The World Geodetic System 1984 (WGS84) is considered a global datum that defines an Earth-fixed global reference frame for the Earth. WGS84 is based upon the ellipsoidal parameters of the Geodetic Reference System of 1980. WGS84 is used for GPS satellites and is defined by a gravity model of the Earth.

WGS is a geocentric datum that made its first appearance in 1960. A product of the U.S. Defense Mapping Agency (DMA) for mapping and charting, the WGS has evolved from the primitive satellite measurements of 1960 (WGS60) to the sensitive Doppler satellite data and satellite data altimetry used in the latest and highly accurate WGS84. With its satellite-driven precision, WGS84 has proved to be a satisfactory reference datum for nearly every Earth location.

Given its Earth-fixed nature, WGS84 offers a standard reference ellipsoid with base parameters being:

Semimajor axis $a = 6{,}378{,}137$ meters
Semiminor axis $b = 6{,}356{,}752.314$ meters
Flattening $f = 0.003352811$
Inverse flattening $1/f = 298.2572236$

Due to its general accuracy worldwide, WGS84 is a highly used, worldwide datum (and reference ellipsoid). In fact, due to its global appeal, many applications require local datums to be converted to WGS84. The transformation parameters provided with the worldwide geodetic datums in Appendix B are conversion factors between the particular local datum and WGS84.

Incidentally, it is anticipated that WGS84 will remain valid until 2010, when it will be revised.

International Terrestrial Reference Frame

Another major global reference datum is the properly named International Terrestrial Reference Frame (ITRF). This reference system is used for a large selection of astronomical, geophysical, and geodetic analysis and information products worldwide, although it is typically more popular in Europe.

The goal of this geodetic datum is the realization of a terrestrial coordinate system through the creation and implementation of a terrestrial reference frame. Positions on the surface of the Earth are indeterminate observations or quantities without a terrestrial reference frame. Thus, the ITRF enables precise positional coordinates that are linked to the terrestrial landscape of Earth. This terrestrial landscape is referenced through an International Terrestrial Reference System (ITRS), which is a dynamic spatial referencing system that adheres to the Earth's rotation and geophysical changes.

The ITRF has proved to be a uniquely useful and precise tool for both the geodesist and GIS user alike. The ITRF maintains precision through use of modern geodesy, GPS, satellite laser ranging (SLR), lunar laser ranging (LLR), very long baseline interferometry (VLBI), and other analysis tools. Additionally, precision is maintained with the aid of measurement for more than 800 observation and control stations worldwide. These observation and control stations are typically located at small distances from major fault lines or areas of seismic activity. The resultant product, namely the ITRF, is a highly precise datum that simulates the present-day terrestrial Earth and captures the minute changes in the Earth that other geocentric datums cannot capture.

The ITRF's base parameters for its reference ellipsoid are identical to WGS84 down to the 10-cm level. This level of accuracy is precise enough to say that WGS84 and ITRF share the same ellipsoid parameters. In addition, ITRF

has no transformation factors to WGS84. As a result, ITRF coordinates can be expressed as WGS84 coordinates at a 10-cm level.

The first adequate version of ITRF came out in 1994. It was revised in 1996, again in 1997, and finally in 2000. At the time of this writing, the latest form is ITRF2000, although plans are set for an ITRF2005.

Geodetic Reference System of 1980

The Geodetic Reference System of 1980 (GRS80) is another widely used geodetic reference system that consists of a global reference ellipsoid and a gravity field model. The GRS80 model provides a geocentric reference ellipsoid used by the ITRF geodetic network. GRS80 supersedes GRS67. Both were developed and are maintained by the International Association of Geodesy (IAG), a division of the International Union of Geodesy and Geophysics (IUGG). The GRS80 model offers a simple yet accurate framework for the definition of a worldwide geodetic datum and the determination of the normal gravity field for the Earth.

The GRS80 ellipsoid encompasses the entire mass of the Earth, which goes beyond the terrestrial mass and includes the atmosphere. The inclusion of the Earth's atmosphere into the ellipsoid measurements was an innovation first introduced in the GRS80 model.

The GRS80 reference system is used by GPS through a standardized realization of the system: WGS84. Given this connection, GRS80 offers a standard reference ellipsoid with similar base parameters:

$$\textit{Semimajor axis } a = 6{,}378{,}137 \text{ meters}$$
$$\textit{Semiminor axis } b = 6{,}356{,}752.314 \text{ meters}$$
$$\textit{Flattening } f = 0.003352811$$
$$\textit{Inverse flattening } 1/f = 298.2572236$$

As mentioned earlier, GRS80 takes into account the Earth's atmosphere, which is conceptually a uniform, condensed layer of atmosphere on the surface of the ellipsoid. In the GRS gravity field model, the variation in density for this condensed atmospheric layer is ignored so that the geocentric gravitational field can be efficiently calculated. The GRS80 gravity field model is defined through the following physical constants:

$$\textit{Geocentric gravitational constant } GM = 3{,}986{,}005 \times 10^{8} \text{ m}^3/\text{s}^2$$
$$\textit{Dynamic form factor } J_2 = 108{,}263 \times 10^{-8}$$
$$\textit{Angular velocity of the Earth } \omega = 7{,}292{,}115 \times 10^{-11} \text{ rad/s}$$

The GRS80 geocentric model is a reference system through which other geocentric and local geodetic datums are based. Its worldwide accuracy has enabled GRS80 to remain a geodetic datum reference of choice for many regions. For instance, the government of Australia used the GRS80 geocentric ellipsoid to define GDA94, a popular Australian local datum.

North American Datums of 1927 and 1983

The North American Datums of 1927 and 1983 were established to provide accurate positional coordinates and increased horizontal control for any location within North America. By the end of 1926, the original horizontal reference system for the United States (North American Datum) was drastically outdated and imprecise, and the U.S. Coast and Geodetic Survey called for a revision to the standard datum. In 1927, the North American Datum of 1927 (NAD27) was developed to include the then newly measured meridian arcs of North America. The new datum was based on the Clarke ellipsoid of 1866. NAD27 proved to be a more accurate geodetic local datum that is still used today.

Similar to the original North American Datum, NAD27 is referenced through a base triangulation station in Meades Ranch, Kansas. This reference station is close to the geographic center of the United States, which helps NAD27 minimize differences between astronomic and geodetic latitudes and longitudes.

The development of GRS80 brought forth the many shortcomings of NAD27 and showed the need for a revised and more accurate North American Datum. The North American Datum of 1983 (NAD83) was subsequently developed through an international effort between the U.S. National Geodetic Survey, the Geodetic Survey of Canada, and the Danish Geodetic Institute.

The resulting NAD83 is a geocentric datum based upon the GRS80 Earth model that uses three-dimensional techniques to establish horizontal control. These (x, y, z) observations are facilitated through the implementation of high-precision measurement tools, namely GPS, Doppler satellite, and VLBI. In fact, precision of these measurement tools is within 2 meters.

As a geocentric datum, NAD83 uses the Earth's mean center of mass as a datum reference, whereas NAD27 uses a reference on the Earth's surface (the Meades Ranch station). Adding to NAD83's importance is its compatibility with the WGS84 (GPS) network. In fact, the differences between the two models are negligible. For the purposes of GISs, these datums are effectively equivalent.

The differences between coordinates in NAD27 and NAD83 range from 200 to 300 feet in the western United States to tens of feet in central and eastern U.S. regions. Coordinate conversion between NAD27 and NAD83 can be done using GIS software or geographic calculators or through the horizontal datum

transformation methods discussed later in this chapter. Eventually, there will be only one North American Datum, since NAD27 is gradually being superseded by NAD83.

The reference ellipsoid parameters for the North American Datum of 1927 are:

Semimajor axis $a = 6{,}378{,}206.4$ meters
Semiminor axis $b = 6{,}356{,}758.8$ meters
Flattening $f = 0.003390075$
Inverse flattening $1/f = 294.9786982$

The reference ellipsoid parameters for the North American Datum of 1983 are:

Semimajor axis $a = 6{,}378{,}137$ meters
Semiminor axis $b = 6{,}356{,}752.314$ meters
Flattening $f = 0.003352811$
Inverse flattening $1/f = 298.2572236$

European Datum 1950

During World War II, the accuracy and compatibility of latitude and longitude positions in Western Europe became an issue. Battles fought on the borders of Germany, France, Belgium, and the Netherlands proved that datum inconsistencies existed, while the mapping of these countries aired several incongruities. The common consensus was that a consistent mapping datum was needed in Western Europe. As such, the European Datum 1950 (ED50) was created after the war.

ED50 is a geodetic datum that proves to be highly accurate in Western European countries. ED50 has abolished the incongruities and incompatibility issues that were faced during the many battles of World War II, while providing a tool to connect the existing and individual country datums.

ED50 is based upon the International 1924 ellipsoid (known as the Hayford ellipsoid) and offers the following base parameters:

Semimajor axis $a = 6{,}378{,}388$ meters
Semiminor axis $b = 6{,}356{,}911.946$ meters
Flattening $f = 0.003367003$
Inverse flattening $1/f = 297$

Similar to other pre-1960 datums, ED50 is referenced through a base triangulation station. This European geodetic datum is referenced at Frauenkirche of Munich in Southern Germany, close to the center of Western Europe's geodetic networks during the Cold War. Before the implementation of GRS80 and WGS84, the ED1950 was widely used around the world. Today, it is still used by default in most of Western Europe except in countries with their own datums, such as Great Britain, Poland, Ireland, Hungary, Sweden, and Switzerland.

Horizontal Datum Transformation Models

With the multitude of horizontal geodetic datums available for any given region, the need for datum consistency is essential for correct and accurate results. Combining coordinates from different datums will produce incorrect results and can even put users in jeopardy. That being stated, often GIS users or others need to transform the coordinates from one geodetic datum to another for the sake of coordinate consistency and accuracy.

Imagine that you are trekking in the backlands of Malawi, Africa, with a region map based on the local datum (ARC1950) and realize you are moving beyond the boundaries of this map. You take out your GPS unit and quickly recognize it functions on a different datum (WGS84). To reach your destination and return safely, you will need to transform your positional coordinates from the local datum (ARC1950) into the GPS-friendly datum (namely WGS84). A datum transformation must be calculated not only to obtain your GPS coordinates but also to link the local map with the GPS unit.

This example is dramatic, but not unlikely. Geodetic datum transformations are common practice for GIS users who are working with existing coordinate data and different geodetic datums. In fact, datum transformation is the most utilized positional management function in core GISs. Geodetic network orientation is frequently mismatched between sets of geographic data and requires correction before properly coinciding in geographic space. A datum transformation provides such correction.

As you might have guessed, there are a handful of accurate transformation models from which to choose. Although many transformations can be calculated using software, the novice GIS user should understand the methods for calculating these transformations. Most applications of these methods seek to transform geographic data to the standard WGS84 from older or more obscure geodetic datums.

WGS84 serves as a common model for all geodetic networks and, therefore, acts as a common ground for many datum transformations. More specifically, many datums are first transformed into the common WGS84 and then transformed again into the desired datum. By expressing datum parameters as

"shifts" to WGS84, the need to define all geodetic networks in terms of all other geodetic networks is alleviated. The worldwide datums table in Appendix B lists an assortment of local geodetic datums from around the world with their *x*, *y*, and *z* datum shifts to WGS84.

Let us examine the two most common geodetic datum transformation formulas: the Molodensky datum transformation method and the Bursa-Wolf datum transformation method.

The Molodensky Datum Transformation Method

The Molodensky (or Molodenski) datum transformation method is by far the most efficient and simplest datum transformation method available. Although sufficiently accurate, its simplicity makes this transformation less precise than others, stemming from the fact that it does not factor in rotation or scaling between datums. The Molodensky transformation is commonly called the *three-parameter transformation method* for its minimal formula involving three datum shift parameters between the two ellipsoids. This transformation method is used when the *X*, *Y*, and *Z* axes of both datums are known to be parallel and at the same scale. Further simplifying the calculation, the Molodensky method employs geodetic coordinates for the Earth's curvilinear surface, which alleviates any rectangular coordinate system conversion calculations.

As illustrated in Figure 7.4, the three geodetic datum shift parameters are defined as

1. Delta X (ΔX), the difference in geodetic longitude in meters between the current datum (#1) and the desired datum (#2);
2. Delta Y (ΔY), the difference in geodetic latitude in meters between the current datum (#1) and the desired datum (#2);
3. Delta Z (ΔZ), the difference in geodetic height in meters between the current datum (#1) and the desired datum (#2).

The Molodensky transformation formulas utilize the three datum shifts to calculate the desired datum coordinates. The formulas are as follows:

$$X_1 = X_2 + \Delta X$$

$$Y_1 = Y_2 + \Delta Y$$

$$Z_1 = Z_2 + \Delta Z$$

S. M. Molodensky first presented his datum transformation method in his classic title, *Methods for the Study of the External Gravitational Field and Figure of*

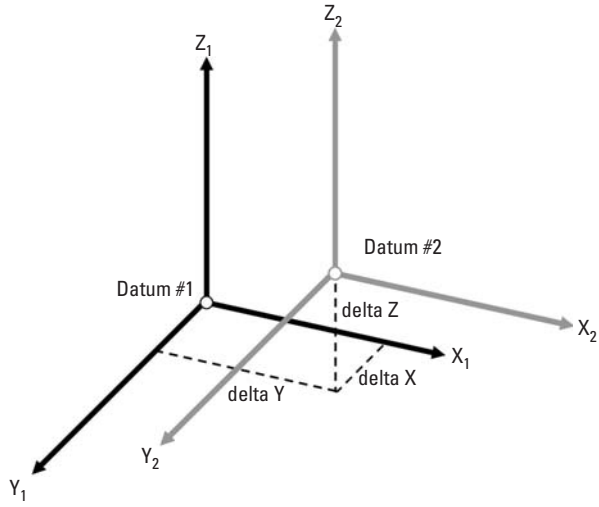

Figure 7.4 The Molodensky three-parameter datum transformation.

the Earth. His initial presentation involved a seven-parameter transformation method, which was further simplified to the current form: three parameters. In the end, the Molodensky datum transformation method retains adequate precision between the datums (within 5 meters) and proves to be a great geodetic tool for GIS.

