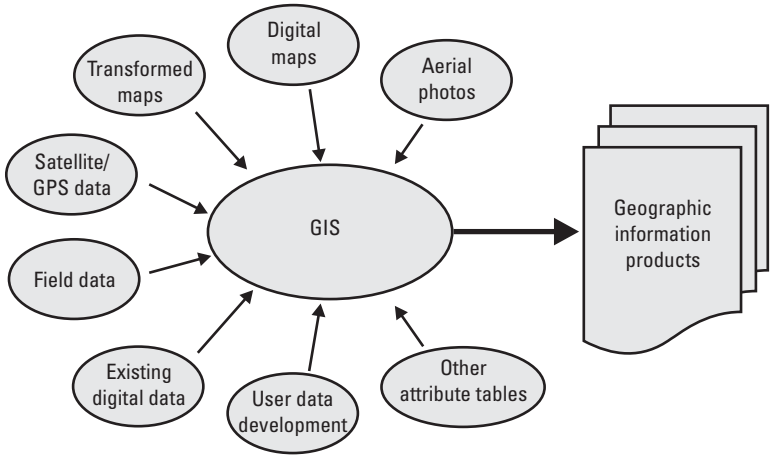

Figure 1.1 The path of geographic information.

- *A GIS performs functions and analysis within a single environment.* These data functions are the literal "doers" of a GIS solution and are known as *geoprocessing* and *spatial analysis.* These operations are available within a single GIS environment and include the generation of features, buffers, view sheds, and cross sections; the calculation of centroids, slopes, statistics, and suitability; and the manipulation of feature attributes, smoothing of lines, feature transformations, and clipping. Both geoprocessing and spatial analysis are discussed in more detail later in this chapter.
- *A GIS serves as a software application and creates useful information products.* GIS environments, foremost, serve as spatially enabled enterprise data management systems and data repositories. These systems are software applications that protect the value and usefulness of the information related to your project. The end result is an information product that enables the user to better manage his or her project.

Through this procedural flow of information, geographic data are transformed into geographic information. GIS environments centralize both data collection and information management to save time, minimize technical effort, and automate known repetitive administrative tasks.

The core data component of a GIS is often represented by a *geographic data model,* which is an industry or discipline-specific template for geographic data. A geographic data model offers the user flexibility in the design of the file management and database hierarchy. Geographic data models typically utilize a grid-based structure (known as raster) or a coordinate point structure (known as vector). Both models are explained in detail in the upcoming chapters.

Facilitating the model is one or more geodatabases. A *geodatabase* is a collection of geographic data sets, real-world object definitions, and relationships. Comparable to a Microsoft Access file, a geodatabase is a collection of geographic data sets and geometric features. A geodatabase furnishes the data organizational structure and workflow process model for the creation and maintenance of the core data product. In essence, the geodatabase is the heart of a GIS's management capability.

Let us now look at each element in the flow of information. We will start at the beginning with the various forms of raw geographic data and work our way to the GIS products.

Geography and Geographic Data

Geography is the study of the Earth's surface and climate, and is the founding science to a GIS. Geography furnishes information about the Earth and

distinguishes how features upon the Earth correlate with one another. For example, a basic geographic study involves how climate and landform interrelate with inhabitants, soil, and vegetation. Data collected from this study are geographically oriented and are therefore geographic data. Any study with a geographic component, regardless of form, produces geographic data.

By their very nature, geographic data comprise the physical locations of objects on or near the surface of the Earth. Data are intimately concerned with the properties of such objects and hold attributes that can be associated to other types of geographic data. For example, a user can have two types of geographic data about a 40-acre stretch of land in New Zealand: one detailing elevation above sea level, and one detailing the various types of soil composition throughout the parcel. Both forms of data can be combined for analysis in a GIS using the land parcel as the common link.

All physical relationships between layers of geographic data are interpreted as coincident relationships, meaning that features coincide in real world space. In the above example, the elevation data and soil composition data would go on separate "layers" in the GIS. Layers are discussed later in this book.

Many times, geographic data are modeled in what is known as vector space. A vector space is simply a platform for geographic vector data, which use *x-y* coordinates with lines and shapes to depict Earth features. Geographic vector data store nontopological coordinate geometry and attribute information for spatial features.

Most standard GIS vector file formats consist of a feature file, an index file, and a linked attribute table. A *feature file* contains geographic object feature information, such as representative point, line, and polygon information. An *index file* contains unique identifiers that comprise more detailed information and help speed spatial feature queries. A linked *attribute table* is a matrixed table that contains explicative attributes for a group of spatial features.

The index file links the feature file data to the attribute table. Consequently, attributes and features exist in a strict one-to-many relationship, whereby geographic features can have multiple attributes. The vector model is readily recognized by those who use computer-aided design (CAD) environments, using feature geometry in a GIS vector model to instantiate points, lines, and polygons as objects. Figure 1.2 details sample vector data.

In most cases geographic vector data are *discrete data* occurring in cases where there are well-defined boundaries for physical representations or limited data values. The above figure involves tax lots that have visibly evident and discrete boundaries. Vector data can be created or modified directly by digitizing features using GIS development environments.

There is another major type of geographic data known as raster data. Raster data are digital images represented by a grid of valued pixels, or *cells*. The image type and the number of colors represented determine the properties and

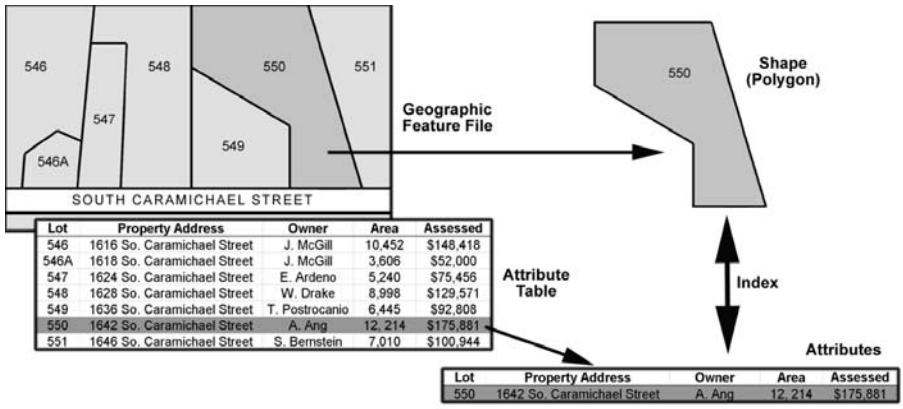

Figure 1.2 Vector data.

appearances of these pixels. Figure 1.3 details sample raster data that utilizes three different cell colors for three different property types.

In most cases, raster data are more suited for representing *continuous data* than vector data. Continuous data are a numeric form of data usually associated with the physical measurement of boundaries that are not well defined. Additionally, the surfaces represented are, in many cases, estimated through statistical

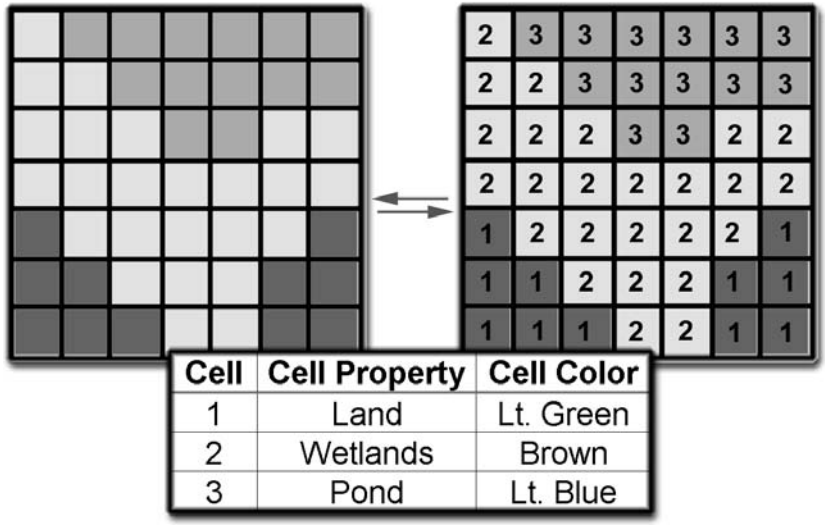

Figure 1.3 Raster data.

analysis. Raster imagery is perfectly suited for GIS sensor webs, a current industry trend that harnesses real-time observation and measurements over large, even global, regions.

Chapter 3 focuses specifically on the raster and vector data and offers a comprehensive discussion of each data model.

Georeferencing

Many data sources lack formal spatial referencing. Some CAD and GIS data sets are developed in a generic "design" space and have unique, often proprietary, types of referencing that simply need reinterpretation to be spatially integrated into a GIS environment. However, many of these sources are scanned raster data (digital imagery) that have only the coordinates of a raw pixel grid from an original scan. While these raster sources are often times unique and critical to a GIS project, images also need to be referenced from scratch, spatially transformed into a defined coordinate referencing system, then integrated and overlaid in a GIS environment. This process is known as *georeferencing*.

The ability to perform accurate and timely spatial referencing adds a measure of customization to any GIS operation or project. Raster imagery, such as hardcopy maps and aerial photography, is the most popular type of data to use with georeferencing, since it is the most commonly available type of data to use. Scanning imagery also alleviates the need to perform time-consuming and repetitive digitization efforts (i.e., transforming hardcopy to an electronic, digital file).

Georeferencing is the art of selecting common point locations in the real world using at least two data sources: an unreferenced source (such as a raster map) and a referenced source of the same area providing positional information. Basic georeferencing procedures involve point selection and transformation. For example, when a hardcopy map is scanned to an electronic file, it has no relationship to any real-world coordinate system. The georeferencing process establishes (or in some cases reestablishes) the relationship between image pixel locations and real-world locations. Georeferencing is accomplished by first selecting points on a source image (scanned raster map) with known coordinates for the real-world surface location (benchmarks, grid ticks, road intersections, and so on). These real-world coordinates are then linked to the corresponding pixel grid coordinates in the raster source image. After the image is georeferenced, each pixel has a real-world coordinate value assigned to it.

Queries: Locations and Attributes

Once data are adequately georeferenced and resident in a GIS, the user can then create a query expression to find the relevant data for a specific application. A

query enables the user to search geographic data to collect location, feature, and attribute information from a relational database management system or geodatabase. The most fundamental test of geographic coincidence between data sources is a query by location in tandem with a targeting expression, such as *Intersection, Within distance of, Contained by, Share features with, Touch the boundary of, Are crossed by the outline of,* and *Completely in.*

Queries can also be executed on feature attribute tables and performed on specific fields. Records are selected in this manner; each record (or "row") in the table corresponds and is linked to a distinct geographic feature data set. Features conforming to certain attribute criteria can be selected and extracted using this method.

Quite simply, queries are the user's refining tool for taking the massive available data and selecting only those pieces that pertain to the application at hand. The absolute function of queries is a GIS staple and, subsequently, will be highlighted both in example and in operation throughout this book.

Geoprocessing

Geoprocessing is the fundamental process of creating a derived set of geographic data from various existing data sets using operations such as feature overlay and data conversion. In a typical geoprocessing environment, the user applies GIS functions to a group of geographic (input) data to yield a precise output data set suitable for a particular application. Geoprocessing functions run the gamut from simple spatial clipping to more complex analytic operations. These software functions can stand alone or be chained to other processes. This ultimately opens the gates for virtually unlimited sets of geoprocessing models and potentially staggering sets of output data to solve specific problems.

Most professional GIS software environments include a mission-specific geoprocessing interface, or "workbench," of geospatial dialogs and tools. These software environments usually include extensible scripting tools and compilers to automate, customize, and document geoprocessing workflows. The most important contribution of geoprocessing to the GIS big picture is the automation of repetitive tasks. Geoprocessing is an elaborate turnkey for efficient and clean geographic output.

Geoprocessors come in different forms. Many geoprocessing functions are embedded in a GIS environment. A GIS environment is a package of integrated GIS components: a geographic map control, a map layout designer, a data tree catalog, and so forth, of which geoprocessing is a member. However, many powerful stand-alone software applications offer specific, related subsets of geoprocessing functionality. Some include file format translators or spatial referencing transformation tools. Many professional GIS efforts actually require

licensing these stand-alone accessories in order to reap the often-advantageous outputs of these stand-alone software applications.

Site selection is a prime example of a geoprocessing application. Another is the function of batch processing in a noninteractive manner. Geoprocessing environments can be considered "robots" that automate geographic data processes and provide storage of geographic data models. Geoprocessing is very reliable. In fact, within the GIS community geoprocessing environments are viewed as software-based insurance policies for the analyst trying to deliver geographic information products on time and within budget.

There are eight categories of predominant geoprocessing operations, or families of operations:

1. *Conversion.* Conversion is completely an issue of formatting. File format conversions (translations) and coordinate system referencing conversions are the most common geoprocessing conversion operations, and serve to characterize the conversion family.
2. *Overlay (union, intersecting).* Overlay involves superimposing two or more geographic data layers to discover relationships. In fact, overlay is intimately associated with the discipline of set topology, which defines the rules for valid spatial relationships between features in a geographic data layer.
3. *Intersect.* Geoprocessing computes a geometric intersection of the input features. The resultant features or portion of features common to all layers or assigned groups of same shape type (called a feature class) will be written to the output.
4. *Union.* Like intersect, union computes a geometric intersection of the input features. All features with the overlapping attributes from the input features will be written to the output feature class.
5. *Extraction (clip, query).* Like overlay, extraction is also intimately associated with the discipline of set topology. Queries help select the geographic data to be clipped or extracted, subject to a specific group of topology rules.
6. *Proximity (buffer).* Proximity is initiated through a query that selects geographic features based on their distance or proximity from other features. Geographic features include lines, points, and polygons.
7. *Management (copy, create).* GIS data management software is generally designed to facilitate the organization of a user's unique personal catalog (or collection) of geographic data. The intrinsic forms of all types of geographic data are accommodated by these applications.

8. *Transformation.* Typically in GIS, the term "transformation" means a spatial transformation, such as a datum transformation or reprojection. Geoprocessing, however, introduces transformations of different types, such as temporal or geometric transformations. This facet of flexibility finds favor among integrated user interfaces, complementing comprehensive spatial analysis within a geoprocessing software environment. Chapters 7 and 8 describe datum transformations in more detail.

In summary, the integration of geospatial data and geoprocessing interfaces into desktop computing makes possible the widespread use of interoperable geoprocessing software. Geoprocessing enables a clear pathway for geospatial data products in the information infrastructure. Geoprocessing opens the doorway to more defined data examination, primarily spatial analysis.

Spatial Analysis

By their very nature, geographic data are intimately related to locations and feature attributes. Spatial analysis harnesses this duplicity through the study of geographic feature locations and shapes. Spatial analysis offers the user a range of procedures, tools, and interfaces varying in application and complexity. For example, creating a simple map in a GIS environment is a basic form of spatial analysis. Spatial analysis is not necessarily complex, but it is a process of reducing complex relationships to something simpler, possibly bringing to attention things that otherwise would have remained hidden to the user.

Spatial analysis relies heavily on the first and most fundamental law of geography: Things closer together in space tend to be more alike than things that are far apart. This law is based upon Waldo Tobler's work, which essentially states that everything is related to everything else, but near things are more related than distant things. GIS does not wholly support this almost philosophical supposition, though it does acknowledge that near things are more related than distant things. In fact, geographic data contain spatial autocorrelation, which is the formal property that measures the degree to which near and distant things are related. GIS functions on spatial data to which it can be supposed that spatial autocorrelation is in essence the first law of spatial analysis.

Positive spatial autocorrelation occurs when features that are similar in location are also similar in attributes. Negative spatial autocorrelation occurs when features that are close together in space are dissimilar in attributes. Zero autocorrelation occurs when attributes are independent of location.

Spatial analysis, be it autocorrelation, overlay, or surface analysis, is an advanced and flexible form of geographic data analysis. A GIS offers the user a

platform for specific application analysis of location and feature attributes. The end result is highly usable and application-specific geographic information. Let us look at the final product: geographic information.

Geographic Information

As mentioned previously, the flow of information begins with a collection of geographic data and through various functions can smartly coalesce in the final geographic information product. This final information product is derived and interactive and offers the user a host of capability, organization, and material for analysis. Geographic information can facilitate the analysis of patterns within nature and human societies, can affect decisions at a low level of political influence, and can even return accurate and subtle answers to compelling questions. The geographic information output obtained from a GIS is virtually boundless, limited only by the adeptness of the user and availability of raw geographic data.

Actual geographic information products vary in form and appearance. They are characterized in three distinct groups: software environments, maps, and documents.

Software environments tend to be the most vital and characteristic of distributed geographic information systems. These environments are usually simple front-end interfaces presented in a dialog-based (or oftentimes wizard-based) package. They facilitate the automation of spatially enabled information management, usually alleviating the dependence upon repetitive tasks in the solution of a problem.

For instance, a shoreline-permitting GIS application can help municipal government administrative personnel make basic decisions concerning the approval of permits for new development on shore land. The administrative employee can enter the required basic information about a particular subject parcel (usually required information on a permit application), launch a dialog-based wizard to organize the input data, and then return an analysis of the site in relationship to natural, sensitive, or protected resources potentially impacted by the proposed construction.

A purer GIS product is much less restricted by process. Some outrageously inventive and complex GIS software environments offer geographic information products in a constant stream. This ultimately poses the convenience and challenge of interactive research for decision making powered by GIS functions. However, in the case of the environmental permitting application, complexity is not necessary and simple output from the system is sufficient. Environmental permitting at any level usually becomes such a contentious process that actual physical maps are required to provide graphic depiction and substantiation of research findings and assertions. The “map” is therefore the most obvious

example of a geographic information product, and satisfies the desire of the public at large to have everything presented in universally recognizable documents. *Maps* are the second facet of geographic information.

Maps represent the surface of the Earth—a surface with which all human beings are intimately familiar. Maps have a variegated array of uses, such as graphics in periodicals to supplement columns and articles, figures in permitting application documents, and large format prints mounted on the wall in the lobby of city hall showing planned municipal projects.

However maps, be they printed on paper or as an electronic image, are static information tools. They are noninteractive documents. GIS software environments are capable of organizing elaborate and diverse computations, occurring simultaneously with attribute or feature data. This is ideal for tabular figure information or in many instances complete report templates. This is the third facet of geographic information.

Tabular figures and other data *documents,* such as reports, charts, and graphs, are the third and final category of geographic information products. The document types help to disseminate computational, research, and spatial analysis results to anyone interested, be it the public or an engineering project manager.

These information products are usually developed and produced within a GIS environment through embedded controls native to the types of desired outputs. In some cases entire software programs for reporting, charting, Internet publishing, and database connectivity are "bundled" with a core GIS environment. This "bundled" convention encourages the user to stay right in a GIS software environment to complete tasks that are not commonly associated with GIS. Approaches like these help to expand the breadth of GIS as a modern technological discipline.

Even though geographic information is the end product of a GIS, it is not the ultimate finish line for geographic information flow. Geographic information moves beyond a GIS to the realm of limitless real-life applications. Traditional applications have been hydrologic plant relicensing efforts, infrastructure planning, shoreline zoning disputes, and wetland delineation. GISs have only just begun appearing in many nontraditional applications, such as defining statewide educational results, marketing efforts, public policy, and, yes, even presidential election result reporting. The only real stifling factor to the use of a GIS and the geographic information it offers is the user's ability to be creative, judicious, and purposeful.

2

Why Use a GIS?

In the previous chapter, we discussed to some degree how a GIS works, though we made no mention to why one would use such a system. For what reasons would someone want to progress geographic data through a transformation into geographic information? We begin this chapter with the intent to answer the question: Why use a GIS?

In 1854, Dr. John Snow did something revolutionary: He turned geographic data into geographic information and boldly stopped cholera. Let me explain. From 1831 through the mid-1850s, London, England, suffered from deadly cholera epidemics. Cholera is an acute infectious disease caused by a bacterium in the small intestines. Back in the early to mid-1800s, the disease traits of cholera were yet to be wholly identified, while outbreak sources were almost always unknown. An outbreak of the disease was a ruthless, communal disaster.

Then in 1854, a severe cholera outbreak caused horrific anguish to Londoners. In the area surrounding the intersection of Broad Street and Cambridge Street, more than 500 deaths were recorded in just 10 days. London's officials were baffled as to a solution and feared the absolute worst.

Dr. John Snow, a British physician, took matters into his own hands and mapped the cholera deaths on a hand-drawn street map of the London neighborhood. It soon became evident to Dr. Snow that a concentration of deaths centered around one particular water pump on Broad Street. He immediately presented his findings to the officials and had the pump handle removed. Immediately afterward, the spread of cholera ceased and the outbreak was finally contained.

Much like a modern-day GIS, Dr. Snow's geographic data, which included a street map and cholera death point locations, developed into a

unique and highly accurate geographic information map. Without the physician's information product, countless more Londoners would have died.

GIS enables developers to take a hard look at their project goals and offers capability for developers to maintain an underlying objective to improve the overall process. Like any pervasive process, a fundamental understanding as to why each goal must be achieved is imperative to the project's general success. This fundamental understanding affords the user new opportunities for use. In fact, many times after project goals are reached, additional objectives and project efficiencies arise out of the accessibility and plethora of GIS data. Dr. Snow reached his goals to preserve human life through technology, but his product and the process by which he reached his goal were reused for new outbreaks.

The following discussions highlight typical GIS products and outline several basic reasons why GIS is the forerunner in geographic intelligence. Even though the days of usable hand-drawn maps are long gone, creative information products, like Dr. Snow's creative methodology, set apart the typical GIS user from the atypical GIS thinker.

Discerning Your Need for GIS

Specific software is designed to satisfy a specific need. Tax preparation software (such as Quicken), for example, is designed to provide systematic tax form preparation, while Microsoft Word is designed to provide powerful word processing capabilities. Each software package has a definite, and separate, function, and ultimately achieves an explicit outcome. While the need for each software package is delineated and valid, the users, in the most basic sense, must first know what they want to accomplish before using the appropriate software package.

GIS is no different. A user must have an understanding of what overall outcome or expectation is desired before implementing and using geographic information systems. Discerning the particular need for a specific application early in the project is crucial to a GIS's overall success or failure. Many times a GIS fails because the project manager hastily implements a GIS for the sake of implementing it and pays little or no attention to what the system can actually do. Failure to initially define the expectations leads to a costly GIS implementation that can increase cost exponentially as the project phases progress. Consequently, a GIS's true capability and core benefits can be lost due to poor management planning.

Unlike GIS users, lawyers are trained to ask only those questions to which the answer is known. In the courtroom, this methodology proves quite efficient. However, in GIS, knowing the actual answer to a data request or the specifics of the geographic outcome is usually never possible. Therefore, GIS professionals and managers alike must generalize anticipated outcomes for the sole purpose of

management planning, such as anticipating a forest classification map of a 10-acre area of rainforest in Belize or a map detailing car theft in Madrid, Spain.

More times than not, the GIS's outcome provides greater detail and a wider range of possible analysis than first anticipated. A wholly environmental-related request can present additional detail for use with agriculture, conservation, and public safety analysis. Users need to define expectations early on, but be aware that the anticipated outcome may be a variant or enhancement of such expectations. As for lawyers and other professionals who need to know the outcome up front, take heed that GIS results can be enlightening and unexpected.

Common GIS Products and Bi-Products

GIS is one of those broad-ranging technologies that seem to have virtually no bounds other than the limit of the user's creativity. GIS, by abstract function, is a theoretical "black box" that takes data input and data requests and outputs the data results. If the user is vastly creative with both the input and requests, then the output will retain a certain degree of inventiveness. What gives GIS the aura of virtually no bounds is that the user can also implement a level of creativity with the data results, which, in the end, can produce an enormously innovative product.

Let us look briefly at the data process. As we know, standard geographic data resources are typically the only forms of basemap data available and used, such as digitized maps, census data, aerial photography, and so forth. These data are relatively static and the user is commonly bound by accessible data sources. Data requests, on the other hand, are formed by a particular application need and afford the user a suitable reason for specificity. This enables a level of user distinction with requests. An impetus for a data request may be the need for wetland delineation data in a square mile section of Brazilian shoreline or concentrations of emitted chlorofluorocarbons (CFCs) throughout Lithuania. Ultimately, geographic data requests allow creativity to enter the data process.

On the other end of the black box are the geographic data results that form the GIS product. We already discussed GIS information products in general and to some appreciable length. The GIS products are where the user's originality truly comes into play. Maps can be overlaid with multiple layers illustrating important and application-specific data.

For example, the New York City Department of Parks and Recreation used GIS to chart and manage the spread of the Asian longhorned beetle (ALB), a degenerative insect that bores holes in trees to lay eggs and whose larva bore additional holes to get out of the tree. ALBs cause the quick decimation of healthy tree populations. Through nontypical agency-created beetle data and Census Bureau data, the city was able to generate an ALB infestation geospatial

application that detailed infested tree density, quarantine zones, and infestation survey areas. These common, though project-specific, GIS products helped and continue to help the agency manage the ALB infestations. Overall, highly usable geographic data sets were created, which have ultimately helped contain the city's ALB infestations to just three incidents.

Another example of common GIS products used for unique scenarios involved a series of dreadful brushfires that ravished Sydney, Australia, in December 2001. Commissioned to discern the extent of the fires by the New South Wales state government, the Sydney Catchment Authority (SCA) utilized prefire and postfire imagery and developed the Satellite Pour L'Observation de la Terre (SPOT2) data set. SCA discriminated the normalized difference vegetation index (NDVI), a gauge of land cover suppleness, for both images and used GIS to calculate burn severity between the same areas in both images. Very little or no change in the NDVI value meant that the area was unaffected by the brushfires. A large change in the NDVI value indicated that the brushfires drastically burned the area. GIS also detailed a scale of varying degrees of forest burning, depicted on change analysis maps with a colored scale. Overall, the SCA's use of GIS not only helped detect the overall extent of the brushfires but also armed the SCA with a better grasp of the nature of similar brushfires.

Common GIS products such as the density maps and graphical visualizations are typical staples for user analysis but can remain distinct through the unique representation of data results. Depending upon the user's pioneering and innovative character, the common GIS information products are not the end of the data process. Many GIS information products possess what are called "bi-products," or developable information products formed as a result of a specific application data process.

Simply stated, geographic information bi-products are potentially exploitable proprietary sets or procedures that come out of a specific GIS process. The New York City Department of Parks and Recreation, for example, was left with a one-of-a-kind geographic data set of Asian longhorned beetle data (GIS bi-product) that may be usable by or salable to some other agency or private firm. Through the brushfire GIS application, the Sydney Catchment Authority developed two bi-products: a reusable procedure for the calculation of burn severity (which is now standard practice at the SCA for brushfires), and the forest burn data results (now being used for another GIS application—Sydney's spatial fire management system).

Bi-products spawn from creative approaches to specific applications. Some unique and profitable bi-products involve geographic data sets and demographics. The process of creating special data sets is tedious, time consuming, and often extremely difficult. In some cases, it can be impossible to get the raw data. Firms are many times willing to purchase prefabricated data sets from distributors in order to minimize project development expenditures and reduce

development time on the project schedule. This need has manifested in the creation and subsequent popularity of online geographic data marts/depots, where distributors compete for sales.

Specific demographics are usually harder to get and can be impossible at times without agency permissions and cooperation. Demographics add substance to a geographic data set and offer the user an enhanced capacity for data analysis. GIS developers know that qualified demographics, especially if you have proprietary access to such data, can be an enormous moneymaking bi-product from a GIS process. In fact, many firms now specialize in one-of-a-kind data sets and demographics, because of their high demand and financial value.

Database Management Systems

This section goes to great lengths to explain *how* database management systems (DBMSs) operate, but in the end the section clearly answers *why* DBMSs should be used and the functional role they play in a GIS. DBMS elements, such as queries and attributes, are covered in the previous chapter, since they are vital components to the overall flow of information but only a fractional part of a GIS's inner working.

A database management system is a program or collection of programs that enables the user to save, modify, classify, select, and extract information from a central database. DBMSs are used throughout the world and throughout almost every industry for the purposes of centralizing information and automating processes. For example, automatic teller machines (ATMs) function by means of a database management system. The user's card number and personal identification number (PIN) are entered into the ATM (database log-in security), information is displayed (database queries), user action is taken (information is sent to the central database, calculations are completed, and the database is appended with the new information), ATM dispenses money (database condition is met and approves machine's mechanical functions), and the user quits the ATM (database is closed, database log-in security activates again).

A typical DBMS is an organized, noninferential, and nonreferential data system that utilizes a file tree structure or file hierarchy. DBMSs are great for single purpose usage, where there are few users at one time and a modest amount of existing data at any one time. Without spatial coordinates, DBMSs can be described as information systems that are used for nongeographical databases (such as in the previous example of the ATM).

Ultimately, DBMSs are tremendous data management tools for small- to moderate-sized applications. These systems handle data rather easily and without much delay. However, problems arise in larger databases. Due to the

amount of data, large databases not only form object-oriented redundancies, they also slow down the query processes and become a substantial programming maintenance liability.

Back in the 1960s, these database problems were already evident. Surely you have heard the stories about the first mainframes and their physical bulk. Some of the largest corporations had buildings filled with room-sized computers that had limited processing capabilities and were getting "tied-up" with tedious database query functions. Databases were highly data dependent and, as a result, the functionality was impaired when large groups of records were accessed. The most prominent and baneful forms of data dependence included ordering dependence, indexing dependence, and access path dependence. The unanimous conclusion was the urgent need for less programming, simplified functions, and compressed data files.

In 1970, Dr. Edgar F. Codd offered a valid solution with his remarkable paper entitled, "A Relational Model of Data for Large Shared Data Banks." Dr. Codd's paper detailed a new method of simplifying database management using relational algebra for simple database functions. Codd's relational model broke new ground for eliminating redundancy and simplifying database functionality through user-defined relationships between data.

At first, Dr. Codd's paper went ignored until developers at International Business Machines (IBM) took notice. Based upon Dr. Codd's groundbreaking idea, IBM developed the first relational database called System/R. As the backbone to System/R, IBM developed and implemented a new form of relational programming language called Structured Query Language or SQL (pronounced "Sequel"). The space- and time-saving element of SQL was that it defined what data operations were used rather than how the operations were performed. As a result, the amount of programming code was drastically reduced through SQL, with many cases being reduced by more than half.

This leads us to the advent of the relational database management system (RDBMS), which is a program or collection of programs that enable the user to build data relationships to efficiently save, modify, classify, select, and extract information from a central relational database. RDBMSs are predominately SQL and Visual Basic-based with some of today's most widely used systems being Oracle, Microsoft SQL Server, Informix, DB2, and Sybase.

Relational databases are typically tabular data with a series of data columns and rows. The columns or *attributes* contain distinct field data, while the rows or *tuples* contain the individual records. The relational aspects of these databases are wholly contained within the attributes. In addition, each record has a unique attribute called a *primary key*, which distinguishes that record. These primary keys can be sequential record numbers or user-defined values that are unique and, thus, not duplicated anywhere within the same attribute throughout the records.

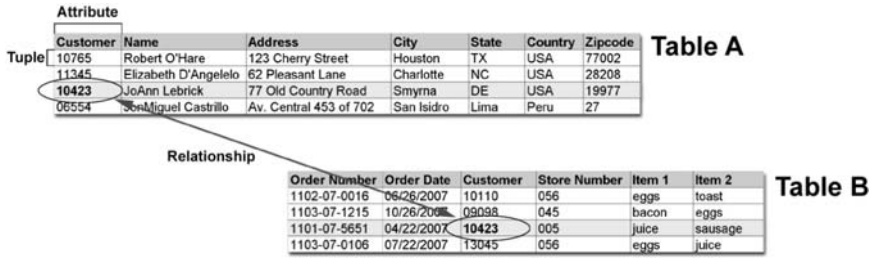
Consider Figure 2.1. Two distinct tables exist with various attributes and records. The relationship between both tables lies within the "Customer" attribute. This single relationship makes available to the user a wide range of query and data selection capability. Attributes "Customer" in Table A and "Order Number" in Table B are the primary keys.

RDBMSs can take on a variety of system architectural types, but the most fundamental and commonly used types include file-based systems, client/server systems, and multitier systems.

A *file-based system* is the simplest of relational database types and uses one file that contains the database tables, queries, security information, and forms/reports. Microsoft Access is a perfect example of a file-based system. The database file can reside on a single user computer or on a network. This type of architecture fails when more than a few dozen users access the database at one time.

A *client/server system* is designed to effectively handle many users accessing the central database at one time with speed and efficiency. The client/server system typically uses a network to connect the user workstations (called clients) to the central database residing on a file server. The system name evolves from this arrangement, hence "client/server." A client accesses the database using SQL and Visual Basic commands, and, in return, receives data from the database file server. The client, in turn, uses his workstation to process the data and perform the necessary calculations and report generation (i.e., information product). The amount of data transmitted from the file server is, in most cases, substantially less through the progressive use of SQL/Visual Basic query commands and user workstation processing.

The client/server system is a remarkable advance from the file-based database system but has one unmitigated fault: scalability. Data scalability involves the power to reduce or increase the amount of data being transmitted from the database to the user. Often, data scalability is warranted when information is presented on the Web or if data accessing rules must be employed.



Customer	Name	Address	City	State	Country	Zipcode
10765	Robert O'Hare	123 Cherry Street	Houston	TX	USA	77002
11345	Elizabeth D'Angelelo	62 Pleasant Lane	Charlotte	NC	USA	28208
10423	JoAnn Lebrick	77 Old Country Road	Smyrna	DE	USA	19977
06554	San Miguel Castrillo	Av. Central 453 of 702	San Isidro	Lima	Peru	27

Order Number	Order Date	Customer	Store Number	Item 1	Item 2
1102-07-0016	06/26/2007	10110	056	eggs	toast
1103-07-1215	10/26/2007	09098	045	bacon	eggs

1103-07-0106	07/22/2007	13045	056	eggs	juice

Figure 2.1 A relationship between tabular data.

The solution to scalability is a *multitier system*, whereby there are one or more data task servers between the database server and the client. A multitier system (sometimes called a three-tier system) functions somewhat like the client/server system, except that there are middle servers, which contain software to perform certain tasks and process some of the transmitted data. These middle servers help reduce the amount of data being transmitted to the client.

The use of multitier systems results in easier application deployment, data scaling for the Web, enhanced security, and the ability to implement data or business rules. Since clients have reduced processing capabilities in a multitier system, they are called *thin clients*. Conversely, clients requiring their own individual rules, such as in the client/server system, are called *thick clients*.

Figure 2.2 depicts the three fundamental RDBMS architectural types and their differentiating physical arrangements.

So now that we have discussed the physical and functional infrastructure of relational database management systems, we can ask: *Where does GIS fit in?*

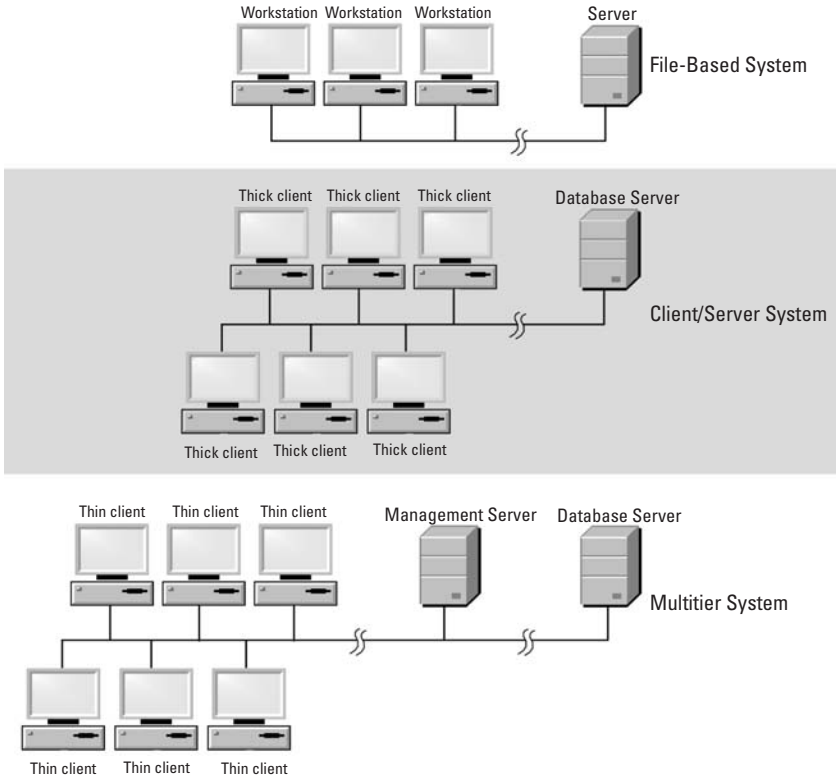

Figure 2.2 Three fundamental RDBMS types.

Geographic information systems follow the multitier system architectural type in that there are typically three tiers: a public presentation tier, a business and data management tier, and the GIS management tier.

The public presentation tier involves general viewing, Web-enabled data access, superficial analysis, and geographic visualization. This first tier is made up of general end users (or public thin clients). The business and data management tier involves users responsible for building the geographic database, site maintenance, critical analysis and visualization, and project management staff. This second tier acts as a filter to what information can and will be presented to the general public, as well as creates the project-specific geodatabase. The GIS development tier involves GIS professionals and systems responsible for data modeling and design, Web site development, low-level programming, and site administration. This third tier can also be called a data tier since it primarily functions to supply the entire database information.

Figure 2.3 depicts the three typical GIS tiers and their interaction with the RDBMS. Notice that the GIS development or data tier provides a relational and

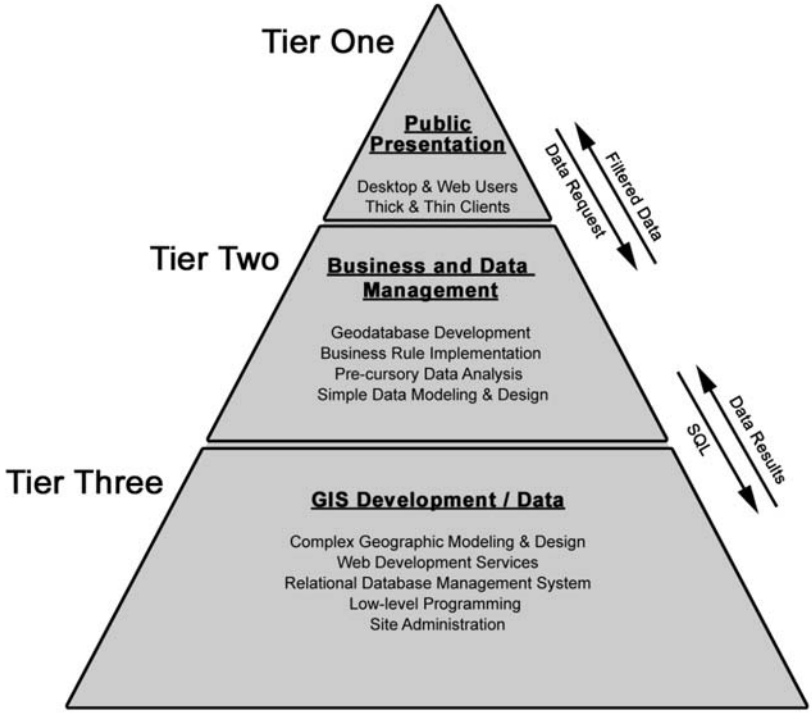

Figure 2.3 The three common GIS tiers.

comprehensive data resource. The business and data management tier takes the entire database and creates a project-specific geographic database, weeding out extraneous information and saving the pertinent. The thin clients then utilize both desktop and Web-enabled applications for viewing and analyzing this data. Overall, a massive relational database management system forms the backbone to GIS.

Let us look at a real-life example to help understand GIS's three-tier system. MapQuest.com is a free GIS-based map-generating product on the Internet, whereby a GIS backbone populates the Internet search capabilities. Although entirely different, GIS and the Internet integrate together to provide a Web-based front for geographic information. In brief, Web users have the ability to enter basic location information and view corresponding maps of that particular world location. Consider the user as the thin client in the public presentation tier (first tier). Users can view maps through minimal location input. Say, for instance, you are the thin client and you request a map of 415 Charles Street in Omaha, Nebraska. The software sends a query for data to the business and data management tier. This second tier receives the request from the user and processes the information. The second tier in turn sends a request to the RDBMS in the data (third) tier for Omaha, Nebraska, map data. The third tier contains every map for every city in the world, scalable to street level. Once it receives the request, all Omaha, Nebraska, map information is transmitted back. The second tier receives the RDBMS information and selects all the Charles Street information. This selected information is then searched by addresses until address 415 is found. The second tier transmits this select data to the first tier software, which, in turn, creates a graphic map. The thin client now has the correct map requested through the Web.

This leads us into the topic of how databases utilize the Web. In fact, there is a delicate bidirectional relationship between the RDBMS and the Web that patterns the very nature, flexibility, and importance of GIS Web services. All RDBMSs are designed to distribute information on the Web with a varying degree of user interaction. To achieve control, RDBMS utilize three types of data distributing Web pages: static, dynamic, and active. Because GIS is a relational geographic database management system, GIS products are portrayed and distributed in the same manner.