The Bursa-Wolf Transformation Method

The Bursa-Wolf datum transformation method is a far more rigorous calculation than the three-parameter Molodensky formula. The Bursa-Wolf method is commonly called the *seven-parameter transformation method* for its lengthy formula involving three datum shift parameters, three datum rotations, and a scale correction factor. The Bursa-Wolf transformation is used when the *X*, *Y*, and *Z* axes of both datums are not parallel (axial rotation exists) and not at the same scale (scale change exists).

Similar to the Molodensky method, the Bursa-Wolf transformation method employs geodetic coordinates for the Earth's curvilinear surface, which, once again, alleviates any rectangular coordinate system conversion calculations. As illustrated in Figure 7.5, the seven datum parameters are defined as:

1. Delta X (ΔX), the difference in geodetic longitude in meters between the current datum (#1) and the desired datum (#2);

2. Delta Y (ΔY), the difference in geodetic latitude in meters between the current datum (#1) and the desired datum (#2);
3. Delta Z (ΔZ), the difference in geodetic height in meters between the current datum (#1) and the desired datum (#2);
4. X-axis rotation R_x, the rotation of the geodetic longitude in arc seconds from the current datum to the desired datum;
5. Y-axis rotation R_y, the rotation of the geodetic latitude in arc seconds from the current datum to the desired datum;
6. Z-axis rotation R_z, the rotation of the geodetic height in arc seconds from the current datum to the desired datum;
7. Scale change S_c, the scale difference between the current datum and the desired datum.

The Bursa-Wolf transformation formula utilizes all seven parameters to calculate the desired datum coordinates. The formula is as follows:

$$\begin{bmatrix} X_1 \\ Y_1 \\ Z_1 \end{bmatrix} = \begin{bmatrix} \Delta X \\ \Delta Y \\ \Delta Z \end{bmatrix} + S_c \begin{bmatrix} 1 & -R_z & R_y \\ R_z & 1 & -R_x \\ -R_y & R_x & 1 \end{bmatrix} \begin{bmatrix} X_2 \\ Y_2 \\ Z_2 \end{bmatrix}$$

The Bursa-Wolf transformation is a subset to the older Helmert seven-parameter transformation method. Both methods share the same formula, but they differ in their conventions for rotational polarity. The Helmert model (known also as *coordinate frame transformation* or *three-dimensional similarity transformation*) defines the rotation of the entire coordinate frame (i.e., all points on the axes). The Bursa-Wolf model (known also as a *position vector transformation*) defines the rotation of the point position with respect to a fixed coordinate frame. The conventions contrast one another and, thus, form two separate transformation methods. Compare Figure 7.5 (the Bursa-Wolf model) to Figure 7.6 (the coordinate frame transformation model).

The rotational polarity for the Bursa-Wolf model is positive clockwise around the datum 2 axes when viewed from the origin. Mathematically, the rotational polarity is reversed when viewing the origin from the axes. Whatever the convention used, the seven-parameter transformation model proves to be a much more accurate datum transformation method, with approximate accuracy held within 1 meter.

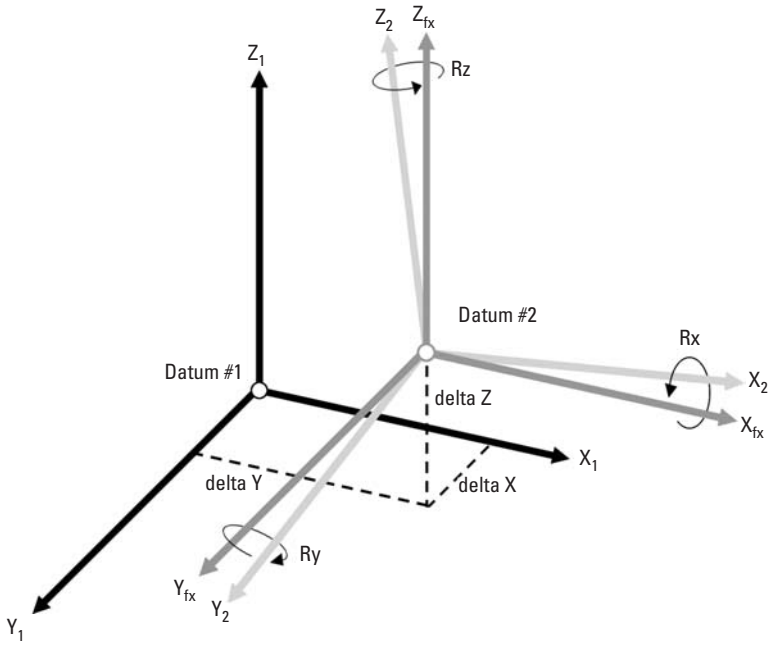

Figure 7.5 The Bursa-Wolf seven-parameter datum transformation.

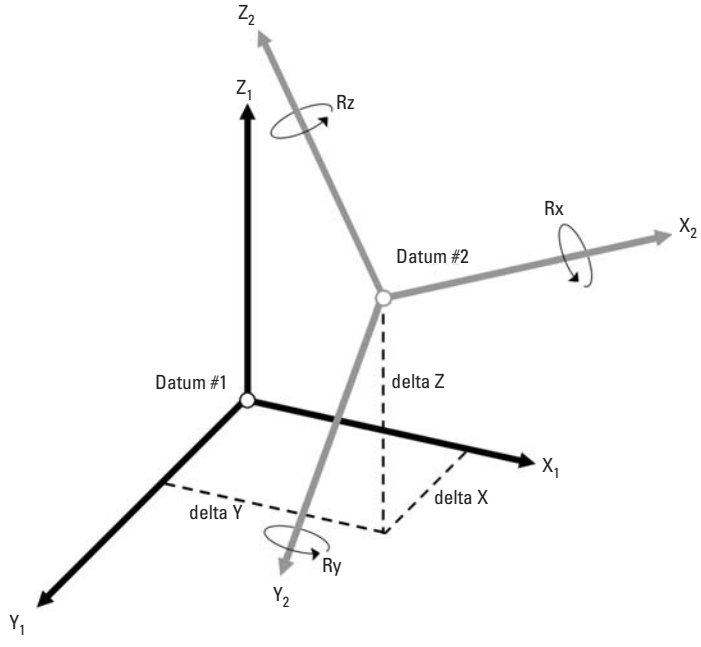

Figure 7.6 The coordinate frame transformation.

Horizontal Grid Transformation Methods

Another popular datum transformation type exists, called *horizontal grid transformation,* that enables discrete horizontal control within a datum. This transformation method is markedly different from both the Molodensky and Bursa-Wolf models. The latter models utilize a set of datum shift parameters that are attributed to a common source. Horizontal grid transformation methods use a set of field-based observations and statistical functions that describe a geodetic datum in a more comprehensive manner.

Adding to the complexity of the calculations but enhancing the accuracy of the results, horizontal grid transformations solve transformation through a mathematical function: bilinear gridded interpolation. This data interpolation technique facilitates the accurate transformation from older datum to newer, more accurate datum. Bilinear gridded interpolation is used by the U.S.-based North American Datum Conversion software and the Canadian National Transformation application. Additionally, this grid transformation technique has been adopted by the governments of Australia, New Zealand, and Great Britain for its high-accuracy horizontal control.

The standard horizontal grid transformation methods provide a greater level of horizontal datum control than that achieved using the Molodensky and Bursa-Wolf models. Adding to the better horizontal control is an enhancement in transformation accuracy, with grid transformations retaining an approximate accuracy within 0.1 to 0.3 meter. To reprise, the Bursa-Wolf accuracy was within approximately 1 meter and the Molodensky accuracy was within approximately 5 meters.

There are three very common horizontal grid transformation methods that warrant discussion: The North American Datum Conversion, the High Accuracy Reference Network, and the Canadian-Australian National Transformations. Let us examine these methods.

The North American Datum Conversion

The North American Datum Conversion (NADCON) is the U.S. federal standard for transforming latitude and longitude coordinates between NAD27 and NAD83. NADCON is a conversion utility that was first developed to facilitate transformations between the datums directly through known grid shifts, alleviating the need for datum parameters or scale changes.

A NADCON transformation is based upon a gridded set of control points that are geostatistically interpolated. NADCON grids are based on more than 150,000 of these horizontal control points. Transformations are based upon the grid shifts measured for the horizontal control point closest to the positional coordinate to be converted.

The NADCON program also provides datum correction for errors that exist in the NAD27 horizontal control datum. When NAD27 was first created, all measurements and calculations were done by hand and retained in hand-transcribed tables. These measurements were formulated in reference to a single ellipsoid surface datum point in Meades Ranch, Kansas. These outdated methods produced numerous inconsistencies and, in some areas of the country, geographic uncertainty due to imperfect measurements.

NADCON provides correction for some of these existing uncertainties and inconsistencies in NAD27 and, as such, provides a relatively efficient method to transform between both datums. With such a direct correlation between datums and focusing on whole grid shifts rather than individual axis or point shifts, the NADCON transformation method proves to be incredibly accurate, far more accurate than the previously discussed datum transformation methods.

The High Accuracy Reference Network

GPS and other present-day advances in geodetic measurement and coordinate position accuracy have allowed for the creation of a High Accuracy Reference Network (HARN). A HARN is a statewide or regional, high-accuracy geodetic network that improves the precision of older datum control networks. The ultimate goal for developing a HARN is to produce a denser geodetic network that will present validated results rather than human estimation.

More specific, a HARN is used to improve accuracy of NAD83 in specific state-based control networks. This increased accuracy has warranted the need for transformation grids to convert from the original NAD83 measurements (implemented in 1986) to current measured values. Prior to 1992, this datum conversion method was known as a High Precision Geodetic Network (HPGN) correction. The acronym HARN has now superseded HPGN.

In order to revise the original NAD83 measurements to the level of accuracy supported by GPS, which was introduced shortly after NAD83, HARNs were implemented throughout the United States. Starting in Wisconsin in 1989, HARNS were set up in every state to remedy and readjust the lower accuracy NAD83 coordinates. In the end, NAD83 was revised and the HARN measurements produced a coordinate set with greater local accuracies throughout the United States. Incidentally, HARN surveys are becoming more popular worldwide, with HARNs appearing in Europe and Central America.

Canadian and Australian National Transformations

Popular grid transformation methods have also surfaced outside the United States, with probably the most common and extensively implemented being the

Canadian Spatial Reference System's NTv2 software. NTv2, which stands for National Transformation Version 2, is a grid shift interpolation software that transforms coordinates (nationally) between NAD27 and NAD83.

NTv2 has been available since 1992, when it replaced the former version. The NTv2 software has proved to be immensely useful in Canada, as well as in other horizontal geodetic datum networks, and has the capability for accurate modeling based upon various national control survey and municipal networks. NTv2 has remained Canada's national grid transformation method.

In November 1997, Australia's Intergovernmental Committee on Surveying and Mapping (ICSM), faced with a recently revised national datum, turned to Canada's grid transformation method. The conversion utility was adopted for Australia's national conversion from the older, less accurate Australian Geodetic Datums of 1966 and 1984 (AGD66 and AGD84) to the GPS-referenced Geocentric Datum of Australia 1994 (GDA94).

Australia implements NTv2 to handle the differences between datums as a national grid shift, with various control stations surveyed throughout Australia. NTv2 is used to provide horizontal control when converting between the two datums and enables accurate positional coordinates through simple software-driven interpolation. Since AGD66 and AGD84 are equally used, Australia utilizes two grids: one to convert AGD66 to GDA94 and another to convert AGD84 to GDA94. In the end, implementation of Canada's NTv2 method will enable Australia to have greater local accuracy nationwide, purported to be within 10 cm.

8

The Vertical Datum

Just as a horizontal control datum requires a reference grid on which all coordinates abide, a *vertical control datum* (or *vertical datum*) demands a contiguous, consistent reference from which topographical elevation and bathymetric depth are measured. Perhaps considered a complex geodetic construct, the vertical datum is used to manipulate and define a positional height as it relates to a determined reference. How can one accurately measure heights when the Earth's surface ranges in elevation from the peak of Mount Everest to the underwater depths of the Pacific Ocean's Marianas Trench? What could constitute a valid reference for precise vertical measurements?

These and other similar questions have plagued geodesists, mathematicians, and mariners alike. The geodesists had standard ellipsoids that proved to be a general, though innately imprecise, height reference. Mathematicians had their mathematical model of the Earth that was, for height, equally imprecise. Mariners had the tides as reference and frequently, due to the ever moving and inconsistent height of the seas, found themselves stuck in sandbars or crashed upon the rocks. The early need for a consistent and accurate height reference was desperate.

Today, vertical datums provide just such a reference from which positional heights on the Earth's topographical surface can be determined with reasonable accuracy. There are two primary reference surfaces used by leading vertical datums: sea levels (tidal) and standard ellipsoids (geodetic). References for sea level–based datums vary from high and low tide levels to an average sea level. Ellipsoid-based datums generally reference the same ellipsoid model used for calculating horizontal datums. By function, GIS utilizes these same reference surfaces when defining general and specific point heights.

Mean Sea Level and the Geoid

In many day-to-day uses, elevations are referred to as height above or below sea level. For example, in the case of the highest and lowest points on Earth, the peak of Mount Everest is 9 km above sea level and the base of the Marianas Trench is approximately 11 km below sea level. The Earth's topology varies 20 km, highest point to lowest point. In the grand scheme of ellipsoids, this variance is nearly negligible (remember the dimples on the golf ball from the ellipsoid chapter). However, when referenced to sea level, the elevation swing is perceivable and affecting. We can easily conclude that height measurements referenced to the ellipsoid are less accurate than when referenced to the sea level.