Static pages display database-driven information that cannot be changed, altered, or modified by the user. In fact, static pages display static Hypertext Markup Language (HTML) content. Dynamic pages, on the other hand, involve some user interaction, whereby the pages display the most recent or dynamic database information as defined by the user. Dynamic pages access a database through a query. MapQuest utilizes dynamic pages. The most common implementations of dynamic pages are with Java, a multiplatform, object-oriented programming language. Active pages involve full user interaction, whereby the user

can request information as well as make changes to and manage the database. Active pages can be considered a comprehensive database terminal with processing logic capabilities. In any case, HTML pages are the most common type of Web page utilized by GIS Internet map servers.

GIS Web services utilize all three Web page types when portraying geographic information. Noninteractive map products would typically be displayed using static pages, since user input is not required. GIS professionals use dynamic pages when the end user requires some functionality, such as turning on and off layers to a GIS product. The United States Environmental Protection Agency (http://www.epa.gov) utilizes dynamic pages so that users not only can search regions for reported environmental hazards but can customize the views through interactive layer selection. Lastly, GISs use active pages so that GIS developers have full control of the background data.

In conclusion, database management systems, both object oriented and relational, are important not only to how a GIS works but, more specifically, to why GIS is used rather than other methods. A geodatabase, for instance, is implemented directly on a RDBMS to take advantage of the system's data management capabilities and system administration tools. In turn, a GIS expands the functionality of a relational database so that it can proficiently handle geographic data, produce custom maps, and perform spatial analytic tasks. Together, GIS and a RDBMS offer the best in database management technology, geographic data distribution, information manipulation, and accelerated processing.

Quality Assurance, Six Sigma, and GIS

A fully implemented GIS adds value to a project while maximizing accuracy and data quality. In today's industries, quality is a big subject. You cannot enter any industry these days, let alone the engineering and environmental fields, whereby quality is not a major factor as to whether you will succeed or fail. In recent years, phrases such as "ISO-certified" (for International Organization for Standardization) and "ISO-9001 standards" are commonplace and, in many cases, required to provide services for certain agencies.

By its very structure, GIS elicits a high degree of data consistency and source data reliability. GIS information products, such as layered maps, contoured reliefs, and point data, offer various automated procedures and same-source data. GIS's process automation is just one placard for achievable higher quality output.

A rising new methodology for achieving quality that is quickly gaining corporate placement is called Six Sigma. Six Sigma stands for six standard deviations from the mean or average and involves a measure of quality that strives for near perfection. The lowercase Greek letter sigma is the mathematical representation

for standard deviation. In practice, Six Sigma is a disciplined, data-driven methodology for eliminating shortcomings and deficiencies in any business process. This perceptive approach can be implemented from the development stage to the service provision stage and involves staff trained in the Six Sigma principles. Large companies, such as GE and Motorola, already implement the Six Sigma approach and have experienced the benefits.

Unlike the ISO or ANSI (American National Standards Institute) standards, Six Sigma is not a regulation or a directive, per se. It is simply a unique way to achieve higher quality and save money. Incidentally, GIS can offer some of the same quality-enhancing results. GIS is complementary to the Six Sigma principles through GIS's data-driven structure, invariable consistency, and ability to improve processes. In addition, like Six Sigma, GIS's capability to reduce data variation and efficiently improve an organization's data quality is quickly becoming the new industry benchmark.

Developers, managers, and users are seeing first hand the far-reaching advantages to implementing an enterprise-wide GIS, from project efficiencies to fiscal brow beating. Its heightened quality enhancements complement existing corporate quality programs. Six Sigma and GIS can become the one-two punch for quality preeminence and knockout ISO/ANSI regulation compliance.

Project Visibility and Popularity

Through fluid Internet accessibility and high-octane map controls, GIS has become the preeminence in data sharing and distribution. Many times local governments and agencies find geographic information systems to be the one-size solution for their communication and public outreach programs. By default, GIS has become the technology of choice for detailing spatially based technical results to nontechnical viewers. The use of data representation and techniques makes analysis easy for those not directly involved with the project or experienced with the processes.

GIS is highly visible. Users can access data results easily through the Web and can manipulate (to some extent) how the data can be presented onscreen. For instance, after September 11, 2001, the U.S. Environmental Protection Agency (USEPA) let users view mapped environmental contamination and air quality data for Lower Manhattan. Users were able to turn on and off information layers over a street map baseline. The USEPA updated the air sample results daily and millions of users accessed the site. Through necessity and huge public interest, this basic GIS-based site experienced incredible visibility and popularity.

On a more fundamental and everyday level, project managers have embraced GIS use because they can efficiently manage the project's document and graphic-based results from a single data location. Through GIS, virtually

limitless project personnel and management alike can review the results in real time via the Web. The increase in project communication and quick project team debriefing has made GIS highly popular in project implementation and administration schemas.

As another example of GIS's popularity and visibility, a soil sample for a transportation rehabilitation project can be taken in the morning and its location, analysis type, and other relevant data can be easily entered into the GIS. Soil sample data locations and base information is instantly accessible by team members and others with GIS access. Soil sample information can be illustrated on a project site map with hyperlinks to soil boring logs and, eventually, the laboratory results. In the end, the benefits of GIS's one-stop shop of project data make GIS an extremely popular and highly exploited project tool.

Benefits, Cost Savings, and Automation

In many businesses where the bottom line drives decisions, GIS is often viewed as an expensive resource. Most decision-making managers have only the vaguest idea of what a fully enabled, successfully implemented GIS can do for their business proceedings. Although the concept of implementing a GIS is typically interesting, the front-heavy costs of implementing the system are not. These initial GIS costs are often enough to scare away most managers, while the proposed automated and cost-saving outcomes get classified as a project whim.

Today GIS is breaking new ground in project efficiencies, data communication, and value-added deliverables. Many private firms and public agencies are now requesting the implementation of a GIS on their projects because of the overwhelming long-term savings and advantages. Especially in local governments, GIS has made great strides to help consolidate the vast types of data and information into one categorical data repository. Local governments have begun learning the wide-ranging savings involved with distributed data throughout their projects. The dreaded fiscal black hole of government data communication is becoming a thing of the past.

One such local government is the Maryland–National Capital Park and Planning Commission (M-NCPPC). In a cost-benefit assessment report from 1999, M-NCPPC detailed the overall impact of the GIS implemented in Montgomery County, Maryland, highlighting the significant changes from the pre-GIS county environment and detailing the outstanding benefits of the GIS. Some of M-NCPPC's pre-GIS problems included inaccurate maps and data; incompatible maps and data sets; limited numbers of maps produced because of the required person-time; and end products not being standard. In total, M-NCPPC detailed nine crucial problem areas in the pre-GIS environment.

Since Montgomery County implemented GIS, a number of benefits were achieved. These benefits were grouped them into five areas: (1) overall improvements in existing operations from GIS, (2) additional capabilities not available in a non-GIS environment, (3) emergency response using GIS, (4) intangible improvements, and (5) product and bi-product sales revenues.

M-NCPPC's end result in its cost-benefit assessment report was that Montgomery County saved a typical annual amount of more than $500,000 from GIS functions alone. Additionally, GIS bi-product sales from fiscal year 1999 amounted to well over $44,000. M-NCPPC's overall conclusion was that the use of GIS had an overwhelming functional and cost benefit to Montgomery County.

Local governments have also experienced the benefit of increased government efficiency with the implementation of a GIS. For instance, the city of Ontario, California, used GIS to audit their billing files and reclaimed $190,000 per year in lost business license fees. In Bucharest, the Romanian National Railways Company implemented an ambitious GIS to automate their railway systems, which ultimately resulted in a geographic inventory of all railway assets, geographic maps for more than 22,000 km of track, and a centralized database to support all primary business unit applications. Additionally, a European Commission–backed project called Bacchus is using European Space Agency imagery and GIS to chart Europe's vineyards in unprecedented detail. The GIS information products provide vine growers with the tools to improve grape production, manage vines, and guarantee grape quality.

Just looking at the enormous benefits and heightened automation within the handful of examples presented, the intrinsic power and enormous impact that GIS has worldwide is easily understood. The key to maximizing all GIS benefits and cost savings revolves around knowing what the user wants from the geospatial application. The earlier the users can define their expectations, the cheaper the GIS implementation. Incidentally, user education is one sure-fire way to secure continued benefits from any geospatial application and helps the untrained user eye become more discriminating from the project start.

Possibly the greatest benefit of GIS is the ability to conduct tasks not previously possible. Whether it is Europe's vineyards or Maryland's local government, GIS has made an indelible mark on the procedures, efficiency, and future health of public and private entities worldwide. If you need additional proof as to the overall success of GIS and more reasons why GIS should be implemented, then peruse the voluminous case studies and success stories available on ESRI.com, Intergraph.com, and the hundreds of local government sites throughout the Web. You will soon recognize that the question *Why use GIS?* has but one accurate response: *Why not?*

3

The Structure of Geographic Data

Geographic data come from a variety of sources, such as digitized maps, aerial photography, GPS, and field data. Valid geographic data serve as a collective true marker as to what level of detail and accuracy a GIS can potentially attain. But, in reality, this is only a half-truth. The manipulation of this geographic data is as important and, often, more suggestive of the outcome's quality.

The appropriate structure of geographic data is considered a top reason why a GIS succeeds or fails. Inappropriate data handling or structure predictably leads to inappropriate geographic information products. To this extent, a user's grasp of the GIS application, the desired outcomes, and the geospatial system's limits are detrimental to realizing how best to treat the geographic data. Ultimately, the successful structuring of geographic data requires a combination of understanding and sound decision making.

Geographic information systems utilize two primary data models to manipulate and structure geographic data: the raster data model and the vector data model. We have already discussed both types briefly in Chapter 1 but now must build upon that initial introduction to gain a better understanding of both the elements and idiosyncratic nature of each type. By examining the nature of each data model you will have a much clearer picture of the important and institutional structure of geographic data, as well as a distinct understanding of the advantages and disadvantages of each.

Raster and Vector Data Structures

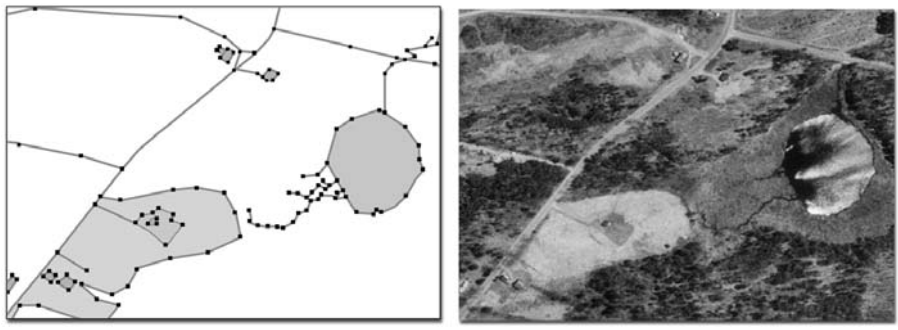
Like any complex data structure, raster and vector data have a myriad of different realizations that vary in complexity through use, appearance, format, and file size.

Although distinctly different, these affiliate data structures share two characteristics: (1) They visually represent real-world features, and (2) they are subject to orientation within the real world. By satisfying both of these characteristics, geographic data are born and made interoperable with other geographic data sources within GIS. Before proceeding further with this discussion, let 'us take a small step back to reacquaint ourselves with the raster and vector data structures.

Raster data structures characterize continuous data (such as imagery) and are exceptionally strong where boundaries and point information are not well defined. Raster data provide data as a pixel grid, whereby each pixel or cell is a feature capable of retaining properties and attributes. These pixels approximate pictures and images in an impressionistic way, with all of the smallish, monothematic cells contributing to a greater whole. Adding further identity, a raster image can vary in file format, color representation, resolution (size of pixels/number of pixels per set area), and potential properties.

Vector data are a bit different. Vector data structures characterize discrete data (such as roads, pipelines and topographic features) and are exceptionally strong where distinct boundaries and point information are well defined. This data structure is constructed on ordered two- and three-dimensional coordinates ([*x*,*y*] and [*x*,*y*,*z*], respectively). Features are represented as geometric shapes defined through single or grouped coordinates on a set grid.

For a clearer understanding of both models, refer to Figure 3.1, which illustrates the visible differences between raster and vector data, as well as how each data set represents Earth features. The original graphic is a raster, high resolution satellite image of a land parcel with infrastructure and a pond. Notice the distinct feature variance between its continuous data image and vector's point representation. It is clear that the raster image serves as a good overall representation, while the vector representation serves as a good individual feature representation.



Vector Representation

Raster Satellite Image

Figure 3.1 Raster versus vector data representation.

Both the raster and vector data structures have inherent advantages and disadvantages that allow GIS users a certain degree of choice. A full understanding of the native characteristics of each data model is a prerequisite for GIS success. Often certain requirements force the use of one data model rather than the other, such as the need for a better output resolution, easy image analysis, or enhanced spatial accuracy.

Raster data, for example, offer a truly simple data structure that involves a grid of row and column data. This simple grid structure allows for easy raster image analysis, as well as analysis among multiple images. Raster modeling is also much easier to implement due to the single-value cell structure and relatively simple software programming.

These advantageous raster capabilities are shadowed only by raster's native weaknesses. Disadvantages to raster data include general spatial inaccuracies and misrepresentations, low resolution, and massive data sets that require significant processing capability. The lack of accurate topology is also a major raster-based limitation.

Similarly, vector data offer their own variation of modeling strengths. Vector data, for instance, are spatially accurate and support a better, higher resolution than the raster data model. The ability to provide topology or feature relationships is a definite advantage, as well as the minimal data storage requirements.

Although seemingly ideal, vector data have their own share of weaknesses worthy of mention. Due to the complex data structure, vector data require a greater and more powerful processing capability. With this comes the need for better, faster workstations to minimize the data processing times that typical computers face. Inevitably, the costs to run a vector GIS and expeditiously process complex geographic data sets can become highly expensive.

Needless to say, both the raster and vector data models have their own brand of geographic data expertise and capability embedded within a GIS. Nowadays, GISs are offered as raster-based systems, vector-based systems, or raster-vector capable systems. When necessary, raster-to-vector/vector-to-raster conversions can be easily accomplished through GIS or third-party conversion software. Undoubtedly, the choice of data model lies with the user and the available software/hardware.

The next few sections examine raster and vector data capabilities that are vastly used in everyday GIS work.

Vector Feature Geometry

Often it is necessary to depict real objects as features on a map and designate object positions within a GIS. These features can range from the simplistic (i.e.,

linear transmission lines) to the complex (a multibranched, nonlinear river). To detail objects as features in a GIS, we must choose the best data model. In most cases, features are defined using the vector data model.

Given the nature of raster data, features are ambiguous in shape and general in position. For applications where specific form or position is not needed, raster may prove easiest. Some possible applications where raster data can be used to define features is on nonprecise maps, such as visitor maps of an amusement park, or macroscopic markers on an overview map, such as a colored box for approximate position.

Alternately, given the accurate, positional nature of vector data, features are best represented by coordinates and geometry. Real-world objects can be represented as individual or a group of geometric shapes called feature geometries. In any geospatial platform, there are three primary types of feature geometries: points, lines, and polygons. As a subset of these three primary types there exists a fourth geometric feature called a polyline. Figure 3.2 illustrates these major feature geometries in both the raster and vector data models. The differences between and usefulness of the models are obvious as they relate to depicting feature geometry.

A point is an individual position defined as a vector *x-y-z* coordinate or as one raster pixel. Lines are two connecting points with two distinct coordinates in vector or a linear block of pixels in the raster model. Polygons are a grouping of vector coordinates connected in a sequential fashion or a group of pixels

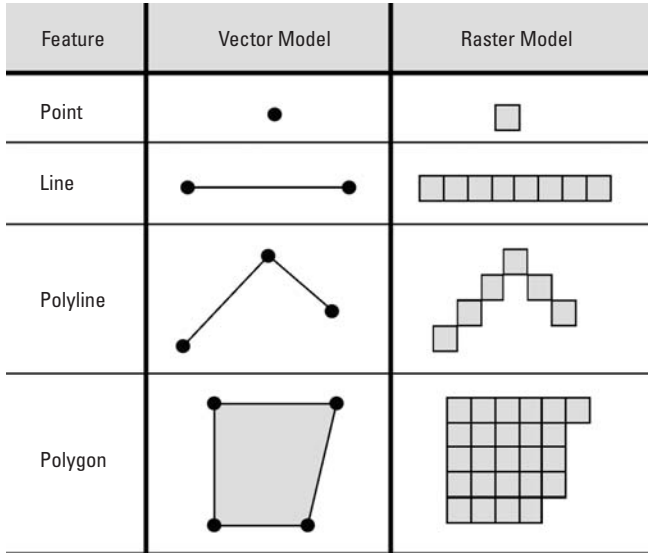


Figure 3.2 Feature geometries in raster and vector.

forming the object's general shape. Lastly, the subset polyline (known also as an arc) is a connected string of vector points or raster pixels. Often a polyline involves two lines sharing a same point or pixel (vertex).

Vector features are constructed on ordered pairs of vertices, whereby these ordered pairs reside in the design plane having known *x*, *y*, *z* locations. The positions of these ordered pairs are recorded in the vector file and often encoded as binary. These vertices are objects and can be grouped to form features that exist as independent entities. This is in contrast to the raster model, where the entire image is an object. In raster, features must first be sampled and then represented as image pixels, which, as we already know, visually approximate the features. Raster images have no independent vector ordered pairs, the actual building blocks of feature-driven spatial information.

Vector data for feature geometry comprise positional coordinates and, for some, other position-defining data, such as inside/outside and left/right. Figure 3.3 depicts the three primary types of geospatial feature geometries, as well as the polyline and the more complex polygon within a polygon (i.e., the "doughnut").

As illustrated in the figure, the point depicts a discreet position in space, defined by an individual geospatial coordinate. The line is defined by two geospatial coordinates. The open-ended third feature is a polyline, which comprises two vector lines sharing a common point (vertex). Interesting enough, polylines are defined not only by geospatial coordinates, but also by left and

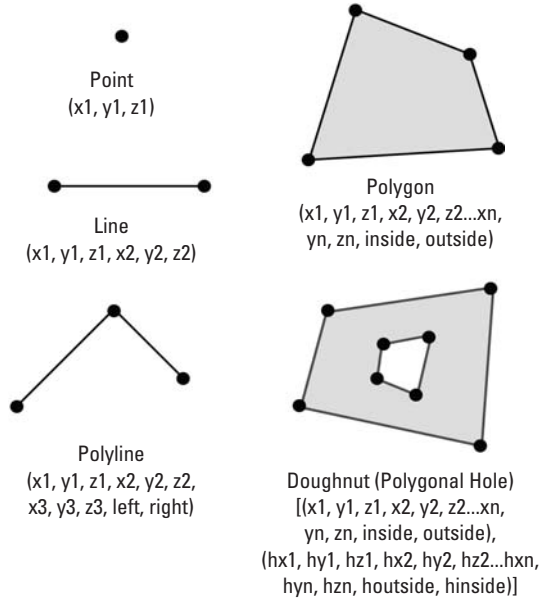

Figure 3.3 Major vector feature geometries.

right characteristics that indicate whether other features are directly left or right of the polyline.

Growing in complexity, the remaining two geospatial feature geometries in Figure 3.3 are closed features and depict specific areas. The polygon involves numerous vector points that are connected in sequence. Polygons are defined with inside and outside characteristics that delineate whether any overlapping geospatial feature geometries exist inside the polygon's boundaries.

The most complex of the geospatial feature geometries presented in Figure 3.3 is the doughnut or polygonal hole. A doughnut comprises a polygon within another polygon. Polygon 1 forms the boundary area and polygon 2 serves as the "cutout" within polygon 1. Think of a doughnut, whereby polygon 1 is the outermost doughnut boundary and polygon 2 is the cutout in the doughnut center (doughnut hole). Each polygon enables coordinate characteristics for inside and outside elements.

To uniformly structure, manage, and manipulate feature geometries like the ones just discussed, a GIS stores vector data in geospatial feature file formats. Common feature file formats, such as the *shapefile* developed by Environmental Systems Research Institute (ESRI) or the *TAB file* developed by MapInfo, are basic geometric containers compatible with an overwhelming majority of GISs. These geographic dataset types store nontopological vector (or coordinate) geometry in the form of real-world spatial features, as well as links to attribute information for these respective objects.

Raster Image Structures

The nature of images, such as aerial photographs and base maps, involves a continuous array of data. As discussed, the raster model provides the best solution for continuous data. Due to the lack of specified feature boundaries, point locations, and multiple objects, vector data are not intrinsically fit to handle the image information. A vector data representation of such an image produces a complex and often massive image structure.

Unlike a vector format, the raster palette is much more desirable for applications requiring the use of photographs or digital scans. Raster imagery instantiates outrageously complex geometries quite easily with the use of attributed image pixels. The essence and value of raster image structures are that raster represents real-world information with native visual properties—a feat vector imagery cannot reproduce.

Because raster images are physically continuous by nature, a reasonably accurate transformation process can be applied to fit raster data onto the real world. In brief, images are "rasterized" or digitally transformed to raster data through a matrix of pixels. Photographs are typically scanned with a set image

resolution defined by pixels per inch (ppi), more commonly known as dots per inch (dpi).

With the use of a GIS, the organic transformation into a raster image can enable users to characterize previously nonattributed existing geographic data material. In fact, solutions produced from this process result in alternative, often unexplored, geographic data sets.

There are times when an existing raster image is not at the desired resolution for the present application and an image adjustment is necessary. Manipulating resolution within raster images is a technique to adequately control and manage the amount of raster data to be processed and the overall image quality. As mentioned earlier, raster data resolution is the result of the amount of row and column pixels used to define an image. Raster image dataset size is directly proportional to the amount of raster pixels used to define an image. The rule of thumb is: The more pixels in the grid, the higher the image resolution, quality, and dataset size; the fewer pixels in the grid area, the lower the image resolution, quality, and dataset size.

Modifying the image's resolution presents varying results within the image. You can easily transform a high resolution raster into a low resolution raster without desecrating image quality. The image size often remains unchanged through an intelligent interpolation that transforms a grouping of pixels into one pixel. However, it is not always easy to reverse this transformation. Taking a low resolution into a high resolution form is not always feasible. To retain moderate image quality, a high resolution raster will take on a reduced, fractional size to that of the original low resolution raster. If image size remains unchanged, the new high resolution image will be relatively unusable and indistinguishable in content. Care should always be taken when modifying the resolution of raster images.

In actuality, geographic information obtained from these types of organic processes may be of critical relevance to future projects and unwittingly provide solutions to problems not yet known. Many times these unforeseen criticalities involve complications put forth by the presence of precious natural resources on a project. The manifestation (or realization) of these transformations is the fundamental building block for geospatial systems and makes available opportunity for other advanced GIS techniques.

Topology

It has already been established that in a vector-based GIS, primary geometries (i.e., points, lines, and polygons) represent real-world features. Topology is the set of rules through which a GIS represents features with the primary geometric shapes (i.e., point, line, and polygon). The vector data model utilizes topology

to organize spatial relationships between discrete features. In essence, the main functions of topology are to define: (1) feature-to-feature locality or, simply, where a feature is in relation to another feature, (2) what is shared between different features, and (3) how features are grouped or connected within a set.

In a GIS, topology establishes geometric harmony within a geographic data set. Illustrating this precept is ESRI's *shapefile*, in which the vector feature file employs a set of natural numbers plotted and structured in binary format. This set of natural numbers delineates the boundaries and coverage of a particular feature. The simple binary structure defines a topological space for the feature and establishes continuity with other features, forming topological relationships.

Topological relationships are defined in all types of feature files and are generally categorized into the three primary functions of topology (previously mentioned):

1. Feature-to-feature locality, called a *complement;*
2. What different features share, called an *intersection;*
3. How features are grouped, called a *union.*

In Figure 3.4, the simplistic Venn diagram depicting two overlapping, amorphous shapes highlights the base concepts of the three feature topology functions.

Within this figure, the lighter areas are considered *complementary* shapes (*A* and *B*), while the darkest area depicts the *intersection* of the two shapes (*C*).

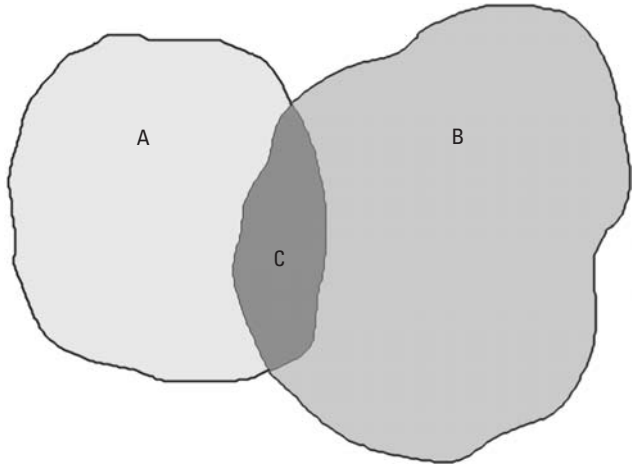

Figure 3.4 Venn diagram.

All three areas together (*A*, *B*, and *C*) form the *union* of the set. Applying these concepts to a vector GIS, shapes *A* and *B* can be considered two separate features that share topologic space (*C*).

Feature topology is also very sensitive to retaining the original shape of different features and the demarcation of each individual feature. In the context of traditional mathematics, topology is the examination of objects and groupings of objects that exhibit a predictable structure. Put simply, topology involves object aspects that remain unchanged even when the object itself is under some form of physical transformation (i.e., intersection). Similarly within the figure, shape *A* maintains its form even when sharing topological space with shape *B*.

All types of geographic data sets can utilize topology within geospatial software environments. These predictable structures (such as shapes *A* and *B*) constitute a set of features (*N*), which represents whole geospatial features. Topology implements a successor function: $s(x) = x + 1$, which succinctly indexes each separate feature for identification (FID). The successor function enables unique identification of each feature within the set. In this way topology serves as a geographic data quality overseer by ensuring the geometric integrity of geographic features between the real world and GIS, as well as retaining responsibility for producing truly clean and representative geographic data products.

Topology also helps to avoid repeating feature data, such as shared boundaries and shared nodes (points). The data model stores a single line to represent a boundary, as opposed to two lines with the same coordinates. This topological quality control helps maintain a smaller data set and vector feature file.

In Figure 3.5, polygon 1 (points *QRST*) and polygon 2 (points *RUVS*) are side by side, connected by a shared border (*RS*). Topology dictates that line *RS* for polygon 1 and line *RS* for polygon 2 are identical and the data model only accounts for *RS* once. Feature topology proves diligent in avoiding topological overlap.

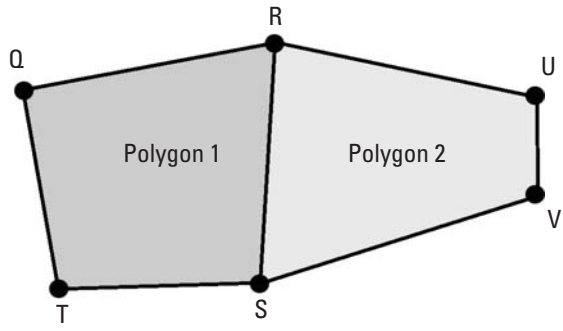

Figure 3.5 Topology of two polygons.

These geometric monitoring techniques allow GIS to control, query, and edit the topological coincidence between geospatial features (objects). Topology introduces the notion of absolute feature continuity, opening the door for numerous potential software compatibilities, including complex mathematics and engineering programs.

GIS Attribute Tables and Indices

In order for a GIS to successfully manipulate and portray geographic data, feature files must be indexed to attributes providing more information. As detailed in Chapter 1, most standard GIS data formats consist of a feature file, an index file, and a linked attribute table, whereby the feature file contains geographic object feature information, the attribute table (file) contains explicative attributes for spatial features, and the index file links attributes with features.

Briefly stated, index files act as attribute pointers. Indices contain unique identifiers that contain more detailed information about a specific feature. This embedded linkage helps speed up spatial feature queries within the GIS and serves as an index file's only true function.

Geospatial attribute tables, on the other hand, drive the spatially enabled database. There are various attribute field data types to handle the multitude of data, differentiated by a specific form of data and the degree of precision. To adequately handle the variants, attribute field data types signify different groupings of data bits, such as incorporating sign (i.e., "+" or "−"), binary, mantissa, and exponent bits, or signify data values, such as text, date, and object ID values. For clarity of this discussion, an *exponent* defines repeated multiplication (i.e., in $2^3 = 2 \times 2 \times 2$, the exponent is 3) and a *mantissa* is the value to the right of the decimal point in a common logarithm (i.e., in $\log 196 = 2.2923$, the mantissa is 0.2923).

The following attribute field data types are most common and are supported in many major GIS environments:

- *Short Integer.* A basic attribute data type that includes one signed bit and 15 binary bits.
- *Long Integer.* A more complex form of the basic attribute type that incorporates one signed bit and 31 binary bits. As you can imagine, the *Long Integer* offers greater precision than the *Short Integer.*
- *Float.* Contains one signed bit, seven exponent bits, and 24 mantissa bits.
- *Double.* A more complex form of the *Float* attribute type with one sign bit, seven exponent bits, and 56 mantissa bits. As with the *Long Integer,*

the *Double* attribute type holds greater precision than the *Float* attribute type.

- *Text.* Contains varying forms of data, such as numbers, letters, and symbols. The *Text* attribute type is a character string that can hold any amount of characters, but each character is stored using eight bits (called a byte). An interesting aspect to *Text* attribute data are that each text value in the same field must have the same number of characters. To achieve this, end blanks are used to fill in the empty slots.
- *Date.* Though not apparent from the attribute data type name, a *Date* type contains date and time data. The value is based upon a standard time format and is automatically transformed into the current day and time within the system's local time zone.
- *BLOB.* Short for *Binary Large Object*. A *BLOB* is a complex (and large) object stored in the database that may include an image, sound, video, or geometry. *BLOB*s allow users the ability to insert any type of multimedia data into the geodatabase.
- *GUID.* Acronym for *Globally Unique Identifier*. A *GUID* is a unique 128-bit (16 byte) number that is produced to identify a particular application, file, database entry, hardware, or user. Each generated *GUID* is "mathematically guaranteed" to be unique since the total number of unique keys is colossal and the probability of generating an identical *GUID* is virtually impossible.

As with any abstract concept, casual or novice users often misunderstand attributes in geospatial systems. With a better understanding of GIS's theory (this book) and real-world practice, these feature-attribute concepts will congeal.

4

Geospatial Metadata

Today's society is information rich. We can walk into any major bookstore and use a computer to locate individual or related topic books, obtain in-stock status, and get exact store location. Let us not forget we will probably be provided a host of other miscellaneous information about the book, such as its ISBN, the number of pages, and reviews. In a matter of a few minutes, we could identify whether or not our visit is fruitless. In that short time span, we not only have discovered whether our desired information is available but also have saved a great deal of time.

This act of information sharing and dissemination is, by all means, not by accident or some form of electronic wizardry. It is a well-organized data retrieval system that retains information in a real-time database. The search function utilizes the searcher's entered information and locates specific record fields or keywords with any associated matches.

Similar to the bookstore's search utility, data resources, such as data sets, images, and documents, are digitally marked with descriptive tags known as metadata and are organized in a specific, universal order. Searches can be made against the metadata to locate these resources quickly. Without metadata description or encoding, each resource must be searched in its entirety for a match. You can just imagine how long it would take to search millions of individual resources in their entirety.

This chapter attempts to take the wizardry and mystery out of metadata. It offers an overview of dataset metadata and demonstrates how a defined metadata structure can serve as a key time-saving protocol for GIS users. It details some of the efforts taken to organize and expand available resource data, while presenting the geospatial paths taken by worldwide governments. Due to

the nature of this book and the wide breadth of metadata, this chapter is limited to an overview. Specific field metadata and metadata authoring (see Table 4.1 later in this chapter) are subjects for further exploration.

What Is Metadata?

Metadata is defined as structured information that enables a resource to be easily identified, used, manipulated, and cataloged. Metadata is often identified as "data about data" and can be applied to various resources, such as images, online documents, maps, library records, data sets, or anything else inherently searchable. In simpler terms, metadata helps resources be suitably found, cataloged, and used.

The concept of metadata is nothing new. In fact, library card catalogs, which have been around since long before GIS, are a form of metadata. The older hardcopy information cards and newer online records hold a selection of basic information and identifiers for the material being sought. Typically, information supplied includes a title, author, date, ISBN or similar identifier, and a unique library location number. This library catalog card/record is identical to metadata since it is data (card information) about data (book or resource material). Figure 4.1 identifies some common manipulators of metadata.

Metadata sometimes is embedded within the resource and other times in a stand-alone document. For instance, Web pages have metadata embedded into their source code, often programmed in HTML, and image files have embedded

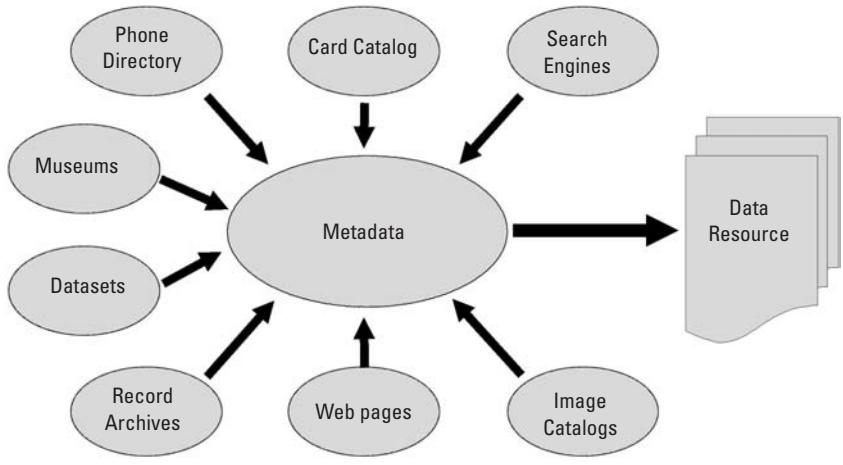

Figure 4.1 Various forms of metadata implementation and use.

metadata in the file headers. An archived map, on the other hand, may have a separate resource document containing the metadata for the map.

Embedded and separate metadata each have certain advantages. Embedding metadata within the resource ensures that the metadata will not be misplaced or lost and alleviates any problems with data-metadata linkage. Sometimes the capability to embed is not possible and, as a result, metadata has to be separate from the resource. This data separation offers easier resource location and retrieval, as well as offering a facile way to manage the metadata. Separate metadata are usually stored in a database and linked to the affiliate resource.

As you may have guessed, the topic of metadata is vast. In fact, it offers so many variations and covers such an array of fields that metadata can form (and has formed) the subject of its own book. Our interest in metadata goes only so far as the basics and those traits relevant to GIS.

Before jumping into the GIS-relevant side of metadata, it is important to understand the various objectives for the creation of metadata. The most primary objective for metadata is resource discovery. Metadata makes the resource "visible" to searchers, making it much easier for users to discover available resources. Other metadata goals include resource identification, enhanced structure, administrative controls, intellectual rights management, and preservation. These metadata objectives are equally important throughout the assorted fields of use.

Geospatial Metadata and GIS

We have already discussed how metadata are uniquely linked internally or externally to various types of data resources. In GIS, the data resource of paramount interest is the data set. Metadata that identifies and describes a data set, be it in GIS or another database management system, is classified as dataset metadata. Furthermore, since a GIS is a geospatial database utilizing a geospatial data set, its metadata are likewise geospatial metadata.

Users of geographic information systems rely heavily on the use of geospatial metadata for identifying and manipulating geographic data sets. Classified as dataset metadata, geospatial metadata are defined as structured information about a specific data set that enables the geospatial resource to be easily identified, used, and cataloged. Geospatial metadata includes at the very least the geographic data's owner, source, description, resolution, scale, and proper use.

Metadata helps GIS users understand the numerous parameters surrounding the data sets. Users can quickly discern the data set's level of precision and usefulness in tandem with other data sets and objects. Well-detailed geospatial metadata directs users on how best to use the resource and to what lengths the

dataset creator went to construct the resource. Through metadata review, an astute GIS user could identify which dataset resources are of high quality, which are beneficial for their application, and which are pure garbage.

Geospatial metadata is used for the wide array of areas that GIS handles but has proved to be particularly valuable in the technical and scientific arenas. New, refined definitions of geospatial metadata are concurrently being constructed to better define and catalog the available technical resources. New pathways for information exchange and sharing have been paved through past metadata initiatives and continue to expand through ongoing initiatives within many progressive disciplines, such as in the biological, natural resource, and social science fields.

Every initiative to define and beneficially structure discipline-specific metadata is based upon an already established metadata format called a *schema* (or scheme). Refer to Figure 4.2 for an overview of a schema. Traditionally, *schema* is used for diagrammatic description and *scheme* is used for textual description. For the sake of simplicity and the nature of GIS data sets and products, we will use the term *schema*. Moving forward, the next section offers insight into metadata schemata and their element sets, as well as offering the particulars of the ones more universally employed.

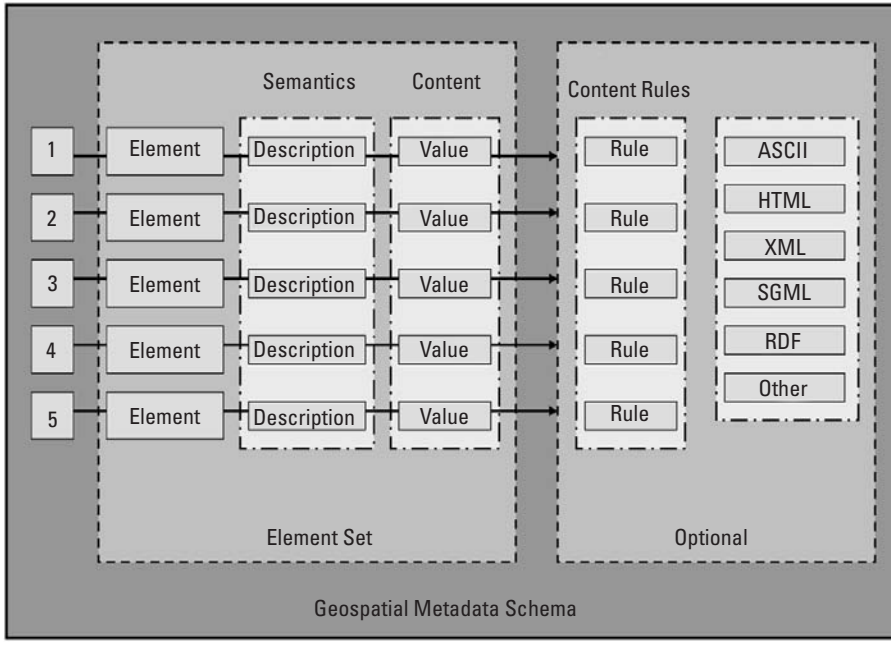

Figure 4.2 Geospatial metadata schema.

Metadata Schemata, Element Sets, and Syntax

A metadata schema is a description of the particular structure, arrangement, or content applied to a set of metadata elements. Alternately, the metadata element set is the collection of individual constituents that form the actual metadata. You can envision the metadata's schema as being the "database," the element set as being the database's primary table, and each element as being an individual data field within that primary table.

Metadata schema elements hold characteristics similar to any spoken or programmed language, whereby they must follow stringent rules for correct usage. The description of a schema element is considered the semantics of that schema and the values given to the schema elements are considered the content. This schema content may be further constrained through schema content rules. For instance, it may be required for a date-related schema element to be entered in an MM-DD-YYYY format. These elemental dictates are part of the overall structure of the schema and help maintain consistency throughout the developed resources.

Imposing further vigilance in metadata consistency, certain schemata must abide by well-defined content-encoding syntax rules. These rules offer a consistent metadata structure and further enhance the resource's discovery. As indicated, not all schemata are required to follow defined syntax rules and, as such, are called syntax independent.

To implement syntax, modern metadata schemata use various frameworks, such as ASCII, HTML, Standard Generalized Markup Language (SGML), Extensible Markup Language (XML), and Resource Description Framework (RDF). Figure 4.3 offers a few samples of metadata syntactic frameworks.

ASCII is the most basic of frameworks, simply because ASCII is nonsyntactic. ASCII is an original computer-based exchange format that is text only and is not capable of any embedded information. Therefore, however the metadata schema structures the data is how the data is displayed, without any content rules. ASCII proves to be minimally useful for resource discovery.

A better framework for geospatial metadata is one of the markup languages. HTML is a base framework that uses embedded element tags to describe the document. Although much more detailed than ASCII, HTML is rather simple and focuses solely on a document's style rather than its structure. XML, on the other hand, is an extension of HTML that uses tags to define and embed structure within the document. XML offers better versatility and enhances resource discovery and data interchange. In recent years, XML has become one of the syntactic frameworks of choice for metadata.