Additionally, since tides are constantly changing, rising and falling, the term "sea level" is considered the average of the tide levels. In terms of datums, we call this average sea level the *mean sea level* (MSL). Figure 8.1 illustrates this relationship.

As represented in the figure, the height measurement is the distance from the control station or geodetic point to the MSL. This is generally called the *mean sea level elevation.* Known formally as the *orthometric height,* the measurement is the height above the MSL and, depending upon position, can be represented as a positive (above MSL) or negative (below MSL) measurement.

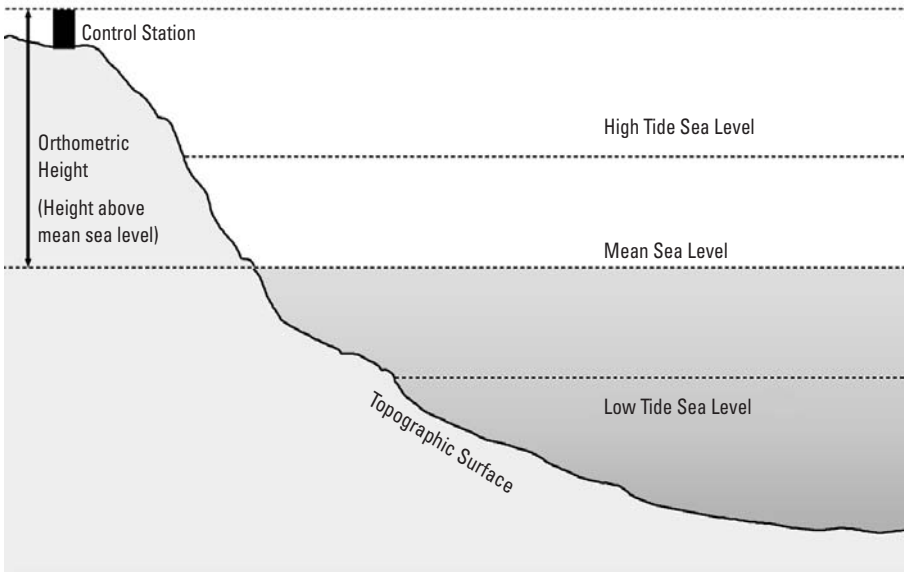

Figure 8.1 The relationship between sea level and height measurements.

As we know, tides are highly influenced by the Earth's gravity field. The Earth's gravity field is defined by two distinct components: the normal mathematical gravimetric earth model and the deviations and disturbances (known as anomalies) from this normal model. In the middle of the ocean, undisturbed by land, the MSL and the Earth's gravitational field coincide. On land, the terrestrial mass and density affect the gravity field and, thus, cause a very small variation between MSL and the Earth's gravity field. Nearly everywhere on Earth, this small variation can be ignored without diminishing the accuracy of height measurements.

Now, imagine if the MSL were to cut through the continents and create a level surface around the Earth. The result would be an exact model of the Earth defined by the MSL that would double as an adequate depiction of the Earth's gravity field. This model is known as the *geoid*.

The geoid is an equipotential (or level) surface of the Earth's gravity field, which coincides with the MSL. For all reasonable purposes, the geoid is defined by the MSL and is considered a good reference by which elevations or heights can be measured.

The geoid is not a smooth surface. The gravitational pull of the Earth is stronger in topology rich in iron and other dense materials, and, as such, causes the geoid to take on a less refined shape. Figure 8.2 depicts how the geoid looks in reference to the standard ellipsoid. Notice its irregular shape, resembling a potato.

The shape differences between the geoid and the standard ellipsoid illustrate just how dissimilar these vertical datum reference surfaces are. To understand the relationship between these reference surfaces, we must examine the separations between the accurate but complex geoid (MSL) and the general but

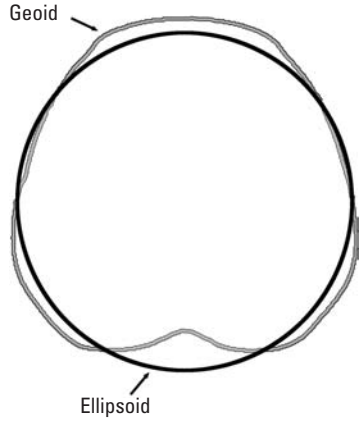

Figure 8.2 The geoid's surface.

simple ellipsoid. These surface separations are called *geoid-ellipsoid separations* or *undulations.*

The Geoid-Ellipsoid Separation

The geoid-ellipsoid separation is an important factor in defining the vertical position as it relates to the vertical datum. Since GPS and certain datums reference the ellipsoid, while other vertical datums reference the geoid, a firm understanding of their relationship is needed to link datums and determine precise vertical positioning between systems. Figure 8.3 details the specific relationship between the geoidal, ellipsoidal, and topographical surfaces

The components to vertical positioning and interrelation between datums can be determined mathematically using the following formula:

$$h = N + H$$

The geodetic height h (also called the *ellipsoid height*) is defined as the height above the ellipsoid to the topographic surface. The orthometric height H is defined as the height above the MSL. The geoid separation N is the distance between the ellipsoid and the geoid. Geoid separation (undulation) values are positive when the geoid is above the ellipsoid and negative when the geoid dips below the ellipsoid. Incidentally, throughout a large portion of the Earth, the geoid is above the ellipsoid (N is positive). In the United States, however, the geoid is below the ellipsoid and N is negative.

The compatibility between various vertical datums is paramount to controlling and manipulating the vertical component in a point position. Understanding geoid undulation enhances datum interoperability and vertical datum

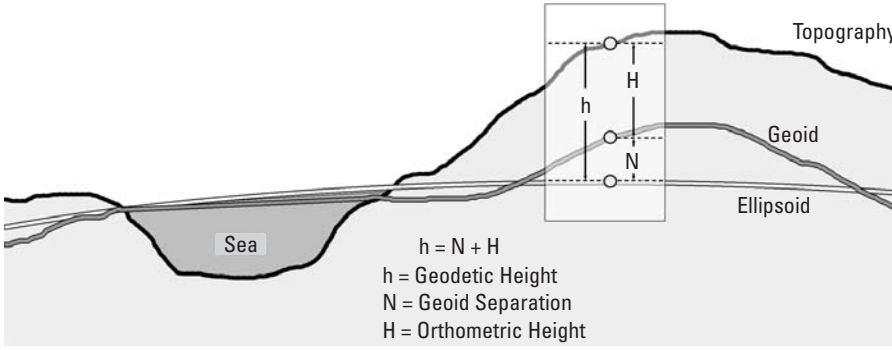

Figure 8.3 The geoid-ellipsoid-topography relationship.

transformations. Let us now examine some standard vertical datums and common transformation methods.

Standard Vertical Datums

The heights or depths of terrestrial points are determined through referencing the defined elevation surface of a vertical datum. Like the horizontal datum, the need for positional accuracy has prompted the development of standardized vertical datums. Once again, each major province or country has its own national standard datum of choice or design. They are used throughout the world for elevation-related reference and precision along the z axis. We will overview four commonly used vertical control datums for the Earth model, namely the Earth Gravitational Model of 1996, the GEOID03 reference family, the National Geodetic Vertical Datum of 1929, and the North American Vertical Datum of 1988.

Earth Gravitational Model of 1996

The Earth Gravitational Model of 1996 (EGM96) is the accurate collaborative product of the National Imagery and Mapping Agency (NIMA), the NASA Goddard Space Flight Center, and the Ohio State University. EGM96 is a geopotential model of the Earth, which means that orthometric height (height above MSL) is adjusted using the differential of gravity with latitude and elevation. Therefore, EGM96 offers heights that are influenced and adjusted by the Earth's gravity.

When working with models accounting the Earth's gravitation field, spherical harmonics are often used to approximate the shape and size of the geoid. A spherical harmonic is a single-valued, continuous, and complex calculation involving longitudinal and latitudinal angular coordinates. EGM96 utilizes a complete set (360 degrees) of spherical harmonic coefficients that offers accurate details of the entire geoid to regions as small as 55 km.

As a complex global reference surface, EGM96 details the variations between the MSL and the ellipsoid, discussed earlier as geoid-ellipsoid undulations (separations), and characterizes how uneven the Earth's gravitational potential is for the MSL.

Information for the development of EGM96 came from a collection of detailed surface gravity data, as well as direct satellite altimetry data, altimetry-derived gravity anomalies, and multisystem tracking of more than 20 satellites. This dynamic level of precision has earned EGM96 worldwide appeal and implementation. In fact, when EGM96 was first released, it was used as a geodetic reference to update WGS84.

As a well-defined global vertical datum, EGM96 is used as a modern reference for numerous applications worldwide, such as bathymetrical and geophysical studies.

GEOID03 and Predecessors

The U.S. Hybrid Geoid Model for 2003 (GEOID03) is a global vertical datum that calculates geodetic heights (height above the ellipsoid to the topographic surface) above the GRS80 ellipsoid. Developed by the National Geodetic Survey, GEOID03 is the latest revision to the U.S. GEOID model, superseding predecessors GEOID99, GEOID96, GEOID93, and GEOID90. With each revision came additional refinement and enhanced precision to the model. Although greatly used in the United States, GEOID03 is an excellent gravimetric geoid worldwide.

The GEOID03 model is considered a "hybrid" geoid, because it was developed using both a very precise gravimetric geoid (U.S. Gravimetric Geoid Model of 2003, or USGG2003) and updated NAD83 GPS ellipsoidal heights on leveled benchmarks (GPSBM2003). Incidentally, through this background infrastructure, GEOID03 is a derivative of EGM96.

GEOID03 remains the leading geoid model in the United States and the foundation for national models elsewhere in the world. The GEOID03 model is accurate to within 1.0 cm throughout the conterminous United States (CONUS). Since the geoid model is calculated using GRS80, it holds positional accuracy equivalent to GPS. In addition, conversion from NAD83 ellipsoidal heights to the North American standard vertical datum, NAVD88 (discussed later), are accurate to within a few centimeters.

The model's revision in 2003 is less obvious with respect to its predecessor GEOID99. Both are extremely similar, having backing from the national gravimetric geoid and NAD83 GPS benchmarks. The distinction is the countless, more explicit local definitions of orthometric heights throughout CONUS. Additionally, GEOID03 was modified in 2005 to reflect the orthometric height changes in the coastal Louisiana region resulting from a series of damaging hurricanes.

National Geodetic Vertical Datum of 1929

The National Geodetic Vertical Datum of 1929, known as NGVD29, is a geodetic reference for elevations based on a mean sea level datum. Formally known as the Sea Level Datum of 1929, NGVD29 has proved adequate for all areas in North America. Although it is an older vertical control datum that is slowly being superseded, it is still very much used throughout the United States and Canada. Many states and commonwealths still use maps based on NGVD29.

The main obstacle with using NGVD29 is that it is somewhat flawed. NGVD29 and its predecessor erroneously set a fixed elevation (zero elevation) by the MSL at 26 tide gauges in North America (21 in the United States and 5 in Canada). Since the Sea Level Datum of 1929 was first calculated more than eight decades ago, the MSL and the sea topological surface of the Earth have changed.

By May 1973, this gradual change in sea level was apparent and, technically, the implication of the old datum name was incorrect. The datum was no longer viewed as a reference to the MSL or geoid. This prompted the National Geologic Survey to change the name to the current National Geodetic Vertical Datum of 1929. Only the name changed; the outdated measurements remained unrevised. Needless to say, elevations measured using NGVD29 and Sea Level Datum of 1929 are different at different times.

During its lifetime, NGVD29 has grown flawed and has lost its usefulness in relation to positional accuracy. Geodesists can now measure these elevation differences more precisely with the latest advances in technology and a sophisticated geodetic network. Many U.S. state agencies and Canadian provinces have either begun or completed the chore of switching from NGVD29 to the more accurate North American Vertical Datum of 1988. In years to come, NGVD29 may be used less and eventually become obsolete.

North American Vertical Datum of 1988

The North American Vertical Datum of 1988 (NAVD88) is a vertical control datum first established in 1991. NAVD88 is considered a modern control datum that institutes what is called a minimum-constraint adjustment of leveling observations in Canada, the United States, and Mexico. NAVD88's minimum-constraint adjustment is a nominal modification to elevations based upon one tidal benchmark at Father Point/Rimouski in Quebec, Canada. The result is a very precise vertical control datum that is responsive with respect to geologic changes and is no longer tied to the time-altering MSL.

As mentioned previously, NAVD88 is superseding the older, less precise NGVD29. This process is not as easily implemented as one would expect given that each location in North America has a different conversion factor between the two datums. U.S. states and Canadian provinces have begun redrawing regional and height-sensitive maps (such as flood maps) with the new vertical control datum. Many regions provide area-specific conversions for use with the existing outdated maps. For instance, Wilkes County in North Carolina uses a datum offset of –0.48 feet and therefore calculates the NAVD88 elevation as the NGVD29 elevation – 0.48 feet.

Eventually, NAVD88 may be the only North American standard vertical datum used for vertical control and height accuracy. As we will discuss in the

next section, transformation software has been developed to help transform height data between NGVD29 and NAVD88.

Vertical Datum Transformation Methods

As with horizontal datums, there is a functional need to transform between different vertical control datums. As we know, heights are dependent upon the reference point (or zero elevation). There are many instances when height (elevation) transformation is warranted. You might want to reference a horizontal datum height to a gravimetric geoid or you might need to transform a height from an older vertical datum to a newer, GPS-precise datum.

Many horizontal datums provide a height quantity or distance along the z axis. To transform heights from one ellipsoid-based datum to a second ellipsoid-based datum, the Molodensky and Bursa-Wolf transformations continue to prove adequate. Both transformation methods were discussed in the previous chapter (horizontal datums), but allow for a position point's z-axis (height) transformation. The level of accuracy is based upon the ellipsoid origin and z-axis datum shift. This type of vertical position transformation does not account for the Earth's gravity field or the geoid.

A transformation from a horizontal datum height to a vertical datum height is sometimes required. These transformations involve referencing a gravimetric geoid, like GEOID03, between the horizontal and vertical control datum heights. For instance, transforming vertical positions from NAD83 to and from NAVD88 requires the typical height transformation with an implementation of GEOID96 or later. The transformation converts the position and the geoid model factors in the gravity field's potential.

The last form of vertical height conversion is a true vertical datum transformation—transformation from one vertical datum to another. The general impetus for implementing such a conversion is to transform older datum positions to newer, more precise positions.

The most common implementation of this transformation is between NGVD29 and NAVD88. To convert easily between the two vertical datums, the National Geodetic Survey devised VERTCON, a vertical model transformation method that computes the difference in orthometric height between NGVD29 and NAVD88. VERTCON was implemented to help state and county agencies revise their maps and charts from the older datum to the newer, GPS-based datum. Both datums utilize the same coordinate grid; therefore, VERTCON is considered a vertical grid transformation model.

The VERTCON model calculates the z value at any point in CONUS through the following calculation: z = NAVD88 − NGVD29. VERTCON highlights, through this simple mathematical equation, the varying inaccuracies

in the older NGVD29 datum. The VERTCON method utilizes a preprogrammed grid on which a transformation is calculated at every point on the ellipsoid. The resultant *z* values serve as a reference for every location in CONUS.

If you have an NGVD29 height to convert, the VERTCON model *z* value for that location should be added to the NGVD29 height (i.e., NAVD88 = NGVD29 + *z*). Alternately, if you have an NAVD88 height to convert, the VERTCON *z* value for that location should be subtracted from the NAVD88 height (i.e., NGVD29 = NAVD88 – *z*).

The VERTCON method is a common, much-used vertical datum transformation model that has warranted its own software. Whatever method you employ for height transformation, the end product will most likely be a more defined height position that not only will conform to modern accuracy standards but also will depict the precise orthometric heights in reference to a common Earth model.

9

The Map Projection

When was the last time you went into a gas station and purchased a projection of the Earth? Believe it or not, it was the last time you bought a road map. Atlases, world maps, and road maps are all projections of the Earth under well defined criteria.

The idea of depicting the Earth on a flat map is easy to imagine and rather simple to understand, but the actual process of a map projection is complex. Maps used in everyday life, as well as maps used in GISs, are created with a specific application in mind.

Mapmakers, or *cartographers*, use map projections to portray the real world with minimal aberrations. This chapter specifies these tools in detail and defines projection techniques and understandings that are not readily discernible from an everyday road map.

The Physicality of the Earth

Before discussing the *what* and *why* of a map projection, let us first recap a fundamental element of Earth science: the ellipsoid. The Earth's ellipsoid rotates upon a single, standard axis, making one full revolution every *sidereal day* (or 23 hours, 56 minutes, and 4.09 seconds). The Earth's overall shape is commonly defined and modeled as an *ellipsoid of revolution.*

More specifically, this axial rotation causes every location on Earth to experience sunlight and darkness, although within the artic and antarctic circles, the axial rotation creates increased lengths of sunlight and darkness. The Sun faces only a portion of the Earth at any given moment. This illuminated portion, over time, rotates beyond the range of sunlight and enters darkness. Almost

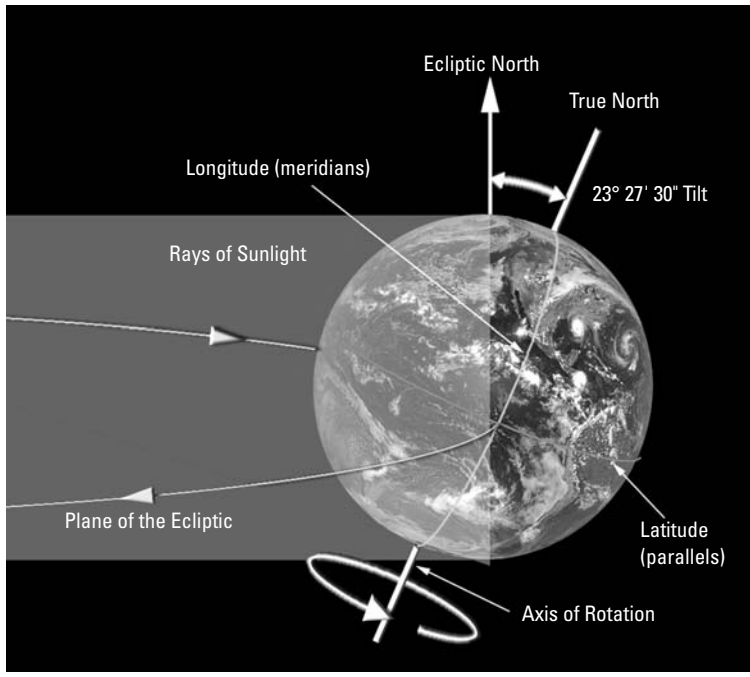

Figure 9.1 The physical Earth.

all locations on Earth experience sunlight and darkness in one day, but areas close to the poles (within the arctic and antarctic circles) experience longer daylight and nocturnal phases. This variance is a result of the Earth's tilt, which extends or diminishes a location's exposure to the Sun (see Figure 9.1).

The standard axis is perpendicular to the Earth's surface and intercepts the ellipsoid's surface through two distinct points known as the Earth's poles: the north pole in the arctic and the south pole in the antarctic. Figure 9.1 indicates this "axis of rotation."

The Earth revolves around the Sun with a single revolution taking 365.2564 days (known as a *sidereal year*) and defining a plane in space called the *plane of the ecliptic*.

The Earth's standard axis runs north and south and is tilted 23 degrees 27 minutes 30 seconds from the plane of the ecliptic. This tilt is the reason we experience the four seasons of the year. For example, in the summer, which starts with the summer solstice (June 21), the northern hemisphere is tilted toward the Sun, causing a rise in temperature. During the winter, which starts with the winter solstice (December 21), the northern hemisphere is tilted away from the Sun, causing a fall in temperature.

The Earth's ellipsoid is partitioned by a network of horizontal (east/west) and vertical (north/south) lines. The horizontal lines are called *parallels,* because they run parallel to one another, while the vertical lines are called *meridians*. The Earth has a prime meridian, which runs through Greenwich, England, and a central parallel called the equator. The equator separates the northern hemisphere from the southern hemisphere. In terms of the Earth's ellipsoid, each location along a parallel has the same *latitude*, or distance from the equator. Similarly, each location along a meridian has the same *longitude,* or angle between the target meridian and the prime meridian (0°). Although the meridians converge at the two poles, the parallels never converge.

The Earth is a complex three-dimensional object with physical dimensions, including height, width, depth, mass, and density. An important physical characteristic is its *curvilinear surface*, which is a surface consisting of or bounded by curved lines. The Earth's nonstraight, curvilinear surface is the sole reason why a latitude and longitude system is necessary. Figure 9.2 depicts the Earth model with its geographic coordinate system.

This curvilinearity also adds complexity to a map projection's transformation of the Earth model or *globe* to a flat surface. In fact, it is the primary reason why map projections are only cultured depictions of the globe and not exact representations. Due to the Earth's curvilinear surface, map projections always hold a degree of distortion.

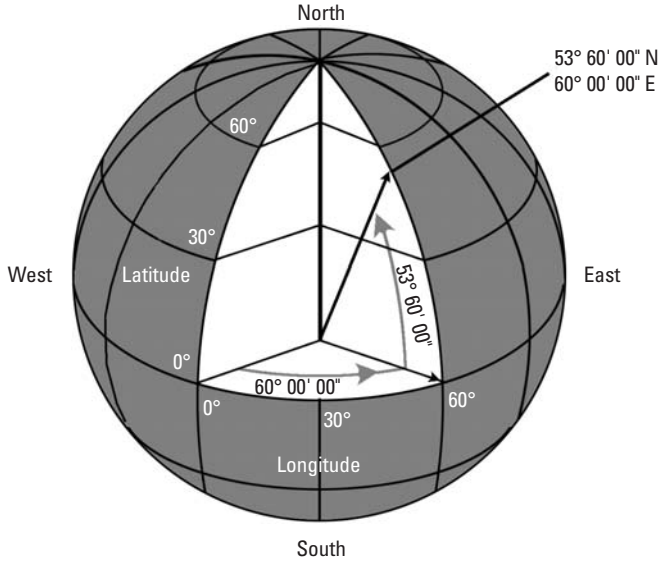

Figure 9.2 Earth model geographic coordinate system.

Scale Reduction: From the Ellipsoid to the Globe

Up until now we have discussed the Earth's ellipsoid in relation to its physicality and true size, but for the purposes of geospatial analysis the Earth's true dimensions are unwieldy. They are simply too large to realistically handle, manipulate, and compute. All GIS applications ultimately use an interpretation of the Earth at a reduced scale. For this reason, before a map projection can be created, the dimensions of the Earth must be reduced.

The process of proportionately reducing actual dimensions into much smaller, more convenient dimensions is called *scale reduction*.

Scale reduction depicts the projecting ellipsoid as a drastically scaled-down model, much like a tabletop globe of the Earth. The Earth's globe offers the user an easily accessible object, capable of depicting a range of geographic data at flexible vantages. Relative to GIS applications, the Earth's globe is typically used in the creation of map projections, since the ellipsoid proves unmanageable.

Let us look at the use of globes in map projections in a more fundamental way: Think of the Earth's globe as being made of transparent glass with a light emanating from its center in a darkened room. The images appearing on the walls in this room are projections of the globe, similar to the shadows around a lampshade as its light bulb burns bright. This Earth model is easily manipulated and projected and properly characterizes the importance of and need for scale reduction.

A scaled-down Earth is absolutely necessary for any GIS application. For instance, a road map printed on a 50-foot mainsail will do you very little good in the car at the stoplight. A letter-size map of the United States will prove futile in assisting you in finding the downtown of a major city from the suburbs. In summary, scale reduction must be used in the creation of map projections to transform the bulky ellipsoid of revolution into the more manageable and easily projected globe.

Transformation from the Globe

The basic purpose of a map projection is to transform the Earth's globe into a useable format for a specific application. A projection systematically transforms the geographic latitudes and longitudes on the surface of the ellipsoid into locations on a plane. Locations in three-dimensional space are arranged to correspond to a two-dimensional representation. Think of the Earth's globe in relation to a flat map of the world.

Projections that perform these systematic transformations from the globe are classified as *geometric*. Geometric projections are subclassified and defined according to the type of object the projection uses.

The geometric map projection methodically transforms all geographic coordinates on a globe into corresponding plane coordinates of a map space. Figure 9.3 illustrates this transformation. A basic projection formula can be expressed as

$$X = Function\,1\,(Latitude, Longitude)$$

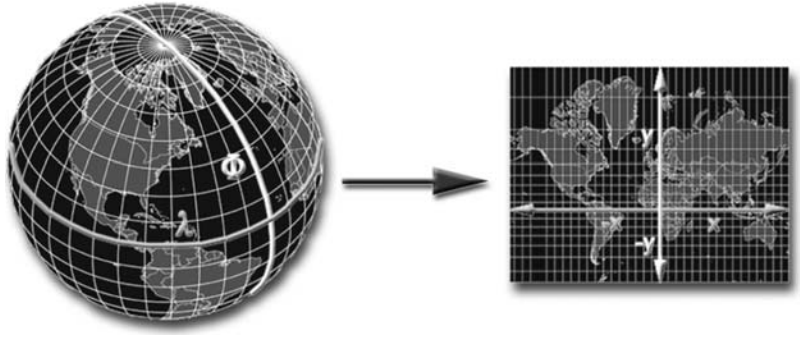
$$Y = Function\,2\,(Latitude, Longitude)$$

X and Y positions on the projected surface are functions of latitude and longitude, commonly represented by the Greek letters lambda and phi (λ and Φ), respectively. These functions must be unique to ensure that a particular point will appear at only one position on the map. They must be finite, or within a limit, so that a particular point will not appear at infinity. They must also be continuous, ensuring that although stretching or shrinking may occur, no gaps are introduced.

The geometric projection uses this formula and these projection methods to initiate a transformation, transferring latitudes and longitudes to locations on a surrounding surface.

What Is a Map Projection?

A *map projection* portrays a three-dimensional object, such as the Earth's globe, in a two-dimensional format. The map projection is quite simply the most intriguing component of coordinate system referencing because it offers a high



Geographic Coordinate System Plane Coordinate System

Figure 9.3 Moving from the Earth's geographic coordinate system to the projection's plane coordinate system.

level of flexibility. Projections are wholly graphical, as evident in the highly used Goode Homolosine map projection of the world (Figure 9.4).

The map projection employs projection formulas that perform the critical task of transferring a three-dimensional spheroid onto a two-dimensional plane surface. This is a complex process because the Earth, like other celestial bodies, is a complex object. While the projection is the easiest coordinate system component to visualize, the projection application is the most difficult. As you will quickly discover, an understanding of the projection application is vital to the success and usability of the transformation.

Map projections, by default, are not true or accurate portrayals of the globe. A two-dimensional plane cannot accurately represent large portions of the rounded, curvilinear surface of the Earth. Figures 9.5 and 9.6 illustrate the Mercator model and projection. Notice the shapes of North America and how different they are from in each other.

To show regions of the Earth on any appreciable area with accuracy, geographic data must be drawn to compromise the distortions of shapes, distances, and directions introduced by the spheroid. The various methods of preparing a two-dimensional plane from the surface of the Earth are critical for the accessibility and presentation of GISs.