SGML departs from the role of essential resource description and structure to something more elaborate and comprehensive. SGML is an enhanced union of both HTML and XML and, as such, is often called an HTML-XML superset.

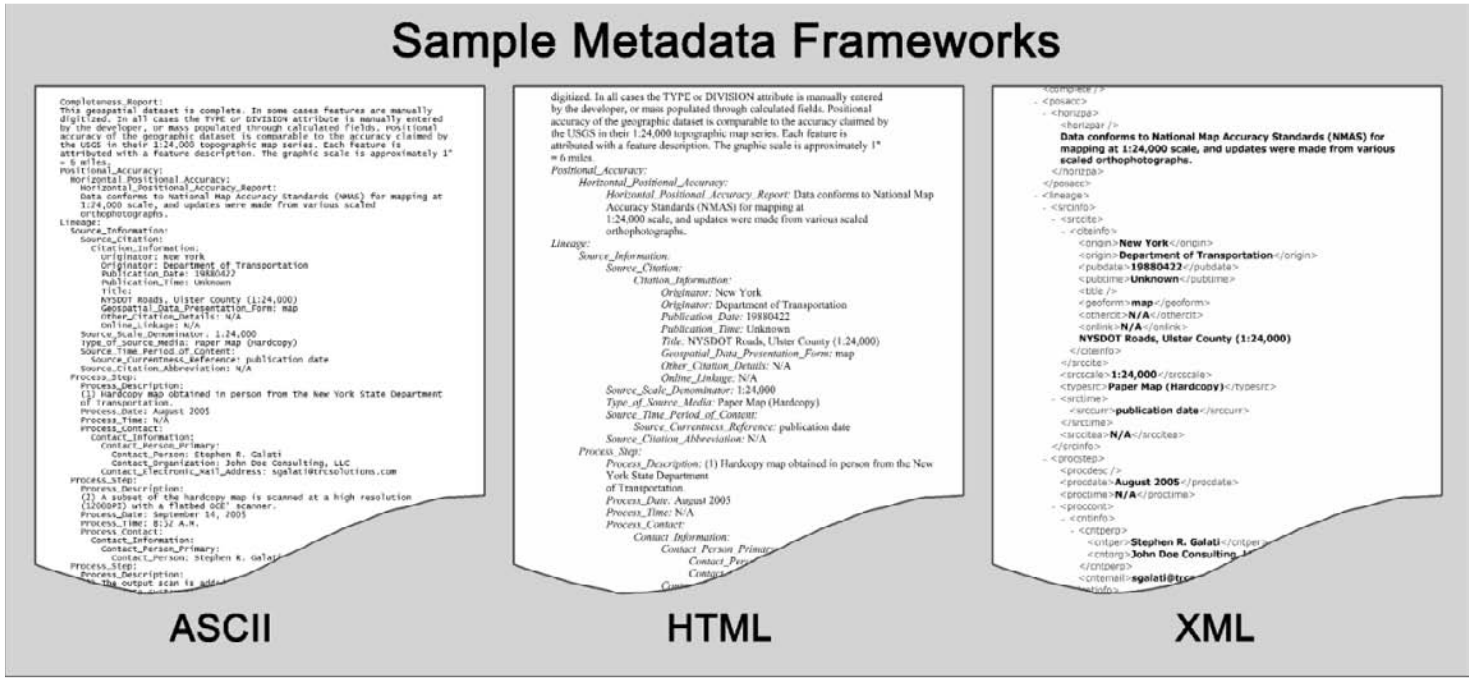

Figure 4.3 Sample metadata syntactic frameworks.

SGML looks much like an HTML document but is a structurally rich version of XML. With more structure descriptors, SGML offers copious description, both in style and structure, within the document. Additionally, the SGML framework offers the best availability for resource exposure and discovery among the discussed syntactic frameworks. However, with so much detail required, SGML is sometimes found too laborious. Figure 4.4 details the unique relationship between the markup language frameworks.

The final syntactic framework we will discuss is Resource Description Framework. RDF takes a different approach toward metadata architecture. As its name implies, RDF is a framework for describing a resource and sharing geospatial metadata. RDF is different from the markup language triad (HTML-XML-SGML) and focuses on the essential information that is needed to simplify metadata data searches, encourage interchangeability between syntaxes, and identify key resource properties.

In terms of depth of description, XML and RDF are the most similar but lack the comprehensive nature of SGML. You may be asking yourself, "Which one is better?" To be honest, it depends on the desired product, as well as the schema requirements, the desired amount of exposure, and the resource creator's effort to describe the resource.

For instance, some schemata (such as the Dublin Core discussed later) prefer RDF to one of the more traditional markup languages due to the ratio between metadata structure simplicity and essential content. Figure 4.5 depicts a sample RDF structure. Whatever syntactic framework and/or standard schema are used, the more description supplied will only benefit resource discovery, interoperability, and use.

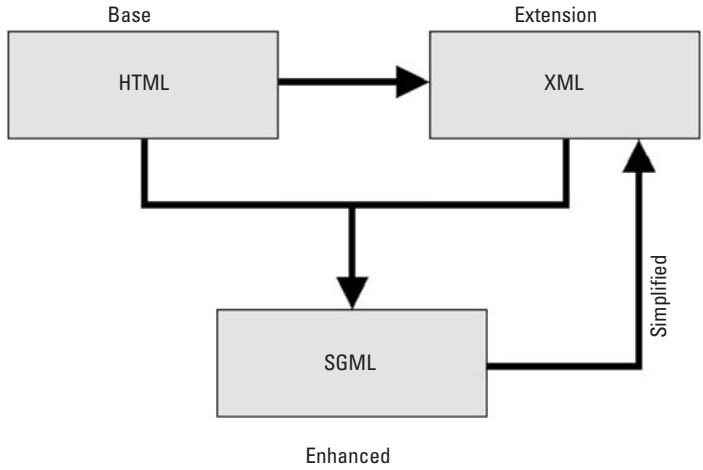

Figure 4.4 The relationship between HTML, XML, and SGML.

Resource Description Framework (RDF)

Figure 4.5 A sample Resource Description Framework structure.

Geospatial Metadata Standards

Throughout the past years, metadata has become a hot topic for discussion. Many worldwide organizations feel that geospatial data should be standardized for swift interoperability and exchange, while others argue that many field- and location-specific structures are needed to keep metadata uniquely keyed toward the individual fields they represent. This also helps capture field-unique

elements that a general standard would omit. As a result, there are numerous initiatives currently defining and instituting field-specific tangents (called profiles) off already established schemata.

Established and officially documented schemata form the current standards for today's geospatial metadata. Standards, as a whole, are valuable within the GIS industry for a number of good reasons. First, standards provide universal terms within the various resources they describe. This universal terminology offers beneficial consistency within the thousands (even millions) of available data resources within which the terminology is enforced.

Second, universal terminology presents the capability of automatic searches for specific terms. Users can program workstations to search for any universal term, such as *author, publisher,* and *source,* and save enormous amounts of discovery time. Automated searches can be done for nonstandard metadata, but these will take much longer and will habitually provide less than satisfactory results.

Third, similar to the second reason, users can quickly search numerous data sets and geospatial objects for specific terms. Having various forms of resources tagged with universal terms once again helps link the resources and produce comprehensive search results. Thus, finding specific information is usually much easier and time efficient within standardized metadata than within a nonstandard format.

Fourth, standards enable simpler information interchange. Since terms are set for individual metadata elements, the crossover between two standards is uniform throughout all associated resources. For instance, Dublin Core metadata can easily be transformed into European CEN/TC 287 metadata, since both are established element sets.

Fifth and finally, certain standards are mandated by governments and are required by local agencies. The U.S. government requires all agencies to use the Federal Geographic Data Committee content standard, while the Australian Government requires the Australian Government Locator Service standard.

Geospatial metadata standards offer the GIS user an efficient way to organize and catalog available images and data sets. As you may already grasp, there are numerous standards available to the worldwide public, with some schemata better for geospatial metadata than others. Some available standards for geospatial metadata include:

- Content Standard for Digital Geospatial Metadata (CSDGM);
- Dublin Core Metadata Element Set;
- European CEN Metadata Standard (CEN/TC 287);
- Australian Government Locator Service (AGLS) Metadata Element Set;
- UK GEMINI Discovery Metadata Standard.

To get a better idea of metadata structure and how each schema differs, we take a brief look at these metadata keystones.

Content Standards for Digital Geospatial Metadata

Under an executive order from the U.S. government, the Federal Geographic Data Committee (FGDC), a 19-member interagency committee, was charged with the task of developing national geospatial metadata standards. As a direct result, the FGDC developed the Content Standards for Digital Geospatial Metadata, or CSDGM. Since its origin in the mid-1990s, the CSDGM has developed into the most widely used metadata standard to date. CSDGM has even become the basis for numerous standards worldwide.

The intent for CSDGM was to help the U.S. government minimize the costs of data acquisition efforts and to promote interagency data sharing. The CSDGM was developed for consistent geospatial dataset description and utilizes a group of seven core (primary) and three floating elements. The core elements make up the major element set, whereas the floating elements are nonessential and wholly optional. Figure 4.6 details the seven CSDGM metadata core elements.

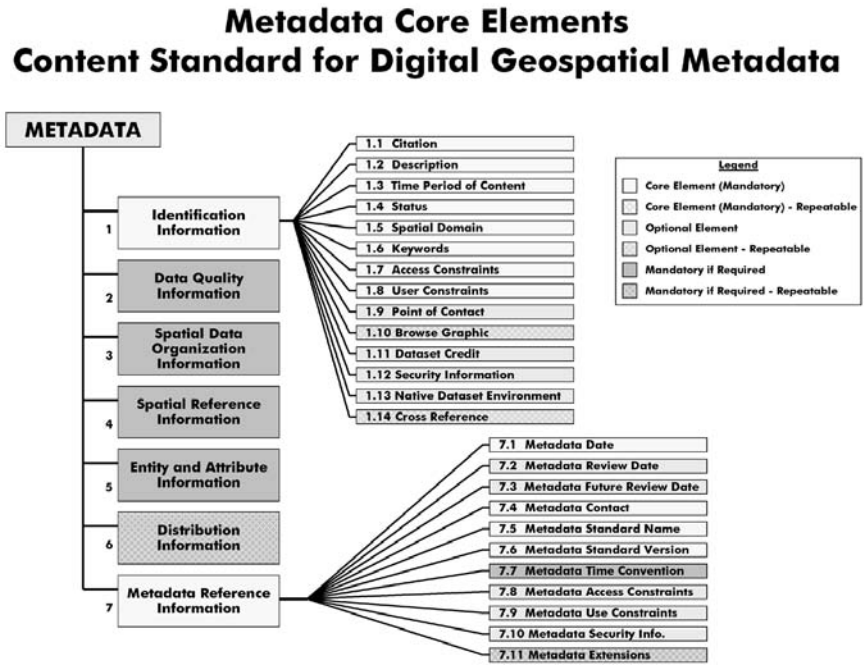

Figure 4.6 CSDGM metadata core elements.

The core elements are separated as *Mandatory, Optional,* and *Mandatory if Required.* The *Mandatory* elements are required in order to be minimally compliant with FGDC's standard. The *Optional* elements can be added or omitted from the metadata without affecting metadata compliance. The *Mandatory if Required* elements are metadata elements that may or may not be applicable, depending upon the resource being described. For instance, CSDGM metadata for a Web page may warrant only the minimal core elements, while a Geocoded map may also require one or more *Mandatory if Required* elements, such as data quality information. Although Figure 4.6 breaks down only the two *Mandatory* elements into their subcomponents, each element has a similar breadth of subsets.

The *Mandatory if Required* status of CSDGM elements adds a level of user flexibility and decision making. As with any form of metadata, the more description included in metadata, the greater the discovery potential. Hence, if the resource information is available to the metadata creator, it is in his or her best interest to include that additional description.

Certain elements and element subcomponents are repeatable, which means that they can appear in metadata more than once. Say, for instance, there was a set distribution for a particular metadata (e.g., 14 college professors). You have the capability within the CSDGM structure to include information about each of the 14 professors within the *Distribution Information* element. As depicted in Figure 4.6, this core element is repeatable and, thus, would be compliant with FGDC's standards.

As a major, widely available metadata element set, CSDGM sets the bar for geospatial metadata consistency and standards and continues to encourage international data exchange. As the leader in the geospatial metadata arena, its structure has been emulated for countless standardized element sets around the world. Adding credence to CSDGM is the fact that it still remains the national standard for the United States.

Dublin Core Metadata Element Set

The Dublin Core Metadata Element Set began as an initiative to advance the discovery of information resources. The initiative, called the Dublin Core Metadata Initiative, started in 1995 with a workshop in Dublin, Ohio, and involved various types of interested professionals, such as researchers, librarians, and content providers. The result of this initiative was the creation of a Dublin Core standards prototype, which involved a rather small group of information descriptors. The Dublin Core standards quickly gained worldwide attention and interest from a wide variety of metadata users.

Today, the Dublin Core Initiative's ongoing progress has produced the Dublin Core Metadata Element Set, a 15-element set that has attained

worldwide acceptance and use within a wide range of content areas. The Dublin Core sets the standard for multidomain resource description and data resource visibility.

Figure 4.7 represent the 15 primary elements that make up Dublin Core metadata. Unlike the CSDGM element set, all Dublin Core elements are optional and repeatable and may be used in any order. Therefore, the primary elements depicted in Figure 4.7 are in no particular sequence and can be changed, duplicated, or omitted from metadata. This innate flexibility has made the Dublin Core standards highly attractive to users worldwide, as well as an excellent schema for geospatial metadata.

Going way beyond the Dublin Core Initiative's original expectations, the Dublin Core Metadata Element Set is a means for individual preference and metadata richness. The element set offers the use of qualifiers, which are bits of additional information that are useful in further exposing the resource for discovery and promoting enhanced information interchange. Qualifiers include such additional information as various encoding syntaxes (i.e., HTML, XML, and RDF), greater content descriptors, and value type description. In fact, Dublin Core users can choose between Simple Dublin Core metadata and Qualified Dublin Core metadata.

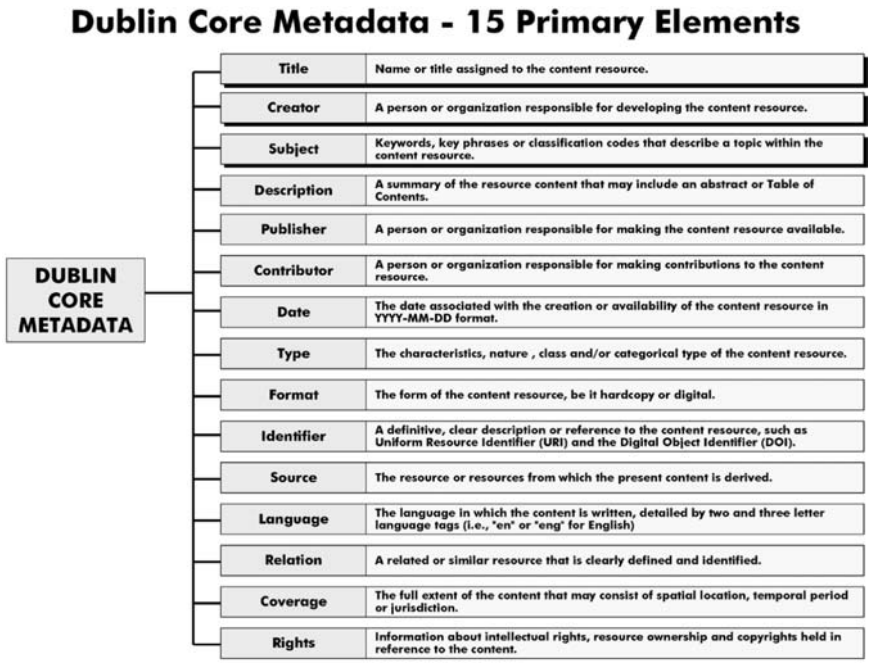

Figure 4.7 Dublin Core metadata—the 15 primary elements.

Simple Dublin Core metadata, also known as Unqualified Dublin Core metadata, involves the use of only the 15 primary elements with simple content and/or values. Qualified Dublin Core metadata goes beyond the simple content within the 15 primary elements and enables the metadata writer to use qualifiers to add a greater level of resource detail. Both forms of Dublin Core standards are efficient, but in some instances Qualified Dublin Core can reduce the interoperability of the metadata and add an unwanted layer of complexity.

As mentioned earlier, the Dublin Core Metadata Element Set also allows for various encoding syntax, which helps interchange Dublin Core descriptors into other metadata schemata. When Dublin Core standards first came out, they were predominately encoded in HTML. Nowadays, the prevailing encoding is XML and RDF, whereby XML is typically used for Simple Dublin Core metadata and RDF for the more complex products. Whatever format Dublin Core metadata takes, its beneficial flexibility and cost-effective simplicity has made it an internationally recognized metadata leader.

European CEN Metadata Standard

Departing from the individual "national standard" ideology, most European countries follow the European CEN Metadata Standard known as the CEN/TC 287 metadata standard for geographic information. Since the late 1990s, CEN/TC 287 has become the most widely adapted geospatial model in Europe that is fully maintained and standardized through a technical committee.

The CEN/TC 287 metadata standard is governed by the Comité Européen de Normalisation (European Committee for Standardization), or CEN for short. CEN was founded in 1961 and contributes to the standardization, exploration, and development of various research programs. It utilizes special technical committees (TCs) for each of its program areas, with TC 287 dedicated to geographic information.

Differing from the FGDC's and Dublin Core's hard-nosed structure, the CEN model offers flexibility with the number of different elements. For instance, the Dutch version of CEN/TC 287 (called NVN-ENV 12657) contains nearly 300 metadata elements. Interesting enough, if you were to compare, side by side, CEN/TC 287 to either the FGDC or Dublin Core standards, you could easily link one CEN/TC 287 element tag to many FGDC/Dublin Core element tags.

Now, GIS catalog software producers are taking notice of the European CEN Metadata Standard. ESRI, in particular, has developed a way to link CEN/TC 287 standards and apply them to FGDC's format. Their ArcCatalog software, for instance, takes CEN metadata and transforms it into the CSDGM schema in XML. As more and more software producers implement the CEN

model, these standards will gain even more popularity within Europe and, possibly, elsewhere.

In recent years, the initial publishing of ISO/TC 211, a widely accepted international geospatial metadata standard, brought the work of Technical Committee 287 to halt. As the ISO/TC 211 metadata standards were disseminated and implemented, CEN realized that TC 287 was again needed, but this time to help implement the new ISO standards within Europe through the CEN model. Therefore, the European CEN Metadata Standard is still one of the industry's major metadata leaders. For more information about the CEN standard, visit their Web site at http://www.cenorm.be.

Australian Government Locator Service Metadata Element Set

The Australian Government Locator Service (AGLS) Metadata Element Set first developed from a National Archives of Australia workshop in late 1997. Since then, the AGLS Metadata Element Set has become the leading geospatial metadata standard used throughout Australia. The AGLS element set is designed to enhance the exposure, discovery, access, and interchange of available government resource information and services.

The AGLS element set is a group of 19 descriptive elements that are intrinsically based upon the 15 element descriptors from the Dublin Core Metadata Element Set. The AGLS element set, however, is much more complex, since it allows richer element description through element qualifiers. These qualifiers enable the elements to describe a greater array of resource categories.

Because the AGLS element set is a derivative of the Dublin Core element set, both are entirely compatible with each other. This fluid data interchange adds to the greater endeavor of universal metadata standardization and enhanced resource access. The AGLS Metadata Element Set remains a modern and attractive standard that not only operates seamlessly with other standards but also adds a discriminating level of geospatial resource description.

The UK GEMINI Discovery Metadata Standard

The UK GEMINI Discovery Metadata Standard is a defined metadata element set used within the United Kingdom for describing geospatial data for faster, more accurate searches (metadata discovery). As such, this U.K. standard focuses entirely on discovery-level metadata, which is the specific metadata responsible for expediting resource information retrieval. The UK GEMINI standard is an element set derived from ISO 19115 (Geographic Information—Metadata) and the U.K. e-Government Metadata Standard (e-GMS). This metadata standard has gained industry respect and use, since it is nourished by the government, academia, and the private sector geospatial community.

The UK GEMINI Discovery Metadata Standard is a distant relative of the Dublin Core standard, since it has been developed to match explicitly with the element tags of e-GMS, a standard based upon the Dublin Core. The UK GEMINI standard uses 32 elements, ranging from *Title* and *Data Format* to *Use Constraints* and *Lineage*. Similar to the CSDGM, there are mandatory and optional elements, specifically 17 mandatory and 15 optional elements. Some of these elements have just a single occurrence, while others are repeatable.