The map projection is an important element in GIS. As discussed in the previous two chapters, we can comfortably surmise that datum superimposed upon the surface of the Earth's globe, or *ellipsoid of revolution*, establishes vertical and horizontal control for the specific area. The projection transforms this specific area from the curvilinear surface of the ellipse to a flat plane upon which an image is projected. This projected area is then implemented within a GIS.

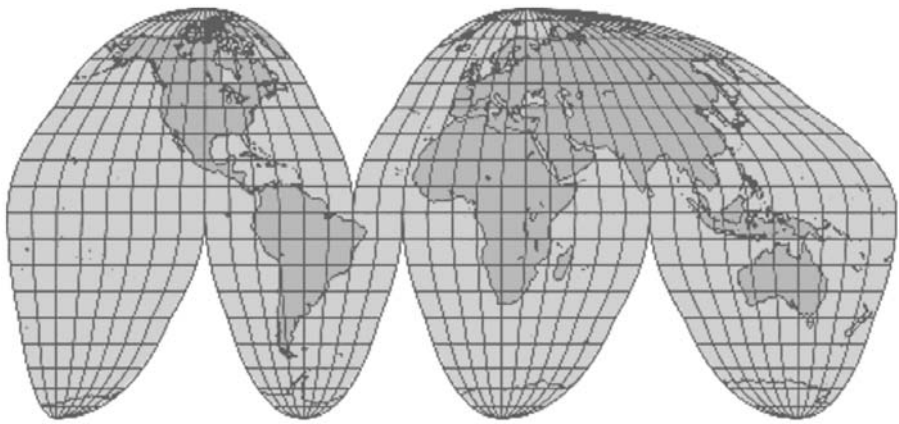


Figure 9.4 A Goode Homolosine 10° equal-area map projection of the Earth.

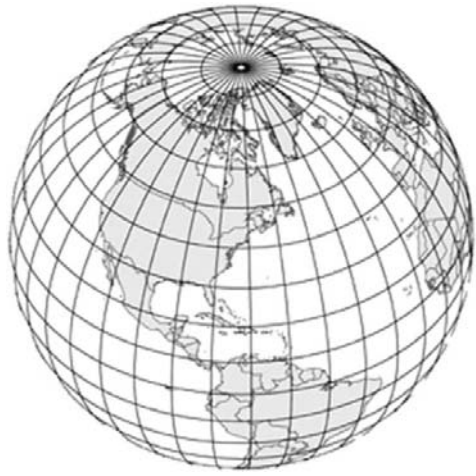

Figure 9.5 Geographic Mercator model.

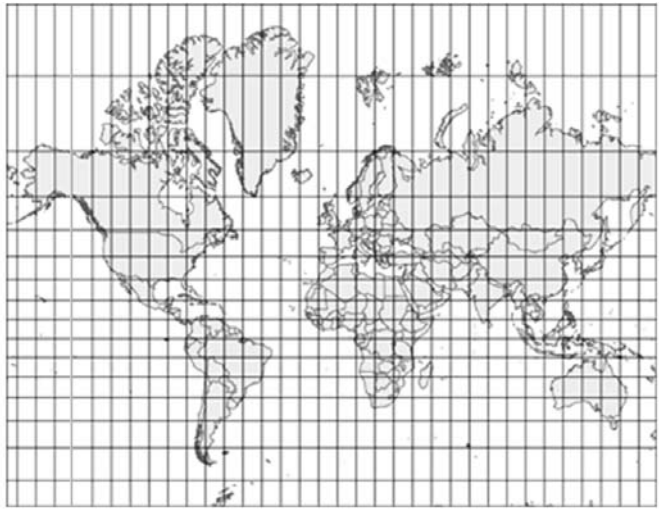

Figure 9.6 Planar Mercator projection.

The Grapefruit Peel Experiment

Let's look at the map projection a different way. Take an ordinary grapefruit and observe its spherical form. This tasty spheroid is a three-dimensional object that is similar, in form, to the Earth's globe. We will make a physical projection of one half of the fruit to help visualize a GIS map projection.

Using a flexible measuring tape and marker, draw a two-inch vertical line on the peel close to its "pole." With a knife, cut the peel perpendicular to the drawn line in one straight cut all around the grapefruit. The drawn line should be away from the peel cut. You can easily imagine each half of the cut grapefruit as a hemisphere. Now, carefully lift off the peel hemisphere (the one with the drawn line) and place it on a flat table so that the widest area is face down on the table. Notice that this object is still three dimensional and has retained the approximate curvature of the grapefruit.

Using the knife, cut the grapefruit's skin from the pole to the edge, keeping away from the drawn line. This step helps control where the skin will rip. With your palm, push down on the peel until it flattens. Creases and tears will form in various locations to compensate for the flattening of the curvature and to conform to the table surface. Once completely flat and neglecting the peel's thickness, the object has theoretically become a two-dimensional representation of the grapefruit hemisphere. Now let's examine this physical projection.

The flattened grapefruit skin does not look like a spheroid anymore and, with the peel's control cut and tears, has become distorted. Take that measuring tape and remeasure that two-inch drawn line. You will notice it is slightly less than two inches now, or that it is torn. The flattening process distorted the line's length, which is a measurement of distance, one of the four major map distortions discussed latter in this chapter.

You have now made a physical (and conic type) projection of the grapefruit. A GIS map projection functions in much the same way as the grapefruit peel experiment, though not quite as crude. When projecting a three-dimensional object onto a two-dimensional plane, various distortions and aberrations occur to functionally portray the object. Maps of the Earth's globe do not precisely depict the real shape of each continent but project the adjusted flat version of the curved landforms. Unlike the grapefruit, tears, aberrations, and distortions can be easily manipulated through projection equations.

Choosing a Map Projection

One of the more difficult parts of the map projection process is the selection of the best projection type for the application. Not only must you fully understand the object being transformed onto the flat surface, but you must also understand the desired properties you want to exhibit.

When choosing a projection, the purpose of the application must first be recognized. Then, once the purpose is understood, a strategic plan can be developed to determine those features that need to be preserved and those features that can be compromised by relative distortion. Even variations of the same projection can be selected for more accurate depictions in specific applications, such as the two Bonne projections in Figure 9.7.

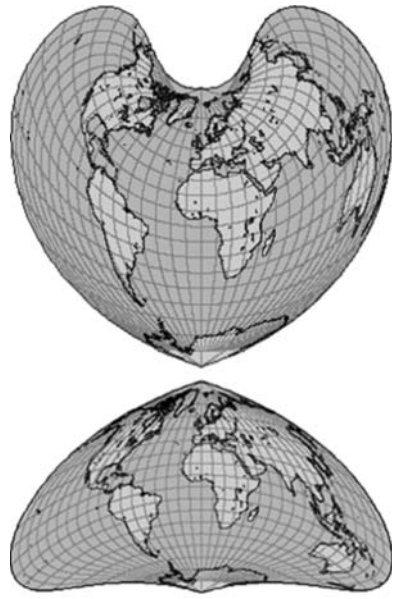

Figure 9.7 Two variations of the Bonne projection, a large-scale topographic map projection: central parallel 45° north (top) and 15° south (bottom).

The projection process is, by far, not a natural rearrangement of aspects from the three-dimensional surface. It is a mathematical condition superimposed on a natural surface to accommodate a man-made interpretation. As a result, the projected plane always has some degree of inherent distortion.

There are four important properties of the Earth model that can be tactically preserved during a projection process: *area*, *shape*, *distance,* and *angles*. These four elements are the essential pawns when projecting a surface. You must come to terms with the hard truth involved in portraying the spherical shape of the Earth on a nonspherical surface: Preserving accurate representations of all four elements simultaneously is impossible.

Important, even vital, characteristics for any projection must be identified and specifically defined early in the process. The proper type and classification of projection capable of preserving these characteristics should be tested, selected, and then implemented. If time is taken to accurately plan a projection, control of the projection will be retained and the various ill side effects from the process will be minimized.

Choosing a map projection involves more than planning; it involves decisions and an understanding of how best to represent the spheroid. Aside from manipulating the four projection elements, there are other choices and degrees

of flexibility available when creating the best map projection for a particular application. The ability to choose the projection's *type*, *aspect,* and *classification* is the ultimate tool for achieving the desired projection properties and for controlling distortion. The following discussions categorically detail each decision element.

Types of Map Projections

As tools in the projection toolbox, there are three distinct types of projections that can be utilized on the projected plane: *cylindric, conic,* and *planar*. Commonly known as *developable projection surfaces*, these types are selected on the basis of characteristic curves. The projected plane inherits the display characteristics associated with each projection type and forms what is called a *graticule*. A graticule is basically a grid of meridians and parallels.

Each projection type implements a particular graticule as a base projection surface. During a projection, a three-dimensional object is transformed onto the projection type graticule and takes advantage of the built-in characteristics. Let us discuss each major projection type further.

The Cylindric Type

The *cylindric* projection type takes on the appearance of a rectangular graph with an *x* (parallel) and a *y* (meridian) axis (see Figure 9.8). The globe's longitudal meridians and latitudes are represented by equidistant, parallel straight lines that intersect one another at right angles. The cylindric type projection is a strict grid representation of the curvilinear surface that is true at the equator and increases in distortion toward the poles.

The Mercator projection is a good example of the cylindric type. The graticule consists of equally spaced meridians but unequally spaced parallels. As the parallels get closer to the poles, the spacing between each becomes wider. With this increase in width, there is an increase in distortion. Therefore, the distortion increases as the projection moves toward the poles. This projection type also safeguards the integrity of features at the central parallel (such as the equator in a world projection) and the regions in proximity.

The Conic Type

The *conic* projection type is fan shaped, characterized by an upside down cone over the sphere. The meridians are represented by a system of equally inclined concurrent straight lines, and the parallels are represented by two concentric circular arcs. The angle between any two meridians on the projection is less than their true difference in longitude on the sphere. Refer to Figure 9.9.

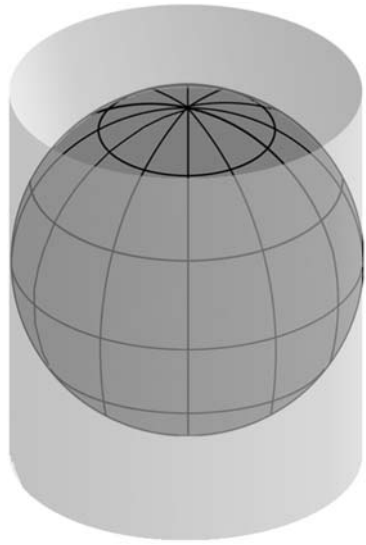

Figure 9.8 The cylindric projection.

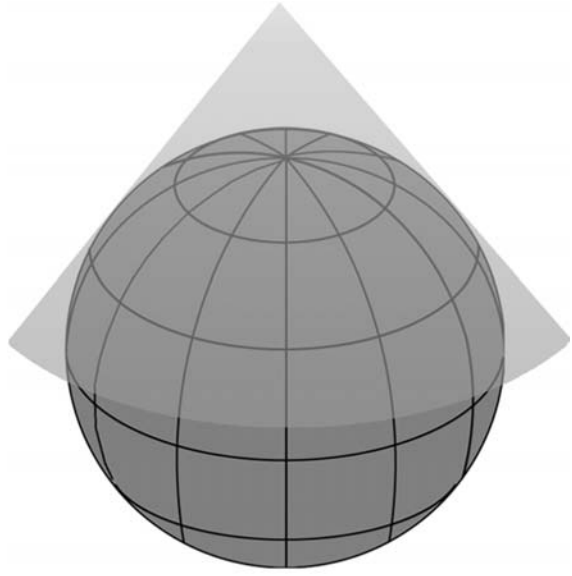

Figure 9.9 The conic projection.

Conic classifications are at an exact scale along a particular parallel, or standard parallel, between the equator and a pole. Distortion increases away

from the standard parallel. According to famed map projectionist John P. Snyder, a typical conic projection will require the definition of two true-scale standard parallels demarking an area of interest.

GIS conic projections will match between geographic data sets only if the standard parallels are the same for every geographic data layer. Current popular conic type projections are the Lambert conformal conic, also known as the American polyconic, used in state plane systems, and Albers equal area, used in small-scale mapping.

Planar Type

The *planar* projection type is an azimuthal orientation of a projected surface, which means that it pertains to the angle (usually in degrees) of an object around the horizon that is measured from north to east. The planar type protects the integrity of azimuths, bearings, and directions from a central point to other more remote points in the plane. Therefore, planar projections are true only at their center point.

The planar graticule represents meridians as straight lines that incline toward each other at their true longitudal difference. Parallels are represented by a system of concentric circles with their common center at the point of converging meridians or pole. The distortions in the planar type tend to be most prevalent along the edges of the projected plane surface. Figure 9.10 illustrates a simple planar projection scheme.

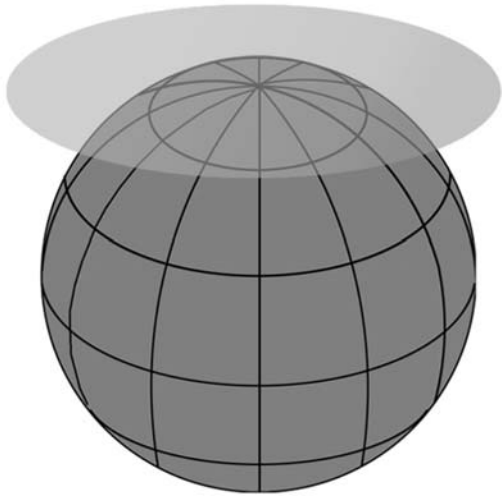

Figure 9.10 The planar projection.

The Aspect of Projection

Projection *aspect* is the relative orientation of the projected plane and the ellipsoid of revolution with respect to the location of an observer. Aspect is a natural projection property. Common with every projected surface is a standard aspect—a point or line of bearing and magnitude on which any given projection is centered.

Take another grapefruit and draw a large dot to represent a pole on opposite ends. First hold it out straight, observing its side with the poles to the north and south. Now twist it around and observe different views of the spheroid. You have the ability to observe the grapefruit from any side, from either pole, at any angle, and somewhere in between. This is exactly what a projection aspect is like; you can view the map projection from various viewpoints by manipulating the angle.

Bringing this projection tool into perspective, there are four predominant types of projection aspects: *normal*, *transverse*, *oblique,* and *polar*.

The *normal aspect* (Figure 9.11) is based upon a standard line along which distortion is minimized. The farther you move away from the standard line, the more the distortion. If this standard line is coincident with the equator, or central parallel, its aspect is considered to be *equatorial*. A normal aspect is considered *azimuthal* if the standard line connects to one of the poles while the axis of

Figure 9.11 Normal aspect.

the projection (conic or cylindric) is coincident to the axis of the ellipsoid of revolution.

An aspect is said to be *transverse* (Figure 9.12) when a standard line (normal) aspect is rotated 90 degrees. This transverse aspect projection minimizes distortion along meridians and can have azimuthal or equatorial alignment.

In the *oblique* aspect (Figure 9.13), the axis of the Earth and the axis of the projection are oriented in an arbitrary manner. The oblique aspect is uniquely suited to be used for geographic areas that are centered along lines that are neither meridians nor parallels but are assumed to be "great circles" passing through the region. Distortion is minimized along the central or prime meridian in a projection. An oblique aspect is often difficult to represent as the graticule for the projected plane. Of the nine potential directions, oblique aspect types tend to be directed northwest, northeast, southwest, and southeast.

The *polar* aspect (Figure 9.14) centers on a single point, either the north pole or the south pole. Meridians are subsequently depicted as straight lines radiating from this pole outward toward the equator. Angles between these meridians are always true in relation to the longitudal distance on the Earth's globe. Latitudes (parallels) are equally spaced concentric circles radiating from this same source pole. Polar aspect projections retain symmetry about any meridian and distort between them.

Classification of Map Projections

The classification of map projections, or *projection classifications*, is used to further organize projection types and serve as another tool to gain better results for

Figure 9.12 Transverse aspect.

Figure 9.13 Oblique aspect.

Figure 9.14 Polar aspect.

an application. While the *types* determine the specific method of physical projection, the *classification* defines the properties of the projected surface. Projection classifications ensure that not only that the desired traits required of the application are satisfied but also that the desired parameters are preserved.

There are four primary projection classifications:

1. Equidistant;
2. Azimuthal;

3. Equal area;
4. Conformal.

Projected surfaces can exhibit the properties of several classifications simultaneously, though any surface will potentially distort shapes, areas, angles, or distances at some level. Since all distortions can be measured or estimated, the selection of an adequate projection requires specific knowledge of the application. As a result, the three types of projections (cylindric, conic, and planar) can be combined with one or more of the projection classifications to control the appearance and distortion for any particular application.

For example, a planar equal-area projection preserves both angles and areas. The region of interest is accurately represented in size while angles to other locations are also preserved. The *distances* between the area of interest and other locations are absorbed by the distortion.

To wholly understand how these classifications aid in accurately projecting three-dimensional objects, each is discussed in detail.

Equidistant Projections

A projection is considered *equidistant* (Figure 9.15) when scale is true along at least one line (a focal line) or from one or two points (focal points) to all other points on the projected surface. The focal points are usually at the projection center or some other approximately central location on the surface.

Although no projection can provide a developable surface with a perfectly uniform scale, equidistant projections retain a true scale along these explicit focal features (focal lines and points). Consequently, if these focal features are properly developed, the entire projection surface will benefit from their true scale. For example, a sinusoidal projection can be classified as equidistant because all parallels and the central meridian are shown at true scale.

As another example, an equidistant projection centered on Bangkok, Thailand, will provide true distances from Bangkok to any other city in the world, such as Dallas, Texas, or Dublin, Ireland. However, that same projection will distort the relationship of distance between Dallas and Dublin.

Azimuthal Projections

In an *azimuthal* projection, all points in relation to a central point (such as a pole) are not deformed during the projection process from globe to plane. The central point occurs at the intersection of the tangential plane to the ellipsoid of revolution, or, simply, where the projection plane and the projected object meet. Azimuthal projections preserve the angular relationship of all features in a plane to the central point. This central point has zero distortion because it is the

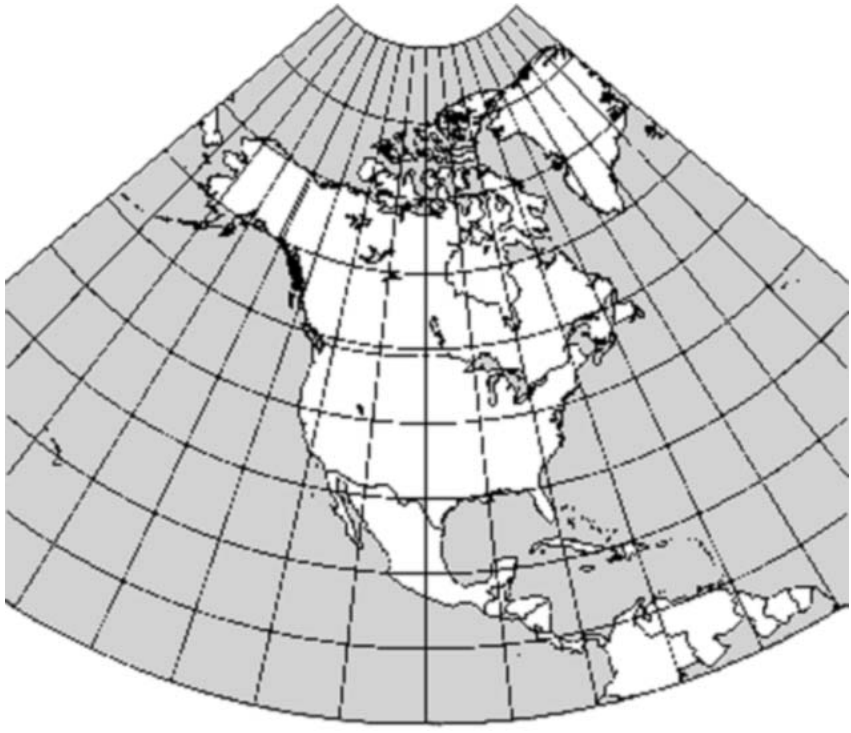

Figure 9.15 An equidistant conic projection of North America.

only point that is being truly represented in the projection. Consequently, distortion gradually increases as distance from this central point increases.

Azimuthal projection classifications are somewhat limited in that they correctly depict directions or angles to all other points in the projection with respect to one or rarely two central points. Figure 9.16 has only one central point, the North Pole.

Equal-Area Projections

The classification is considered *equal area* when the relative sizes of all features on a globe are maintained during the projection process. An equal-area projection vigilantly retains area properties of the spheroid on the plane surface through the use of compensatory scale factors. This means that if area is to be preserved but scale cannot be, then any given feature on a globe (such as a state) requires a scale factor greater than 1.0 in one direction and less than 1.0 in the other direction. Both scale factors compensate for one another and, in doing so, retain the area characteristic.

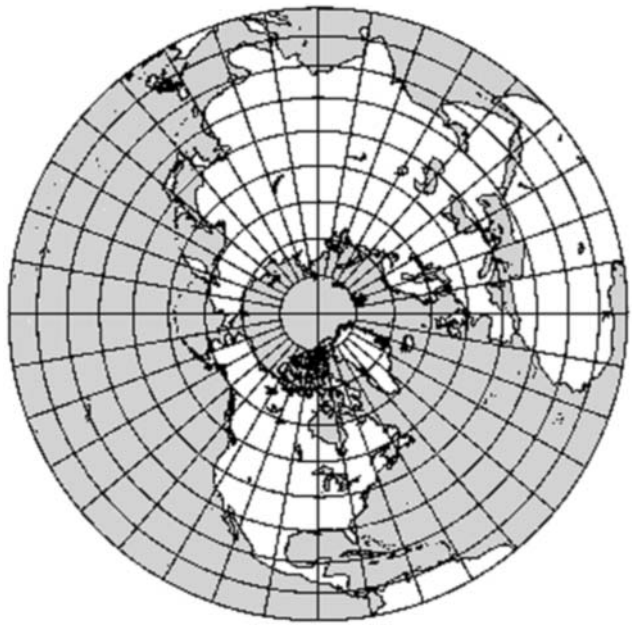

Figure 9.16 Lambert azimuthal equal-area projection of the Earth.

Using compensatory scale factors in equal-area projections, a circle on a globe will project as an ellipse on a plane surface. For example if a coin is placed on any area of a projected surface, it will cover as much of the surface of the sphere as if it were placed elsewhere on the projected surface.

When an equal-area projection is used for small-scale applications that show larger regions, such as in Figure 9.17, the distortion of both angles and shapes increases as the distance of an area from the projection origin increases. Although multiple projection classifications can be concurrently employed, a projection surface cannot exhibit equal-area and conformal classification properties simultaneously.

Conformal Projections

Unlike equal-area projections, *conformal projections* have equal scale factors in all directions at any one point on the projection surface. Instead of preserving area or size, conformal projections preserve shape. For this reason they are also referred to as *orthomorphic* projections.

A conformal surface is also defined as a plane on which all angles at infinitely small locations are correctly depicted. This projection classification increasingly distorts areas away from the point or lines of true scale (a scale

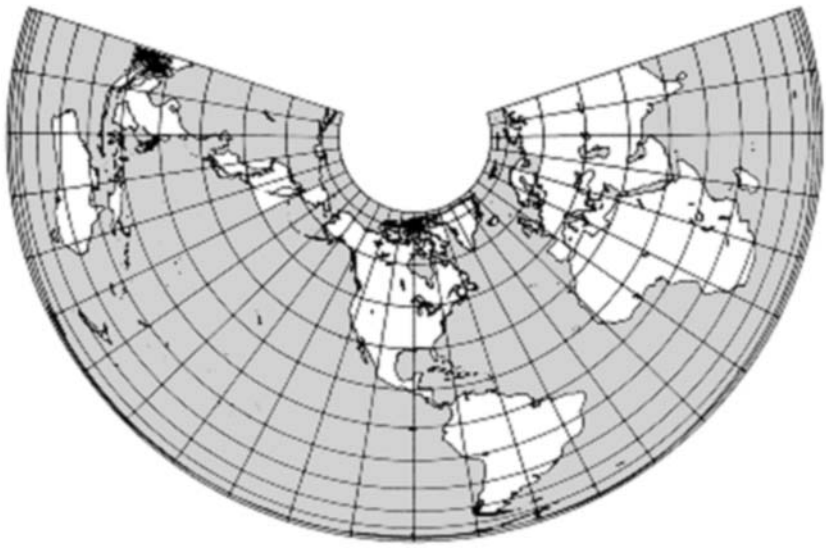

Figure 9.17 Albers equal-area conic projection.

factor of 1.0) on the plane. A good example is the Lambert conformal projection (Figure 9.18). Conformal projections, like the Lambert projection, are ideal for medium- to large-scale projection applications.

Conformal projections are also ideal for constructing plane coordinate systems for use in regional grids. These projections are conducive to managing groups of adjacent systems. Since there is a single scale factor controlling the

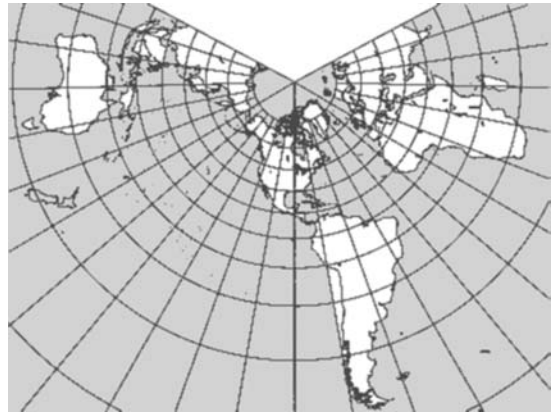

Figure 9.18 Lambert conformal conic projection.

projection, angles retain their integrity in the projected surface. This scale factor, generally not true scale, applies to all distance measurements, unless the distance is of great length or precision. For example, a circle on the globe will render as another, smaller circle in the conformal projected surface.

Distortion

Now that we have discussed the basic tools to transform a three-dimensional object and manipulate the projection, we must look at distortion. We know that the presence of feature distortion is unavoidable when a three-dimensional surface is reduced and projected to a two-dimensional plane. In order for a feature or set of features to be projected without appreciable distortion, it must be *explicitly accommodated* by the entire projection structure (i.e., classification, type, aspect, and so on). Features that are not explicitly accommodated may or may not incur the distortion of geometric properties, regardless of the intention.

The goal of any projection is to minimize the effects of unwanted distortion; therefore, a clear segregation of explicitly and nonexplicitly accommodated features must be made. Geometric integrity is compromised or sacrificed in one feature for the benefit of another. The distribution of these features varies by situation and the specific application.

Distortion Type

Projection distortion is a window into the projection, where its true strengths and weaknesses are revealed. Though most projection distortion is angular or *areal*, a projection can potentially distort five spatial properties of a developable surface: *area*, *angle*, *shape*, *distance,* and *direction*.

For each of these spatial properties there are two primary considerations: How much distortion is present and what is the effect of distortion in the projected surface?

Distortion Magnitude, Distribution, and Overall Effect

Distortion magnitude, or the amount and density of distortion in a projection, answers the question: How much distortion is present? A general rule of thumb is that the larger the area, or *region of interest*, the more pronounced the distortion becomes. This is particularly noticeable in small-scale applications, where distortion magnitude is at its peak. A fine example of a small-scale application is the world map. In small-scale applications, the projection area is large and the scale factor is small, whereas in a large-scale application the projection area is small and scale factor is large.