Adding to the level of discovery the UK GEMINI standard offers is the depth of description and information attached to each element. Each element not only has the typical name, description, and value but also has extra description information including equivalent e-GMS and ISO 19115 element names and the element's data type. Given the added information, the UK GEMINI standard fulfils its main purpose of heightened geospatial metadata discovery.

Executive Orders 12906 and 13286

In the 1990s, the U.S. government became very interested in the retention, organization, and dissemination of geospatial data. By this time, GIS, GPS, and satellite imagery were being used in full force throughout the federal and local levels of government. As public interest in natural resource stewardship, environmental protection, and economic development soared, so did the plethora of data resources, duplication of data efforts, and inconsistencies in resource retention. It became clear to the government that standardization and assemblage of data resource dissemination was desperately needed.

Acting as a geospatial impetus, Federal Circular No. A-16, originally published in 1953 for survey and mapping issues and revised in 1967, was again revised in 1990 to include spatial data. This second revision marked the origin of the FGDC and took the first steps toward a comprehensive National Spatial Data Infrastructure (NSDI).

On April 13, 1994, President Bill Clinton signed Executive Order 12906, which was a giant step toward coordinating geospatial data acquisition and access. In it, the NSDI was formed and a mandate for the FGDC to create geospatial data standards was enacted. FGDC's Content Standard for Digital Geospatial Metadata was essentially born.

Even more specific to GIS, Executive Order 12906 detailed plans for a national digital geospatial data framework, whereby all federal agencies and organizations were required to document their geospatial data using the FGDC's standard. Additionally, all published metadata now had to be distributed and made available through a clearinghouse system. As you can imagine, this executive order proved to be the push needed to set the geospatial community in motion.

Contributing to the release and dissemination of geographic and geospatial information came a second significant executive order from the U.S. government. On March 5, 2003, President George W. Bush signed Executive Order 13286, which amended Executive Order 12906 to represent changes in government, as well as to represent changes in geospatial management, changes in technology, and clarifications to FGDC responsibilities. Without question, these federally imposed geospatial dictates helped to build the enormous data repository available today and to disseminate the importance and efficacy of geospatial metadata.

The National Spatial Data Infrastructure

With the signing of Executive Order 12906, the FGDC was charged with the task of developing the NSDI. The original concept was to have a centralized architecture for geospatial data policies, standards, and procedures. The NSDI was the conceived solution to disseminate geospatial data in a consistent fashion, while flattening the growing costs of duplicated governmental geospatial data collection.

As part of the vision, NSDI would provide an infrastructure through which data producers and users could share geospatial data. This producer-user relationship has already started to emerge from FGDC's efforts. Through the NSDI, the FGDC has begun to make key partnerships with public and private data producers to increase data availability to geospatial data users.

Incidentally, one valuable outcome of the NSDI is that it affords emergency services the capability of accessing geospatial data in an easy, expedited manner. In emergency situations, such as natural disasters, terrorism, and accidents, expedited and consistent data retrieval can truly hold life and death in balance. As the NSDI continues to develop and grow, the scope of available benefits and innate advantages will become ever clearer.

Although in recent years the FGDC has made great strides in implementing the NSDI, more work is needed. NSDI is still a work in progress. FGDC's effort is ongoing and is in cooperation with many organizations from state, local, and tribal government levels as well as the academic community and the private sector. The U.S. government places great trust in the fact that this infrastructure will provide substantial cost savings and facilitate enhanced decision-making. The truth of the matter is that the NSDI is still in its early stages and, in the coming years, may prove to be the resource that was originally envisioned. As with all things, only time will tell.

Geospatial Metadata Clearinghouses and Publishing Resources

As mentioned previously in this chapter, the U.S. government mandated that all published geospatial metadata be made available through a clearinghouse system. A metadata clearinghouse is an online or offline reservoir of published metadata that is being offered to the public. These clearinghouses in general offer freely distributed metadata, although some provide for-purchase variations of hard-to-obtain information.

Table 4.1 details just a small selection of international geospatial metadata clearinghouses. All of these sites have free metadata. There are, however, hundreds of available metadata clearinghouses available, mostly online.

Often these geospatial metadata clearinghouses also offer free and for-purchase geospatial data sets. We discuss these particular geospatial data clearinghouses in more detail in Chapter 15. For now, focus on the geospatial metadata these data bureaus provide and understand that the best way to create your own metadata is to examine what has been done by industry peers.

Take some time to explore the clearinghouses detailed in Table 4.1. You can gain a great deal of understanding by examining the language, syntax, and structure of a few good metadata samples. In fact, these samples will serve as distinct resources as to how compliant metadata are written.

If you want to try your hand at writing metadata, a good place to start is with the U.S. Geological Survey and, in particular, Peter Schweitzer's work with metadata. Mr. Schweitzer has written numerous documents on metadata basics and created software to help people write formal metadata (Unix-based XTME and Windows-based TKME editors), preparse it for proper structure [i.e., "chew and spit" (CNS) metadata preparser], and parse it for compliance with FGDC standards [metadata parser (MP) software].

In addition to the FGDC-compliant software, each metadata standard (e.g., Dublin Core) has its own editors and parsers for compliance with its standards. Check out the particular standard's Web site for more information on its available software and requirements. Once you become more comfortable with metadata and GIS, you will be able to create your own metadata and publish it to a clearinghouse.

Part II:
Geodesy, Earth Models, and Coordinate Systems

Understanding the Core GIS Environment

5

The Basics of Geodesy and Scale

The story of Christopher Columbus and his bold testament to the Spanish monarchy that the world was round and not flat is captivating and has remained an interesting tale within world history. Learning of Columbus as a child, I remember thinking: how could they believe the Earth was flat? I now look back and realize that science had proved the common understanding of the Earth's shape long before you and I were born. In fact, we were born into a society holding common and mature geographic knowledge, much different from Columbus, who was born into a society with varying images of the Earth, abundant misunderstandings, and science in its infancy.

So where does that leave us in terms of GIS? Well, for starters, through the discussions in Part I, we have begun clarifying the role of GIS by way of a primary understanding of GIS's groundwork. Let us now go further, tackling the core of GIS, the nature of geographic data, and the backbone to correct geographic representation and structure. Therefore, the science behind the Earth is our next destination, since it serves as a logical path to understanding GIS and its employment within our society. For this, we are directed toward the study of the Earth and the principles behind its shape, its size, and the laws that govern its portrayal. Let us begin Part II with geodesy.

What Is Geodesy?

Geodesy is the division of science associated with the measurement and portrayal of the Earth. Geodesy, known also as *geodetics,* is intimately concerned with the determination of the size and shape of the Earth, as well as its elements.

These Earth-based elements include its terrestrial gravity, magnetic field, tides, geologic and crustal movement, and polar motion.

As a study of the Earth and its rudiments, geodesy covers a large analytical landscape and combines the sciences, mathematics, physics, and observation. This analytical landscape and questions surrounding Earth's geodetic elements first initiated the science of geodesy. The study of geodesy began as mere curiosity and an undying human will to explain the Earth's unknowns through logic. There exist the first remnants of geodetic analysis starting as far back as the early Greeks. Homer, Pythagoras, Plato, and others all had ideas about the shape of the Earth. Homer, for instance, held the idea that Earth was a large flat disc, while Pythagoras, a mathematician, viewed Earth as an idyllic spherical figure. Plato logically guessed that the circumference of the Earth was 40,000 miles.

This early form of geodesy was based upon visual observations, logical assumptions, and crude calculations and transformed the notion of a flat Earth to the idea of a curved surface. In fact, Greek sailors took notice that as they came closer to land the visible high points seemed to ascend from the water. Others noticed that astronomical events such as a lunar eclipse occurred high in the night sky on one end of the Mediterranean while on the other end of the Mediterranean it occurred closer to the horizon. These observations added reason to the common consensus in a round or curved Earth.

Many, like Plato, made educated guesses as to the size of the Earth, but they were just guesses. Archimedes went one step further, providing an educated approximation that the circumference of the Earth was 30,000 miles. However resolute, no one could definitively prove the Earth was round or determine its true size. Along came Greek mathematician Eratosthenes who with curious mind and mathematical craft created a method to answer these geodetic unknowns.

Eratosthenes had taken notice during a summer solstice (longest day of the year) that a stick placed straight up in the sand cast no shadow and that the midday sun (directly overhead) shone to the very bottom of a well. Both observations occurred in his home town of Syene (now Aswan), Egypt. Eratosthenes also noticed that at the same time, the sun was not directly overhead in Alexandria, a town roughly 500 miles away. As a result, a shadow was cast against the vertical in Alexandria that was equal to 1/50th of a circle or 7 degrees 12 minutes (7° 12′). See Figure 5.1.

Eratosthenes took his summer solstice observations and applied some assumptions: (1) The distance between Syene and Alexandria was 500 miles; (2) since Syene's midday summer solstice sun was directly overhead and, on that day, the sun moves along the tropic of Cancer, it was concluded that Syene was on this tropic zone line; and (3) Syene and Alexandria lie on a direct north-south line.

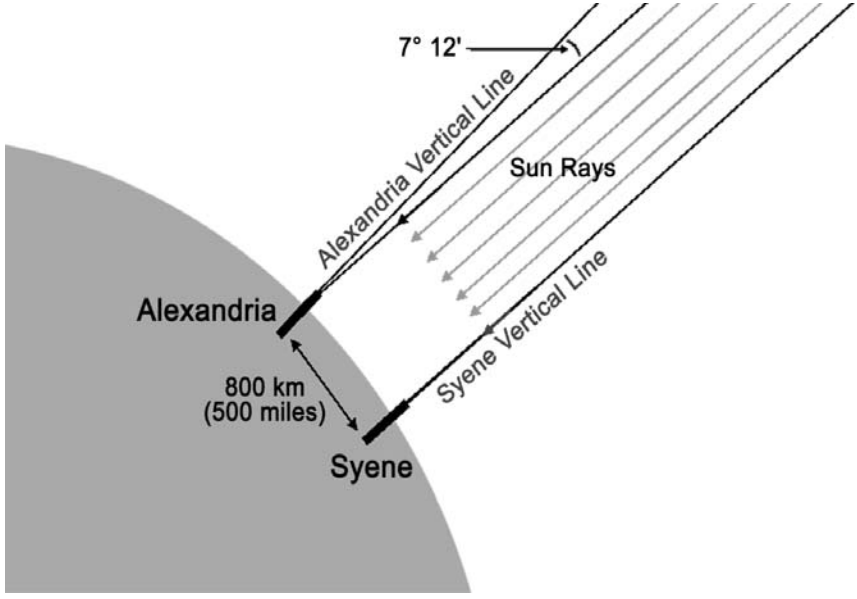

Figure 5.1 Eratosthenes's method of calculating the Earth's size.

Based upon these assumptions and the measured shadow, Eratosthenes concluded that the distance between Syene and Alexandria was 1/50th the circumference of the Earth. Mathematically it can be explained as:

$$1/50 \times \text{Earth's circumference} = 500 \text{ miles}$$

$$\text{Earth's circumference} = 50 \times 500 \text{ miles} = 25{,}000 \text{ miles}$$

Remarkably, Eratosthenes made a nearly accurate measurement of the Earth's size given that today's accepted World Geodetic System (WGS) calculation is 24,901 miles! However, Eratosthenes's calculations were somewhat incorrect, since every assumption was a bit erroneous. We now know that (1) the real distance between Syene and Alexandria is 453 miles; (2) Syene lies 37 miles north of the tropic of Cancer line; and (3) Syene lies 3 degrees 30 minutes (3° 30′) east of Alexandria's north-south line. Additionally, Eratosthenes's calculation of 7° 12′ from the vertical is actually 7° 5′. Despite these facts known in hindsight, Eratosthenes became the first to substantiate the calculation of Earth's size.

After Eratosthenes, others continued to revise the Earth's measurement with varying results. It was not until after the invention of the telescope,

development of the logarithm tables, and progressive understanding of the Earth's true shape that more exact Earth size measurements were calculated. With these new measurements and Earth size-shape concepts came the maturation of geodesy and the development of the current conventions.

Present-day geodesy is well beyond questioning Earth's overall shape and size; it now focuses upon Earth's actual shape with its unique physical terrain. Geodesy centers upon Earth's significantly vast landscape with its drastic elevations and varying land forms. This deviating terrain is a true surface and includes high mountain ranges, sweeping plains, and variable geologic surfaces. This true surface adds countless levels of scientific complexity to geodesy and, in conjunction with the desire to measure and represent the Earth, forces concern about both accurate Earth positioning and the determination of Earth's actual shape. Thus, reducing the Earth to a simple shape (i.e., a spheroid) is of menial scientific interest in current-day geodesy other than for simple calculations and geographic representation.

Present geodetic concerns subsist within a three-dimensional time-varying space. This means that over time the Earth's surface changes due to temporal surface variations, geologic events, the gravitational field, and other surface-altering episodes. Erosion, for instance, will permanently change a coastline over time, or a river basin swollen by excess storm water runoff will temporarily alter features on the Earth. Both, however, alter the true shape of the Earth at any given time. These sometimes unpredictable changes add layers of geodetic complexity to the accurate measurement and representation of the Earth.

Geodesy has also advanced and now, to some extent, relies upon two forms of terrestrial measurement: geomensuration and surveying. *Geomensuration* is the measurement of the Earth as a whole (i.e., on a global level), while *surveying* is the measurement of individual parts on the Earth's surface (the ever-changing physical terrain). Both techniques offer credible measurements wholly useable toward accurate geodetic positioning, surface shape, and size. GIS employs these forms of terrestrial measurement through various data sources, such as satellite, GPS, and field measurements. As such, geodesy serves as an important science and elemental backbone to GIS.

With this understanding, we are now ready to discuss the pertinent geodetic elements that define geodesy and provide crucial pieces of geographic information. Specifically, the reference Earth shape (the ellipsoid), geodetic positioning (geodetic datum and coordinates), the true Earth shape (the geoid and vertical datum), and the usable portrayal of the Earth (map projections). The next four chapters go into great detail about these geodetic elements; however, before we move into these areas, we must first discuss the principles of map scale. In short, map scale provides the exact geodetic relationship between the GIS information product and reality.

Understanding Map Scale

You are driving on a desolate back road in Montana and your car's gas light turns on. Nervously you reach down and grab a road map. You easily find your position and pan the paper map for the nearest town that would have a gas station. Three inches from your position is a reasonable sized town by the looks of it. From experience you know that when the gas light turns on, there is enough fuel in the tank for another 40 miles. Three inches isn't that far, right?

As the dread of waiting for a tow truck fills your mind, you notice in the corner of the map the words, "One inch represents 20 miles." You swiftly conclude that 3 inches must represent 60 miles and that you can reach the town before running out of gas. You continue toward town with newfound peace of mind.

We have all been in a similar situation, though maybe not as dramatic. The group of words that ultimately informed and relieved the Montana traveler is called a map scale. A map scale, in its most common treatment, relates to the size of map-based features in relation to their actual, real-world size. Specifically, map scale is the relationship between a distance on a map and its corresponding distance on the ground.

Although detailing the same information, not all map scales look alike. In fact, there are three common forms of map scale: verbal scale, graphic scale, and ratio scale. Refer to Figure 5.2 for a graphic illustration of each discussed map scale.

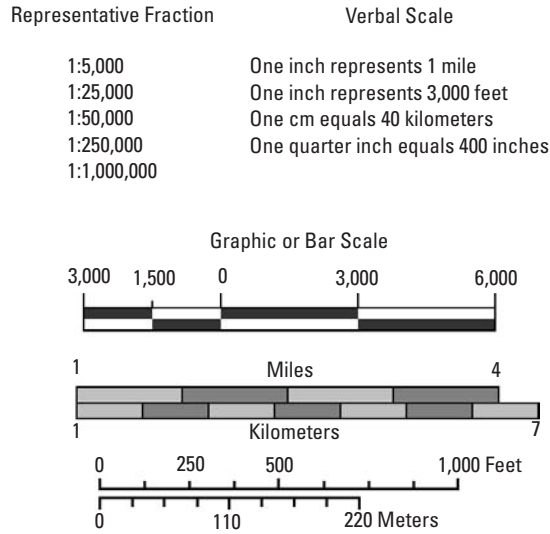

Figure 5.2 Key map scales.

In the example Montana situation, a *verbal* scale was used. Verbal scales express the map-to-ground relationship in words, such as "One inch represents 20 miles" or "One inch equals 20 miles."

A *graphic* scale or *bar* scale depicts a bar of a certain length that represents a distance length. Graphic scales enable the map user to visually recognize distances with relative ease. Because of this simple understanding, graphic scales are undeniably the most used form of map scale. One striking feature of the graphic scale over verbal and ratio scales is that graphic scales remain accurate if the map is photographically enlarged or reduced.

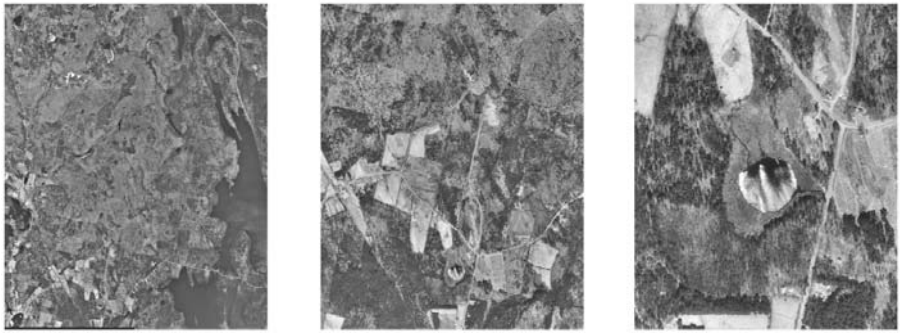
A *ratio* scale, more formally known as representative fraction and less formally as natural scale, reduces a map's distance to 1. One unit on the map corresponds to a distance in the same units on the ground. In a typical 30-minute series topographic map, the representative fraction is shown as either "1/125,000" or "1:125,000" whereby the 1 and 125,000 are the same unit of measure.

When dealing with GIS products, the term *scale* can also be used in a wholly different manner. The term holds significance to describe the working size of an application or project area, specifically *small scale*, *mid-scale,* and *large scale*. Parameters for each distinction are highly flexible, based upon individual judgment rather than a specific criterion.

Small-scale applications involve relatively large areas, such as a map of the world, the continent of Australia, or the city of Rome, Italy. A typical small-scale representative fraction can be assumed anything greater than 1:500,000. Large-scale applications involve small areas of focus, such as a community, a city block, or a university campus. A typical large-scale representative fraction can be assumed anything less than 1:50,000. Mid-scale applications, on the other hand, fall right in the middle of large- and small-scale applications, with a typical representative fraction ranging from 1:50,000 to 1:500,000.

As stated earlier, parameters for this scale nomenclature are determined by the individual user or the specific application. What is considered large scale for one application may be considered as mid or small scale on another. Figure 5.3 presents an example of this flexible scale nomenclature. Notice that the relationship between representative fraction and scale nomenclature is different from our previously stated "typical" ranges. This specific application's overall area covers roughly 20 square miles with the small-scale view covering the entire area and the large-scale view covering less than one square mile.

It is easy to get confused with this scale nomenclature, thinking a small-scale application should show only a small area. This, of course, is wrong. There is a rule of thumb to remember when using this scale terminology: Large scale has a large representative fraction [i.e., the denominator (number after the colon) is small] and small scale has a small representative fraction (i.e., the denominator is large).



1 : 126,000
Small Scale

1 : 61,400
Mid-Scale

1 : 7,880
Large Scale

Figure 5.3 Large-, mid-, and small-scale applications.

Simple Map Scale Calculations

Regardless of specific format, map scale can be calculated using the following equation:

$$\text{Map scale} = \text{Distance on map}/\text{Distance on the ground}$$

In the Montana example, every map inch (distance on the map) represented 20 actual miles (distance on the ground), thus, map scale = 1/1,267,200.

There are many instances when map scales need to be converted into another form, such as a verbal scale to a representative fraction or vice versa. These scale transformation calculations are simple and prove worthwhile for various cartographic and GIS applications. Let us take a look at these calculations in Table 5.1.

Scale and Accuracy

An important characteristic of geographic data is that it can be represented differently at different scales. Proper map scale within GIS and on hardcopy maps enables the user to display accurate geographic data that is easily discernable, representative of the particular application and wholly successful in its implementation. Geographic features that are prominent at 1:24,000 scale are many times indistinguishable at 1:1,000,000. As with any GIS function, a user's knowledge of the final use is pertinent to the quality production of geographic information products.