Small-scale distortion, especially in the world map application, is an issue that has captivated scientists for nearly 3000 years. In fact, Greek astronomer Claudius Ptolemy (circa 150 A.D.) worked with geospatial projections on a small scale, while projections, in general, are known to have been in use some three centuries earlier.

The *overall distribution* and effect of substantial geospatial distortion is often apparent to the eye. By just looking at the projection, you can see where the distortion occurs and how this distortion affects the surface features. For example, a Mercator projection of the world shows the area of Greenland larger than the area of South America, when in reality the area of Greenland is a fraction of the area of South America. These landforms are profoundly affected by the increasing distortion of the Mercator projection toward the poles. The Mercator projection retains the integrity of angles but not areas, resulting in a distributed surface that visibly distorts the appearance of substantial northerly and southerly features.

As discussed previously in this chapter, projection classifications can be used to minimize certain forms of distortion. Classifications enable the user to manage the overall distortion distribution and effect for a specific application. For instance, if a Mercator is projected on an equal-area surface, the area of landforms is retained while the other feature characteristics, such as angles, shapes, and distances, are compromised. Manipulating distortion for a particular application is your best means of properly creating and using a projection.

The Tissot Indicatrix

In 1881, cartographer Nicolas Auguste Tissot published his groundbreaking approach to distortion analysis, now known as the *Tissot indicatrix*, in *Memoire sur la Representation des Surfaces et les Projections des Cartes Geographiques.* The Tissot indicatrix is a helpful tool for visually modeling distortion and for graphically analyzing the distortion properties in a projected surface. Tissot's approach to distortion analysis was clearly the most innovative in his day and still remains an effective method of interpreting a projection. He first began describing this approach as early as 1859, and it has now joined other nineteenth-century mathematical and geographic innovations like the least-squares method or conformal mapping.

The success of the Tissot indicatrix resides in that it is a simple method for visualizing distortion. It has two primary elements: the projected graticule and geometric deformation indicators. Simply stated, the indicatrix depicts the projected graticule as a distortion graph and shows distortion as circles or ellipses at the specific intersections in the plane. A circle represents conformality (no distortion in shapes), while the relative flattening of an ellipse represents the extent

and type of local distortion at the intersection where the object is plotted. These circular or elliptical objects, known as *geometric deformation indicators*, are fixed at a finite scale with explicit locations in the projected surface.

Figure 9.19 depicts a basic Tissot indicatrix with deformation indicators. Figure 9.20 illustrates a standard transverse Mercator projection with its related Tissot indicatrix. Notice how the distortion indicators become larger as they move away from the two central points.

Geometric deformation indicators are circles or ellipses that represent the distortion scale factor at the intersection of any perpendicular graticule line set on the ellipsoid of revolution. The determination of such indicators is the primary driving concept of Tissot's indicatrix and projected surface deformation theory.

Tissot also treats the projected space as a plane with the same size as the region of interest on the reference ellipsoid. For instance, an infinitely small circle on the surface of the Earth model (reference ellipsoid) is identical to an infinitely small circle on the surface of the projected plane.

For the purposes of enhanced visualization and practical appearance, the indicators are significantly enlarged in the indicatrix graph. Although not drawn to scale, the indicators are scaled proportionately to other indicators in the same solution. Accordingly, these geometric deformation indicators depict the characteristics of the projected plane at or nearly at the intersection where they are plotted.

Figure 9.20 (a) Transverse Mercator projection and (b) its Tissot indicatrix.

Methods for Distortion Management

We have discussed map projection distortion in great detail within this chapter but have mildly addressed methods for distortion management. The following methods are tried and true ways to manipulate and manage distortion within any geospatial projection.

Redistribution of the Scale Factor

A proven method of manipulating the effects of and controlling the location of distortion is to modify or redistribute the scale factor. As discussed in detail previously in the chapter, all dimensions of the Earth are changed proportionately when the Earth is reduced from actual dimensions to a globe model. As the surface of this generating globe is further transformed into a projected surface, some dimensions remain unchanged. For example, in a cylindrical projection, as the cylinder is unrolled and developed, the equator maintains its original length and true scale. This *standard line* or line of exact scale is represented by a true scale factor value of 1.0.

The scale factor on any projected surface can vary at any location, since no projected surface has a uniform scale. Scale within a projected surface may also vary at different *directions* at the same location. For instance, in a particular conformal projection the scale is 1.0 (true) along each standard parallel, while other points between the standard parallels are at a scale *less than* 1.0. Accordingly, points outside the standard parallels are at a scale *greater than* 1.0. The resulting conformal projection creates a continuous error surface, in which any line (other than a standard parallel) within the plane has a unique scale factor and any line of substantial distance crosses many different scale factors.

Proportional to the original object, scale factor has innate characteristics that are linear in nature. For example if a line is doubled in length by the projection in the output surface, the scale factor of the projection is 2.0.

A basic formula to use when calculating the scale factor for distortion manipulation is

$$Scale\ factor = \frac{Distance\ on\ the\ projected\ surface}{Distance\ on\ the\ spheroid}$$

Distortion can be manipulated by redistributing the scale factors of the standard lines. The shorter the distance between the standard lines, the lower the distortion, and conversely, the longer the distance, the greater the distortion. A good implementation of this method is to position your particular area of interest in between two standard parallel lines. The projected area benefits from the true scale factor of the standard lines, while distortion is significantly reduced within the projected area.

Changing Projection Aspect

A change in the projection aspect is the most obvious and fundamental method to minimize unwanted distortion. Simply put, it is a change in the location of the projection's center point. When a projection aspect is changed, the distortion pattern in the projected map space is modified whereby areas of least distortion are relocated. An adept user can determine which projection aspect offers the most advantageous distortion relocation for the specific application.

Other Successful Methods

Aside from the two most prominent projection distortion management techniques, there are alternative methods that have proved adequate for particular applications. Here are some fine methods to employ:

- *Visual-logical analysis.* A visual examination of graticule patterns is useful for identifying local distortions (anisotropy).
- *Familiar shapes.* Recognizable features, such as coastline shapes or inland characteristics, provide important clues to distortion patterns and imbue an overall impression of major distortion points.
- *Color differentiation.* Mapping three color scales at locations within the developable surface provides insight into the projection distortion patterns. Color scales are imposed upon the *x, y* range and angular convergence parameters. Prominent differentiation between color scales offers a clear layout of definable distortion points. This color differentiation method lends itself to the structure of raster data.
- *Isarithms (isolines).* The isarithm method provides a good vantage of the overall distortion patterns in a projection. Isolines are basic contour lines that identify the differing plateaus of distortion within the projection. The result can be likened to a topographical map with designations not of elevation but of distortion magnitude. This is particularly helpful in the analysis of equal-angular or equal-area distortion. However, like the indicatrix, isarithms are static objects that are unable to accommodate the diversity of continuous application.

As we have discussed throughout this chapter, a well-planned and adeptly created map projection is critical for the basis upon which to build a GIS. In fact, the success or failure of the application resides initially with the projection. A good understanding of the final application and a basic command of projection elements will ensure a solid GIS foundation.

10

The Coordinate System

Up to this point, we have only touched the surface of coordinate systems, both in theory and function. In the past chapters, especially the chapter on map projections, coordinate systems have taken a nominal role in support of the main topic. We have already heard the likes of geographic and plane coordinate systems but have discussed very little about what these systems do. Concluding this book's theory-intensive Part II to understand the core GIS environment, we will explore coordinate systems and the role they play in a GIS.

What Is a Coordinate System?

A *coordinate* is a number set that denotes a specific location within a reference system. Typical coordinates are the *x*-*y* set ([*x*, *y*]), which is used in a two-dimensional system, and the *x*-*y*-*z* set ([*x*, *y*, *z*]), which is used in a three-dimensional system. With that stated, a coordinate system is the reference system upon which coordinates are defined. A coordinate system is often structured in a two-dimensional or three-dimensional plane that consists of a set of reference points and rules that define the spatial position of points.

In reality, coordinate systems are extensions of mathematics, particularly algebra and trigonometry, and come in various formats. Planar systems have *x*- and *y*-axes, while three-dimensional systems have an additional *z*-axis for height. Terrestrial coordinate systems, such as the ones on geographic maps, utilize a system of latitudinal and longitudinal coordinates. Polar reference systems utilize positional coordinates consisting of the distance from the origin *r* and its angle of inclination Θ. Ultimately, each coordinate system format is used on a specific type of plane.

Coordinate reference systems can also be created for specific regions or particular applications. For instance, the New York City is considered a structured, planned city, whereby streets and avenues intersect, forming a defined grid. Essentially, this is a citywide reference system upon which positions can be easily defined and understood. You can say your position is at 44th Street and 6th Avenue and immediately your position is understood within the boundaries of the city.

This same premise goes for road maps, which commonly have a zoned grid defined by horizontal numbering and vertical lettering. These zones do not define exact positions, but a grid rectangle (area) in which the target resides and the locator can search. For example, you can find a particular town by locating and searching its particular zone (i.e., A6). If there are multiple page maps, the zone must be detailed with the page number (i.e., page 6, A6) since most multipage maps use the same grid identifiers on each page. This procedure of "zeroing in" on a target's position dramatically reduces search times and is comparable to stating the city street you are on (zone) and not the actual address (position).

Mathematics and the physical Earth require the use of various standard coordinate systems. In relation to GIS and geodesy, there are a handful of important reference systems worthy of discussion and necessary for the novice GIS user to understand. These coordinate systems include the Earth-based geographic coordinate system, the vector-based Cartesian coordinate systems (both two-dimensional and three-dimensional versions), the zone-based Universal Transverse Mercator and Universal Polar Stereographic systems, and the U.S.-based State Plane Coordinate System. Let us take a brief look at each.

The Geographic Coordinate System

A geographic coordinate system is a three-dimensional positional reference that utilizes latitude, longitude, and ellipsoidal height. We have briefly explored the geographic coordinate system in our map projection discussion. This positional reference system is among the most used today for global locations and is typically associated with geodetic datums.

To recap, the Earth's three-dimensional ellipsoid is mapped through a series of horizontal and vertical reference lines, which form a set of standard reference lines. As we know, the horizontal lines are called *longitude* lines. Longitude lines are parallel with one another and are therefore often called *parallels*. The vertical lines are called *latitude* lines. Since latitude lines meet at the poles, they are often called *meridians*. Figure 10.1 illustrates Earth's latitude and longitude lines.

Earth's parallels intersect every meridian at right angles. The central parallel, located exactly between the poles, is called the equator. This central,

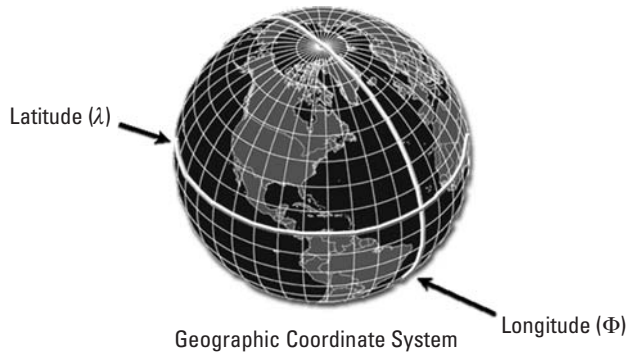

Figure 10.1 Earth's latitude and longitude.

standard parallel holds a longitudinal value of 0°. The remaining parallels are assigned angular values relative to their direction and distance from the equator. The lines of longitude progressing toward the north pole are assigned parallels ranging from 0° to 90° north. Likewise, the lines of longitude progressing from the equator toward the south pole are assigned parallels ranging from 0° to 90° south.

Earth's meridians run from pole to pole, and unlike Earth's parallels, meridians convene at each pole. The center meridian is called the prime meridian, which is the line of latitude that crosses through Greenwich in the United Kingdom. The prime meridian is the primary latitude reference line and is assigned an angular value of 0°. The remaining meridians are assigned angular values relative to their direction and distance from the prime meridian. Meridians progressing east of this center meridian are assigned angular values ranging from 1° to 180° east. Similarly, the lines of latitude progressing west of the center meridian are assigned angular values ranging from 1° to 180° west.

The geographic coordinate system uses geodetic latitude and longitude to define position on an ellipsoidal surface and, as such, to form the geographic coordinates. Geodetic latitude and longitude are identical to the Earth-based system. In addition, the geographic coordinate system provides a quantity for geodetic height. Geodetic height at a point is the distance from the reference ellipsoid to the point in a direction normal to the ellipsoid. Figure 10.2 illustrates the geodetic latitude, longitude, and height.

The geographic coordinate system provides a solid reference through which any location on Earth can be uniquely distinguished and identified. As we have seen with map projections, GIS generally transforms three-dimensional geographic coordinates to other coordinate systems in order to clearly portray point positions on a two-dimensional information product. This leads us to our second coordinate reference system, namely, the Cartesian coordinate system.

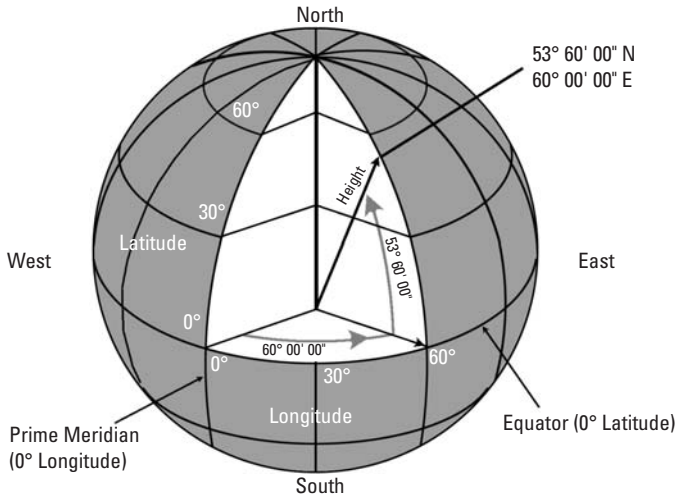

Figure 10.2 Geodetic latitude, longitude, and height.