Table 5.1
Scale Transformation Calculations

Conversion from Verbal Scale to Representative Fraction
1 inch represents 4 miles
1 inch equals 4 miles
1 inch = 4 miles
1 inch = 4 miles × 5,280 feet/mile
1 inch = 21,120 feet × 12 inches/foot
1 inch = 253,440 inches
1:253,440
Conversion from Representative Fraction to Verbal Scale
1:100,000
1 inch = 100,000 inches
1 inch = 100,000 inches × (1 foot/12 inches)
1 inch = 8,333.33 feet × (1 mile/5,280 feet)
1 inch = 1.578 miles
1 inch represents 1.578 miles

For specific applications or to develop certain targeted information products, geographic data representation can be manipulated by increasing or decreasing map scale. For instance, state planners targeting an individual land parcel would employ parcel maps at 1:24,000 or larger scales. If they were targeting regional land parcels instead, area maps at 1:250,000 or smaller scales would be the most useful.

When scale is adjusted by enlarging or minimizing the area view, accuracy of the data becomes a concern. Typically, as scale decreases, the number of specific features and the detail of those features also decrease. As such, data accuracy is lessened to the extent that the overall representation is more general than descriptive. When scale of the original data is increased, accuracy is not improved, but features are enlarged.

For example, take another look at Figure 5.3. The frozen pond prominent in the large-scale view (1:7,880) is but an indistinct feature among the landscape when scale is decreased to a small-scale view (1:126,000). As apparent, the amount of feature (pond) detail in the large-scale view is much greater than in the other two views. Consequently, when the scale gets reduced (large to small), feature detail becomes too little to see and cannot be adequately represented.

Proper map scale is directly proportional to accuracy. Sometimes when map scale is decreased and maps become small scale, geographic detail is lost. This can cause serious user problems, since geographic unknowns arise and accuracy diminishes. For instance, imagine if a person new to Interstate 81 in Virginia used a map of North America instead of a state map to get from Pulaski to Harrisonburg. The user may or may not get to his destination, since the North American map is dramatically less accurate in terms of Interstate 81.

In short, scale and accuracy go hand in hand with both GIS-based products and hardcopy cartographic maps. Every data source has accuracy limitations, and users must make every attempt possible to define the legitimacy of data sources. If scale and accuracy are used appropriately, the geographic information product will be used as intended and offer a well-defined and highly efficient representation.

Geographic Data Generalization

Geographic technologies represent the real world mainly for convenience, similar to the role played by hardcopy paper maps used by our wandering ancestors. For example, a traveler cannot simply fold up a true representation of his 100-mile route and stick it in his coat pocket. For the sake of convenience and portability, the 100-mile route is reduced to a scale of 1:100,000 (i.e., 1 inch equals 100,000 inches), which is then drawn and portrayed on paper, folded, and placed in his pocket. This diminution of scale is adequately achieved through generalization.

Generalization at its core is a method to manage and reduce unwieldy or overly numerous input data sets. Through this process of reduction, the real-world data source is rendered in less detail and, as a result, is somewhat distorted from reality. Each level of generalization introduces a greater degree of distortion; however, immediately, generalization affects the overall appearance and, even more important, the precision of the output data. Smart geographic data users are aware of the precision of data they use because it has a direct correlation to and effect upon the ultimate usability of their geographic information products.

Even by today's technological standards, an extremely hefty 500-gigabyte high-resolution image is not a manageable quantity of input data. Like trying to eat a 6-foot sandwich all at once, it is simply not feasible. So what is considered a manageable quantity? Every user has an individual parameter for manageability, which takes into consideration the computer and hardware specifications, the patience for waiting out long processing tasks, and the ultimate goal of analysis. A median case could potentially involve generalizing the 500-gigabyte image to

a more tolerable 1.2-gigabyte image, resulting in a sleeker file more adaptable and friendly to geoprocessing.

All geographic data are in some way generalized. This is an inevitable, astringent process that alters the actual character of the data into a simplified and shrunken model of the real world. Ultimately, scale dictates the severity of generalization, varying in level from project to project. For instance, a map drawn to 1:100,000 scale (smaller scale) is more generalized than the same area drawn to 1:24,000 (larger scale), thus the smaller the scale, the greater the level of generalization. Chapter 11 take a much closer look at scale factors and the resultant degrees of distortion.

Figure 5.4 exemplifies geographic data generalization, wherein a physical structure is portrayed in relation with two different interpretations of the same roadway.

Figure 5.4 illustrates the quintessential "house on the wrong side of the road" problem. The 1:50,000 scale details a generalized road condition and offers severely less detail. The 1:10,000 scale details a close representation of the actual roadway, with the appearance of blatant roadway shape changes. A house (physical structure) is shown close to the roadway. In reality and as depicted on the larger-scaled (1:10,000) roadway drawing, the house appears left (or west) of the roadway. However, on the smaller-scaled (1:50,000) roadway depiction, the house is on the right (or east) of the roadway, forming a basic generalization of actual position and real-world physical shapes.

Decisions concerning the use of geographic data and their suitability for any given application are paramount to the validity of the geospatial system. Selecting an adequate scale for a project is a balance between positional accuracy and the amount of geographic data processing. For instance, take the more generalized road and apply it to a tourism booklet's map. Geographic data requirements are minimized. Additionally, the effect of the rounded road is perhaps negligible considering the native generality of the tourism application. However, take that same geographic data with the same "rounded" characteristics and apply it to an emergency vehicle deployment routing application. That mistake in judgment may have taken someone's life! The depicted geographic data at a 1:50,000 scale are generalized beyond minimum suitability for the emergency deployment application. The vehicle drivers are looking for a specific house on the left that is actually on the right! A 1:10,000 scale would be a more suitable level of generalization for ensuring the system's integrity for positional accuracy and left-side/right-side roadway events.

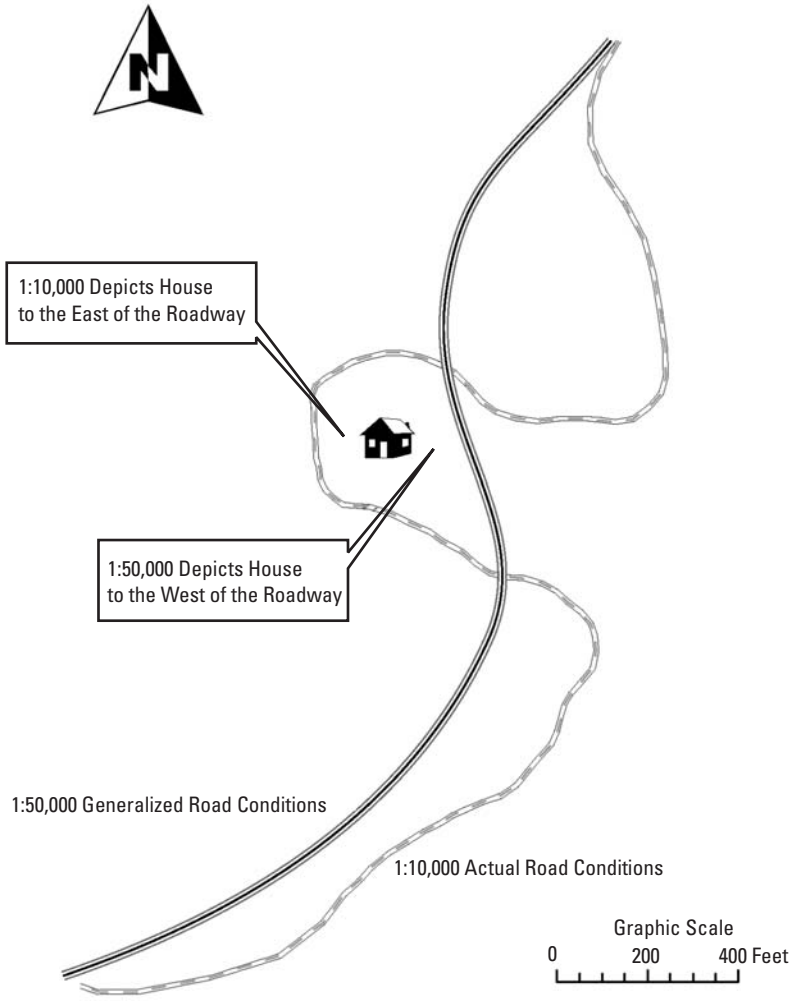


Figure 5.4 The "house on the wrong side of the road" problem.

6

The Ellipsoid

Throughout the early years of geodetic understanding, some of the most important components of geodesy were realized through innovative thinking, physical science, and debate. The spherical Earth-flat Earth debate previously discussed initiated the science of geodesy and spawned numerous attempts at defining the circumference of the Earth. By the seventeenth century, scientists, mathematicians, and others had begun to realize that the Earth wasn't quite perfectly rounded as first believed. New theories soon emerged out of the scientific communities, and the quest for the true Earth model began. This quest ended with the ellipsoid and subsequently recast physical science and geodesy forever.

Today's precision GIS is built upon the advances in modern geodesy and the finely tuned knowledge of the Earth's true shape. With satellite imagery and modern physical science, there is now no question as to what the world looks like and what shape best represents the Earth—a nearly round object that bulges in the middle. To this end, ellipsoids are exceedingly important to GIS because they pose a near resemblance to the Earth's shape without the inherent complexities. In short, ellipsoids simplify GIS.

To truly understand the core GIS environment, we must first understand how we got from Eratosthenes's curved Earth and the pure sphere to an ellipsoid, a much closer physical representation (model) of the real Earth. We will discuss the physical parameters of the ellipsoid and how this elliptical Earth model is manipulated and referenced within GIS.

History of the Earth Model

From the time Eratosthenes calculated the Earth's circumference in the third century B.C., the Earth model for many took on the shape of a sphere. Generally, a sphere is a symmetrical three-dimensional shape, in which the distance (radius) from the surface to a common center point is identical anywhere on the object (i.e., height equals width). It can be thought as a circle rotated around an axis.

The sphere shape for the Earth model was the initial conclusion based on a combination of minimal information and poor measurement tools. It was the logical curved successor to the "flat Earth.. To its credit, it remained a favored Earth model from the third century B.C. to the seventeenth century A.D., when science made it possible to measure distances and gravity with precision. Telescopes were invented and became indispensable tools for early geodesists.

Soon, imperfections in the Earth's curvature became widely apparent with the recognition and measurement of dissimilarities in different locations. This dissimilarity invoked new theories concerning the Earth model. As a direct result, two predominant and disputing theories emerged from the geodetic community, namely from the French and the British communities. Figure 6.1 details the competing Earth model theories.

The story of the British-French rivalry concerning the Earth model is legendary and quite interesting. Both wanted to be correct in order to attain a level of international excellence and scientific supremacy. Leading the French were the Cassinis, a renowned family of geodesists. After taking measurements in France from Paris to Perpignan, Jean-Dominique Cassini and his son, Jacques

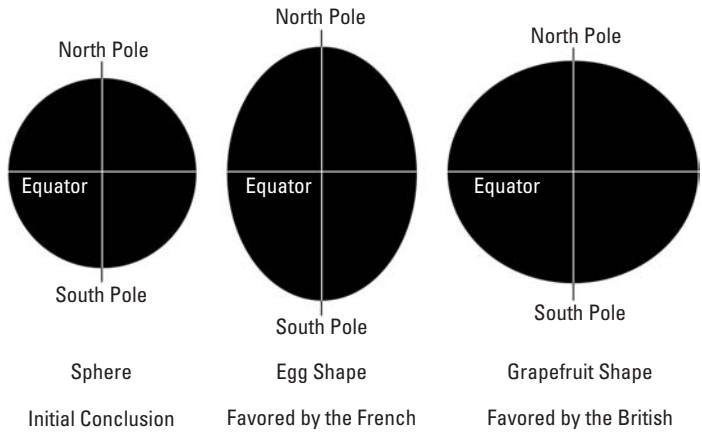

Figure 6.1 The predominant Earth models.

Cassini, were certain the Earth pointed toward the poles and flattened at the equator. As a result, the French model was a prolate ellipsoid and egg shaped.

The British took a different approach. They were armed with Isaac Newton's then recently released gravitational theory published in Newton's *The Principia*. The British were equally certain that the Earth was flattened but that it was occurring at the poles. The British model was an oblate ellipsoid—grapefruit shaped and bulging in the middle.

The competition became serious as international interest grew. In fact, the contrasting theories invoked an international debate with the Earth *elongators* favoring the French model and the Earth *flatteners* favoring the British model. In an effort to end the dispute and determine who was truly correct, the French Academy of Sciences devised a plan that involved measuring a 1° arc in the North and on the equator. If the arc in the North was shorter than the arc on the equator, then the French would be correct. If the North arc was longer, then the British would be correct.

The French Academy of Sciences sent out two teams to make 1° arc measurements in Peru and Lapland. Peru was a reachable point near the Equator and Lapland was reachable and near the North Pole. This meridian arc measurement expedition started in April 1735 as the first team was deployed to Peru. In April 1736, just two months shy of the first team reaching the site in Peru, the second team was deployed to Lapland.

By August 1737, the Lapland team was already finished and back in Paris. The Peru team, on the other hand, had a much harder time with its meridian arc measurement. Due to the extraordinarily rough terrain in the Andes mountains, the team did not complete its measurements until 1743 and did not return to Paris until February 1745. Incredibly, the French Academy of Sciences' resolution took nearly 10 years to complete. In the end, the British were proved correct and the Earth model took on its new form: a grapefruit-shaped oblate ellipsoid.

Shape of the Earth

The ellipsoid, also referred to as a *spheroid*, is a much better approximation for the shape of the Earth than the sphere; the poles are slightly flattened and the equator bulges. Unlike the sphere, the ellipsoid can handle dissimilar dimensions. GIS relies heavily upon geographic positioning and the Earth model; therefore, the closer a model comes to the actual surface of the Earth, the better for geographic positioning. A sphere proves adequate along the equator (equatorial plane) but fails at locations closer to the poles. For this reason a GIS based upon a sphere model would produce flawed information products for most locations throughout the world, especially within the arctic and antarctic circles.

This Earth flattening defines our contemporary understanding of the shape of the Earth. Pull out a table globe and examine its features. Although difficult to immediately recognize on a globe, notice how the nearly spherical shape that ancient theorists surmised as "perfect" slightly bulges at the equator. Now imagine placing an invisible measuring stick through the core from the north pole to the south pole. It would measure 12,713,505 meters. Imagine placing another measuring stick through the Earth's core from one point on the equator to another. That stick would measure 12,756,274 meters. This relatively tiny difference in measurements causes the Earth's subtle bulge and defines the nature of its flattening.

Figure 6.2 offers a bird's-eye look at ellipse flattening as a whole. As you can see, a circle has zero flattening because the horizontal and vertical measurements are equal. When the measurements differ, that is, when the horizontal measurement is larger than the vertical measurement, ellipse flattening increases. Alternately, a larger vertical measurement defines an ellipse elongation.

Figure 6.2 illustrates flattening with large, visually dramatic flattening scenarios. However, in the case of the Earth, the north-to-south measurement is only slightly shorter than the east-to-west measurement and has a small flattening of approximately 1/300.

What makes the ellipsoidal model useful in GIS and other real-life applications (i.e., GPS systems, military artillery, science, and so forth) is its ability to

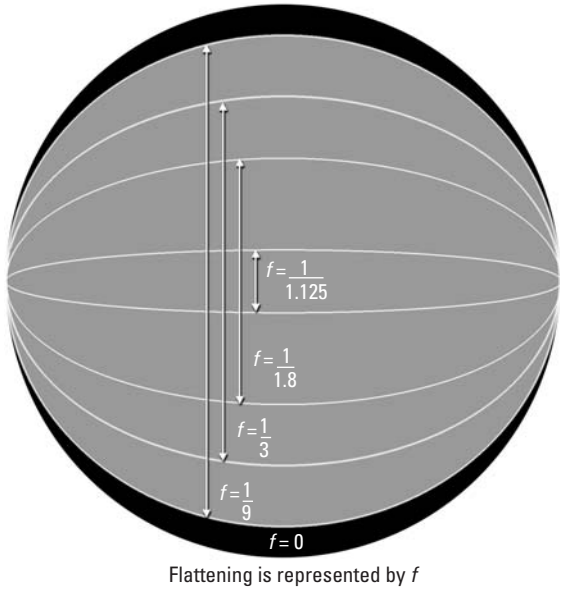

Figure 6.2 Various levels of flattening.

handle the Earth's flattening with ease and within the simple constructs of a relatively smooth shape. Now, the Earth is hardly smooth. We have mountains, plains, and valleys on land and deep, cavernous terrain within the oceans. We have cities that are below sea level (such as New Orleans, Louisiana) and others many miles above sea level (such as Katmandu in Nepal).

You might be thinking, how could the Earth's various terrains be served adequately by a smooth ellipsoid? Well, let us look at this question on a global level. The highest feature on Earth is Mount Everest at about 9 km above sea level. The lowest feature is the Pacific Ocean's Marianas Trench at roughly 11 km below sea level. The topographic height variation from highest to lowest is 20 km. Given that the shortest core-to-crust radius is 6,356.7 km, this topographic height variation would provide a minuscule surface change and is therefore negligible for Earth-modeling purposes.

We can liken these relatively subtle topographical height variations to the dimples on a golf ball; the overall shape is spherical, but the actual surface varies slightly in height. For ease, we use a smooth ellipsoid as the basis for calculations and geographic positioning. The difference between a smooth ellipsoid and one with topographic feature heights is negligible for many base-level calculations and for Earth referencing in GIS. We will look at these topographical height variations in greater detail in upcoming chapters.

Mathematical Model of the Earth

To adequately represent the shape of the Earth in scientific and real-life applications, a calculatable, formula-driven figure of the Earth is needed. Let us go to the basics of an ellipsoid to build a mathematical figure of the Earth. In its most basic sense, an Earth ellipsoid is a *flattened* sphere that bulges in the middle and has two imaginary lines traversing its core: one from north to south and one from east to west. Each imaginary line is called an *axis*.

The ellipsoid's flattening causes two unequal axes: a longer axis and a shorter axis. The north-to-south axis through the Earth's core is the shorter axis and, as such, is called the *minor axis* or *polar axis*. The east-to-west axis through the Earth's core is longer and is called the *major axis* or *equatorial axis*. Figure 6.3 illustrates a three-dimensional model and highlights the ellipsoid's flattening.

The Earth's ellipsoid is an ellipse rotated upon its minor axis, which is functionally called the *axis of rotation* or *axis of revolution*. The purpose of a mathematical model is to simplify calculations. Since an ellipse is a two-dimensional shape and an ellipsoid is a more complex, three-dimensional object, we utilize the figure of an ellipse to achieve this mathematical simplicity. Figure 6.4 details this two-dimensional mathematical model of the Earth.

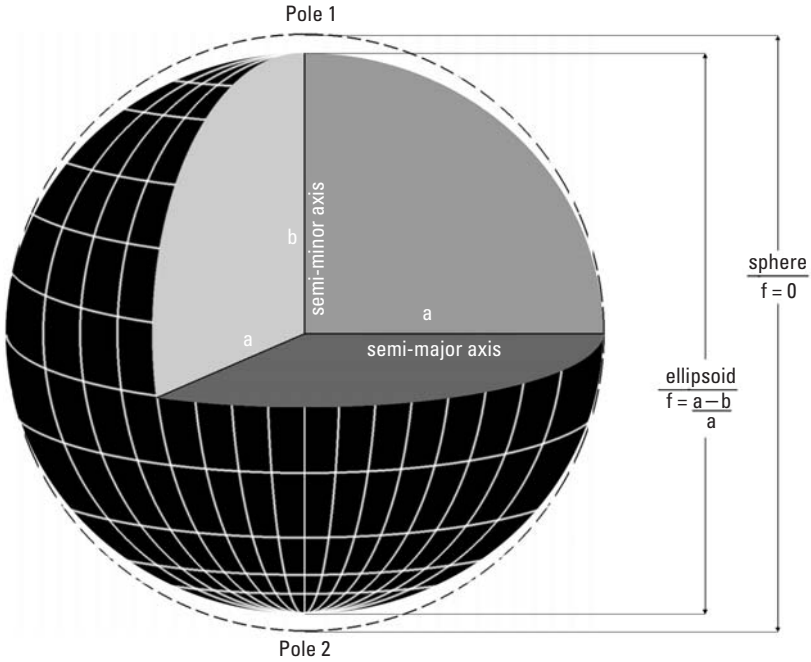

Figure 6.3 The three-dimensional oblate Earth.

Due to the Earth's symmetry and to minimize complexity, the mathematical model targets one quadrant in the ellipse and imparts six key parameters for calculation. The six parameters are the semimajor axis, the semiminor axis, flattening, inverse flattening, eccentricity, and second eccentricity. Let us go through each one while using Figures 6.3 and 6.4 for visualization.

The semimajor axis is an equatorial radius and is defined as one-half of the major axis. Alternately, the semiminor axis is a polar radius and is defined as one-half of the minor axis. Both hold major roles within the mathematical model and are represented by *a* and *b*, respectively. As we will see in the next two chapters, both the semimajor and semiminor axes are instrumental in defining accurate GIS point locations.

We have already discussed flattening but have not fully addressed its calculation. In brief, the flattening of the ellipse is directly related to the differences in both the semimajor and semiminor axes. It is represented by the formula

$$Flattening\ f = \frac{a-b}{a}$$

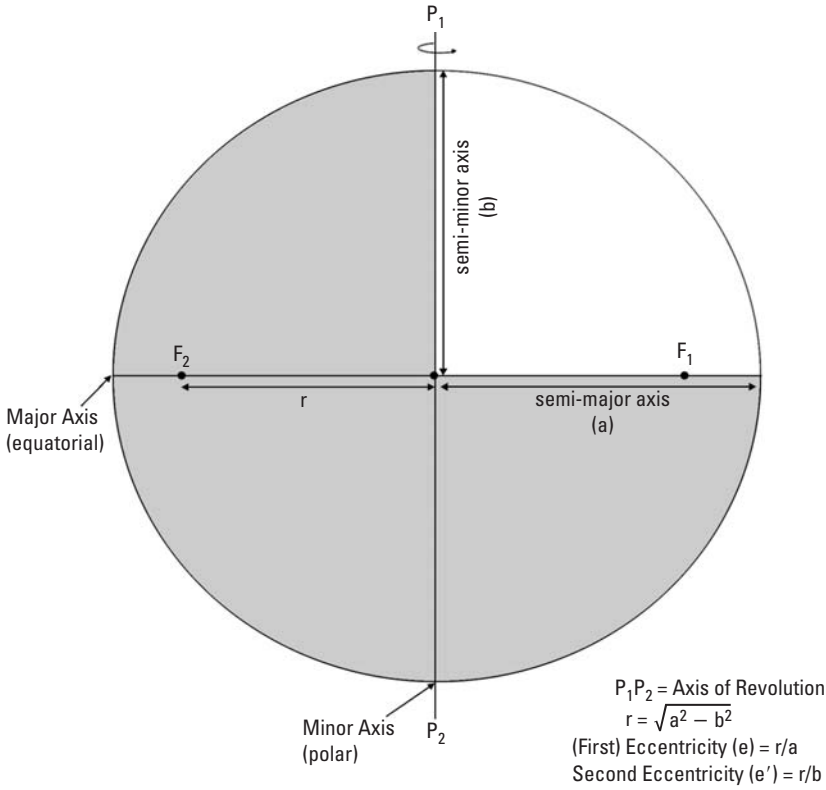

Figure 6.4 The two-dimensional, six-parameter mathematical model of the Earth.

Typical of this geodetic application, ellipse (and ellipsoid) flattening is a very small number holding many decimal places. In GIS, science, and mathematics, flattening results can be onerous to transcribe from tables and presents an opportunity for human error. To minimize error and help simplify conveyance, the Earth's flattening is sometimes displayed as a reciprocal called the *inverse flattening*. For instance, a flattening of 0.003389831 (or 1/295) can be portrayed as an inverse flattening of 295. As you can understand, the inverse flattening is much easier on the eyes and even easier to incorporate into dense calculations.

The formula for inverse flattening is straightforward, represented as:

$$\textit{Inverse flattening } f^{-1} = \frac{1}{f} \textit{ or } \frac{a}{a-b}$$

The final two parameters, namely eccentricity and second eccentricity, have more to do with the mathematical nature of the ellipse than its geographic use. Both eccentricities uniquely characterize the shape of the ellipse through a relational measurement for the degree of flattening.

Eccentricity e is the first eccentricity, whereby the descriptor *first* is typically implied. It measures the degree of flattening as the relationship between the focal radius, or radius from the center point to the foci (i.e., F_1, F_2), and the semimajor axis. It is calculated through the formula

$$(First)\ Eccentricity\ e = \frac{Focal\ radius\ r}{Semimajor\ axis\ a}$$

In any ellipse, the focal radius $r = \sqrt{a^2 - b^2}$; therefore,

$$(First)\ Eccentricity\ e = \frac{\sqrt{a^2 - b^2}}{a}$$

Second eccentricity e' measures the degree of flattening as a relationship between the focal radius and the semiminor axis. The formula for second eccentricity is

$$Second\ \ Eccentricity\ e' = \frac{Focal\ radius\ r}{Semiminor\ axis\ b} = \frac{\sqrt{a^2 - b^2}}{b}$$

Eccentricity (first and second) is constant throughout the entire ellipse and ranges from 0 to 1, or more simply from an ellipsoid with no flattening (circle) to one totally flat (line). Since a circle has no flattening, its eccentricity equals zero ($e = 0$). As e becomes larger and approaches 1, the ellipse becomes flatter until it is a straight line ($e = 1$).

Figure 6.5 illustrates this proportional relationship and endorses the eccentricity rule of thumb: The closer eccentricity is to 1, the flatter the ellipse.

Typical Earth Shape Calculation

To understand how the mathematical model is used for typical Earth shape calculations in GIS, let us calculate the Earth's six key parameters using the derived mathematical model as illustrated in Figure 6.4 and the standard measurements of the Earth's axes from the World Geodetic System 1984 (WGS84).

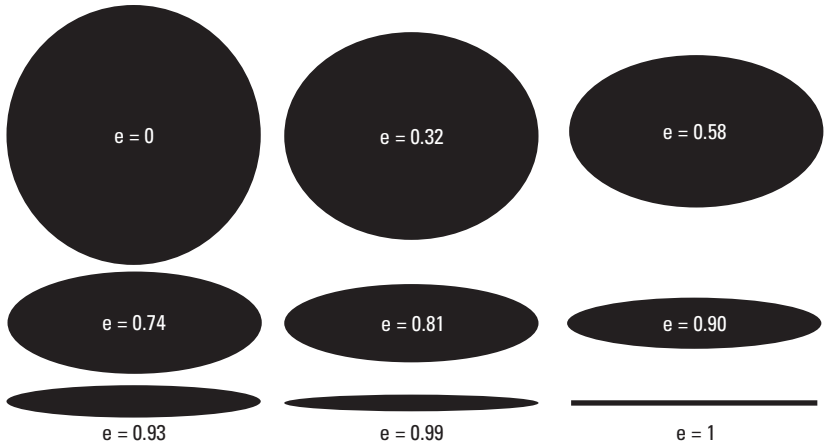

Figure 6.5 The constant eccentricity of an ellipse. (*Source:* D. Downing, *Dictionary of Mathematics Terms*, 2nd ed., Hauppauge, NY: Barron's Educational Series, 1995, after Figure 47.)

WGS84 Constants

$$\textit{Major axis} = 12{,}756{,}274 \text{ meters}$$

$$\textit{Minor axis} = 12{,}713{,}504.628 \text{ meters}$$

$$\begin{aligned}\textit{Semimajor axis } a &= \tfrac{1}{2}\,\textit{Major axis}\\ &= \tfrac{1}{2}(12{,}759{,}274)\\ &= 6{,}378{,}137 \text{ meters}\end{aligned}$$

$$\begin{aligned}\textit{Semiminor axis } b &= \tfrac{1}{2}\,\textit{Minor axis}\\ &= \tfrac{1}{2}(12{,}713{,}504.628)\\ &= 6{,}356{,}752.314 \text{ meters}\end{aligned}$$

$$\begin{aligned}\textit{Flattening } f &= \frac{a-b}{a}\\ &= \frac{6{,}378{,}137 - 6{,}356{,}752.314}{6{,}378{,}137}\\ &= \frac{21{,}384{,}686}{6{,}378{,}137}\\ &= 0.00335811\end{aligned}$$

$$\text{Inverse flattening } f^{-1} = \frac{1}{f}$$
$$= \frac{1}{0.003352811}$$
$$= 298.257$$

$$\text{Eccentricity } e = \frac{r}{a} = \frac{\sqrt{a^2 - b^2}}{a}$$
$$= \frac{\sqrt{6{,}378{,}137^2 - 6{,}356{,}752.314^2}}{6{,}378{,}137}$$
$$= \frac{\sqrt{272{,}331{,}609{,}224.645404}}{6{,}378{,}137}$$
$$= \frac{521{,}854.0114}{6{,}378{,}137}$$
$$= 0.081819191$$

$$\text{Second eccentricity } e' = \frac{r}{b} = \frac{\sqrt{a^2 - b^2}}{b}$$
$$= \frac{\sqrt{6{,}378{,}137^2 - 6{,}356{,}752.314^2}}{6{,}356{,}752.314}$$
$$= \frac{\sqrt{272{,}331{,}609{,}224.645404}}{6{,}356{,}752.314}$$
$$= \frac{521{,}854.0114}{6{,}356{,}752.314}$$
$$= 0.082094438$$

Reference Ellipsoids

Before leaving the subject of the ellipsoid, we must define its function within a GIS. Basically, every GIS and geographic information product is based upon a reference ellipsoid, which is defined as a standard ellipsoid with proven and measured parameters. The reference ellipsoid enables GIS to define point locations with regional accuracy.

Throughout the years, numerous reference ellipsoids have been developed by various geodesists with measurements taken at different source points on Earth. These reference ellipsoids are only slightly dissimilar. Because of this

differentiation in source data locations, certain reference ellipsoids work better than others for certain applications and for certain regions. For example, the reference ellipsoid Bessel 1841 is better suited for European GIS products than American GIS products and will produce more precise results due to its European-based measurement site.

Unlike Bessel 1841 and other major area-specific ellipsoids, WGS84 is much more universal and, as a result, is one of the most widely used reference ellipsoids available. It can be used for any location on Earth with a high degree of precision and flexibility and is backed by satellite measurements.

Appendix A, entitled "Reference Ellipsoid Parameters," lists many of the key reference ellipsoids available to GIS users. The appendix provides their associated equatorial radius, polar radius, and inverse flattening parameters, which are all necessary for proper designation in GIS. Since all geographic information products are built upon a reference ellipsoid, we will frequently refer to Appendix A throughout this book.

7

The Horizontal Datum

During the "Shock and Awe" military mission in Iraq, the U.S. armed forces were responsible for destroying enemy targets with missiles. The challenge was that these targets were in the heart of downtown Baghdad, near schools, mosques, and neighborhoods. The accuracy of missiles had to be extremely precise so that only the target was destroyed and the surrounding innocent people were not killed. Using standard ellipsoids to model the Earth helped bring the science of geodesy into a manageable and useful format for various applications. However, launching those missiles using positions on a standard ellipsoid would have been catastrophic, since positional accuracy would have been generalized, and thus the target's position would have been generalized. To maintain precision, U.S. missile systems implemented GPS-based targeting systems for the highest level of accuracy and to minimize collateral damage.

Sometimes standard ellipsoids provide enough accuracy and prove sufficient for small- and large-scale GIS applications. However, similar to the military missile systems, often a greater degree of precision and positional accuracy is needed. To help bridge the standard ellipsoid to a more exact Earth position, a precise reference point called a *geodetic datum* is used. Incidentally, specific geodetic datums are used to manipulate GPS properly and help guide missile targeting systems.

Let us examine these precision-enhancing ellipsoid references to obtain a clearer understanding of their importance and implementation within GIS. The complete discussion of datums is somewhat lengthy. In an effort to simplify and help organize the explanation of the topic, I have divided it into two logical parts: the horizontal control datums and the vertical control datums. This chapter focuses on datum theory, as well as horizontal control datums. The next

chapter completes the discussion with a detailed examination of vertical control datums.

What Is a Geodetic Datum?

By the purest sense of the word, a datum is any set of numeric or geometric parameters used to accurately measure or define another quantity. More specifically related to GIS, a geodetic datum is a "curved Earth" reference model that associates a geodetic reference ellipsoid (i.e., "parameters") to a coordinate system (i.e., "another quantity").

As previously discussed, a geodetic reference ellipsoid is attributed with certain characteristic parameters, such as the semimajor axis *a*, the semiminor axis *b,* and flattening *f,* while a coordinate system defines a geodetic space through orientation, position, and scale. Both are brought together with a geodetic datum, which, in itself, is purely a mathematical Earth model. Given this mathematical union it can be determined that any reference ellipsoid can support an infinite number of datums; however, each datum can only be defined by one ellipsoid.

Geodetic datums are generally classified as either a geocentric datum or a local geodetic datum. A *geocentric datum* is globally centered and adequately approximates the Earth's size and shape as a whole. The center of the reference ellipsoid coincides with the Earth's center of mass. See Figure 7.1.

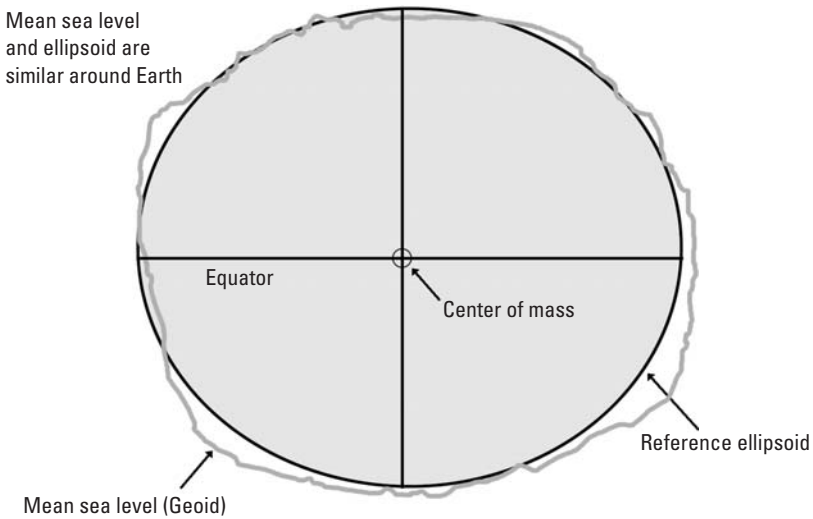

Figure 7.1 The geocentric datum. (*After:* [1], diagram 6.)

A geocentric datum is not designed to best characterize a particular area but instead is best used when applications are global in nature. GPS, for example, utilizes the common geocentric datum WGS84.

A *local geodetic datum* is used to characterize a particular region where the reference ellipsoid and the Earth's shape coincide. The center of the ellipsoid is often located away from the Earth's center of mass, thereby providing a poor representation of the Earth as a whole. Figure 7.2 illustrates how the ellipsoid's surface and Earth's surface coincide within a particular location and diverge elsewhere.

Both figures depict the Earth's mass as a geoid or mean sea level model. This is a typical convention with geodetic datums, especially when defining the height of the Earth from its core. Since we are detailing the relationship between the Earth's center of mass and the center of the reference ellipsoid, as well as the surfaces of both these shapes, the geoid proves to be a fair Earth shape parameter. We will examine the true function of the geoid in the next chapter.

Primary Types of Geodetic Datums

The classification of geodetic datums offers a degree of user control as it relates to which datum suits the application or location best. For instance, you would never choose NAD27, a North American datum, to map the city of Tokyo in Japan. The Tokyo datum has been devised specifically to handle that terrestrial location. This form of user control surrounds the act of selecting a

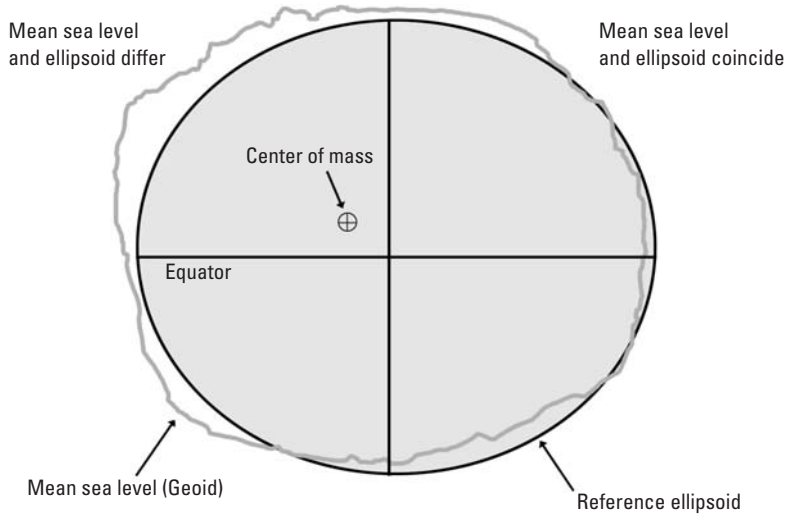

Figure 7.2 The local geodetic datum. (*After:* [1], diagram 5.)

location-specific datum based on individual characteristics, rather than manipulating a more general datum.

Geodetic datums empower the user with a referenced-based geographic coordinate system within which accurate point positions can be determined. In a two-dimensional space, point positions are defined by a coordinate pair (*x*, *y*) on a uniform plane. Think of a single point on an *x-y* grid drawn on a piece of paper. Every *x-y* positional coordinate on that paper is at a uniform height (i.e., uniform plane). In the real three-dimensional world, height (*z*) is as important a distinguisher as the *x* and *y* coordinates. The three-dimensional point positions involve a horizontal component (*x* and *y* coordinates) and a vertical component (*z* coordinate).

At any given point on the Earth's surface there exists a horizontal level that runs parallel with the surface (ground) and a vertical level that runs perpendicular to the surface (ground). Refer to Figure 7.3.

Imagine holding a plumb line or a weighted string so that it remains suspended in the air aiming toward the ground. The imaginary line running through the string and weight into the ground provides that point position's vertical level. Likewise, a glass or cylinder containing water and placed on the ground presents the horizontal level for that position. Since horizontal and vertical levels exist for every point position, positional coordinates can be adjusted as needed along these planes.

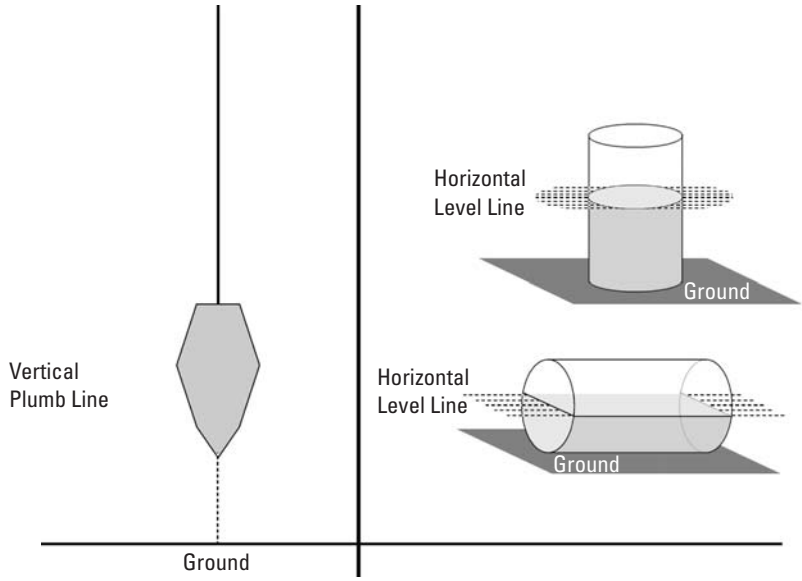

Figure 7.3 The vertical plumb line and the horizontal water line.

Geodetic datums, both local and geocentric, offer the opportunity to manage these horizontal and vertical levels for greater positional accuracy. This leads us into the two primary types of geodetic datums: horizontal control datums and vertical control datums.

A *horizontal control datum* (or *horizontal datum*) is used to manipulate and set a position in the *x* and *y* directions. Horizontal datums are often defined by a reference ellipsoid and a coordinate origin. Alternately, a *vertical control datum* (or *vertical datum*) is used to manipulate and set a positional height in the *z* direction. Vertical datums provide a level from which positional heights can be determined.

Both primary types of geodetic datums provide a favorable degree of positional control. As mentioned earlier, the remainder of this chapter will examine the standard types of horizontal datums and various methods to transform between two horizontal datums.

Standard Horizontal Datums

As we already understand, horizontal datums take on both geocentric and local geodetic forms. Each major province or country has its own standard datum or simply a datum of choice. Standard horizontal datums cover large geographic areas. They are used throughout the world for simplicity and local datum reference. We will briefly examine five commonly used horizontal datums and reference systems for the Earth model.

World Geodetic System 1984