The Cartesian Coordinate System

Perhaps the most used coordinate reference system in mathematics, science, and GIS is the Cartesian (or rectangular) coordinate system. The Cartesian system is a reference structure in which point positions are measured along intersecting planes in two and three dimensions. The common coordinate or intersection point for all planes is called the origin. All measurement distance increments are consistent on every intersecting plane and throughout the system. These planes are detailed along the *x*, *y*, and/or *z* axes.

The Cartesian coordinate system was named for famous French mathematician, scientist, and philosopher René Descartes (1596–1650). Descartes, known also as Cartesius, is often dubbed the "Father of Modern Mathematics" for his mathematical genius and his creation of analytic geometry. In his *Discourse on the Method to Rightly Conduct the Reason and Search for the Truth in Sciences* (usually shortened to *Discourse on Method)*, Descartes detailed his method of translating geometric problems into algebra using a coordinate system. This mathematical innovation paved the way for later mathematical advances, particularly calculus.

The Cartesian two-dimensional coordinate system involves two axes: the horizontal *x* axis and the vertical *y* axis. The origin is detailed as coordinate (0, 0). This planar, two-dimensional model is divided into four quadrants by the perpendicular, intersecting axes. These are labeled quadrants I through IV, starting in the upper right-hand quadrant and progressing counterclockwise. These quadrants take on the following structures:

- Quadrant I: *x* axis is positive, *y* axis is positive (+*x*, +*y*);
- Quadrant II: *x* axis is negative, *y* axis is positive (−x, +*y*);
- Quadrant III: *x* axis is negative, *y* axis is negative (−*x*, −*y*);
- Quadrant IV: *x* axis is positive, *y* axis is positive (+*x*, −y).

Figure 10.3 offers a good line drawing of the standard two-dimensional Cartesian coordinate system.

As you might have guessed, the Cartesian coordinate system is perfect for plotting and measuring vector-based feature geometry. A GIS references the positions of feature-defining points, lines, and polygons using the Cartesian system of coordinates. In addition, you may remember that a map projection brings three-dimensional geographic coordinates (latitude and longitude) into two-dimensional Cartesian (or planar) coordinates.

Often points are located in a three-dimensional space and a height measurement is necessary. Height is measured along a third axis—the *z* axis.

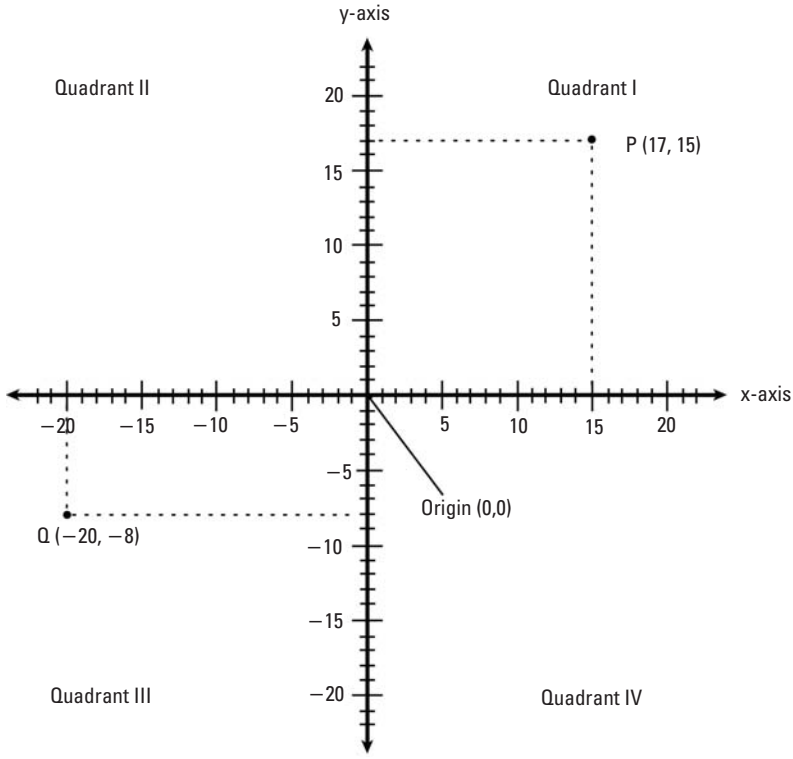

Figure 10.3 Two-dimensional Cartesian coordinate system.

Three-dimensional objects, like the Earth's ellipsoid, utilize a height measurement for positional accuracy. Consequently, geodetic datums use this system. Figure 10.4 details the three-dimensional Cartesian coordinate system.

Frequently, the Earth is set to a three-dimensional Cartesian system called the *Earth-centered, Earth-fixed* (ECEF) Cartesian coordinate system. ECEF is used to define three-dimensional positions with respect to the earth's mass center of gravity and the center of the reference ellipsoid. The Earth's center serves as the origin (0, 0, 0). You may want to refer back to Figure 10.2, which details an ECEF system as it relates to the standard lines: the equator and prime meridian.

This form of Cartesian coordinate system is especially useful for geodetic structures. It is called Earth fixed because each axis is fixed in respect to the orientation of the Earth. For example, if the Earth rotates, the axes rotate sympathetically and proportionately.

Before leaving the Cartesian system discussion, we need to explore an important terminological matter. Habitually, cartography and surveying practices use Cartesian coordinates to define positions on maps. As a matter of function and ease, the *x*-axis is considered an *easting* and the *y*-axis is considered a

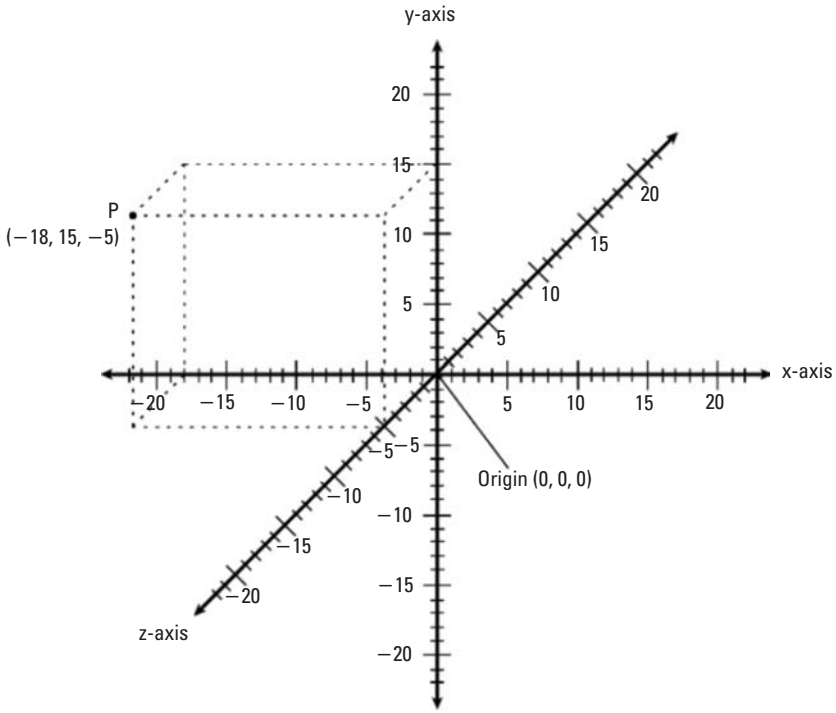

Figure 10.4 Three-dimensional Cartesian coordinate system.

northing. The northing-easting terminology is used to help efficiently relay position, while avoiding signage and coordinate errors.

An easting is the distance east from a north-south reference line, or meridian. Often the prime meridian is used as this reference line. Similarly, a northing is the distance north from an east-west reference line, or parallel. The equator is often used as this reference line.

Furthermore, to simplify positions in the northing-easting reference method, negative numbers are eliminated. To do this, *false easting* and *false northing* constants are used. A false easting is an adjustment constant added to *x*-axis coordinates to eliminate negative numbers. Likewise, a false northing is an adjustment constant added to *y*-axis coordinates to eliminate negative numbers. On maps using the northing-easting terminology, false easting and false northing values are supplied.

Universal Transverse Mercator

The Universal Transverse Mercator (UTM) is a global map projection that transforms the three-dimensional world into a two-dimensional system. The UTM employs an international plane coordinate system that extends around the world from 84° north above the equator to 80° south below. It is extended an extra 4° in the North to cover the northernmost land on Earth. This bounded coverage is because the UTM projection distorts near the north and south poles. The Earth's polar regions are handled by the Universal Polar Stereographic projection, which is discussed later in this chapter.

The UTM coordinate system is set upon a zoned grid, which divides the Earth into 60 equal zones that are all 6° wide in longitude (east-west). The UTM zones are numbered 1 through 60, starting at the international date line (zone 1 at 180° west longitude), progressing east past the prime meridian (zone 30), and back to the international date line (zone 60 at 180° east longitude). Figure 10.5 illustrates the complete UTM zones.

As depicted in the figure, each zone extends in both the northern and southern hemispheres and employs the northing-easting methodology for position identification. Since the equator separates the hemispheres, it serves as the zone's standard parallel. Each UTM zone refers to its own central meridian located at each zone's middle (3°).

Given that the northing-easting method does not allow for negatives, the equator separates each zone into two positive sections: a north section and a south section. Each section then employs its own rectangular grid system using the equator and the zone's central meridian as the two standard references for each system. In total, the UTM comprises 120 separate coordinate systems.

Coordinate positions referencing the UTM system must be indicated with the zone number as well as its northing and easting values in meters. The easting

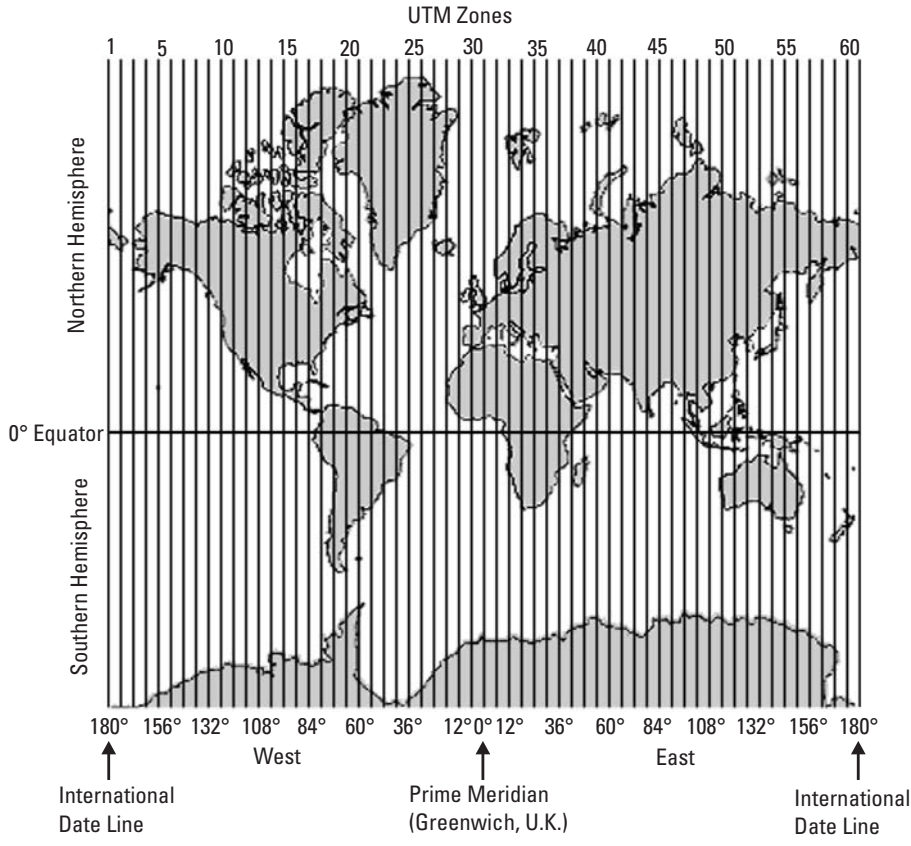

Figure 10.5 The Universal Transverse Mercator zones.

value is always a six-digit value in meters, while the northing value is nearly always a seven-digit number in meters. For example, a typical UTM coordinate for zone 13 would look like *13 645,000mE 2,870,000mN*. Furthermore, to ensure positive coordinates, each UTM zone utilizes a false northing value of 0m in the northern hemisphere and 10,000,000m in the southern hemisphere, and a false easting value of 500,000m.

The UTM system is used worldwide for a multitude of applications, although it may not always be an identical system. For example, in Europe, the Kruger-Gauss projection is used, and the system is consequently called the Kruger-Gauss Transverse Mercator. In the United States, the military uses a modified UTM system called the Military Grid Reference System (MGRS), which further divides the UTM zones into 8° latitudinal divisions (the last division with 12°) designated with a letter. The MGRS starts at C at the 80° south latitude and progresses to X ending at the 84° north latitude. The X latitudinal

division is the only division 12° high. Additionally, to avoid user error, the letters I and O are not used because of their similarity with numbers.

In summary, the UTM is a widely used planar coordinate system quite capable of representing the Earth's geographic coordinates on a flat, northerly-easterly plane. The UTM is used worldwide, and in many countries it serves as a basis for their national grid, particularly the United States and the United Kingdom. Incidentally, the approximate scale distortion of the UTM system is only 1 part in 2,000, proving that the UTM is a highly accurate system. Still, as mentioned earlier, the UTM projection cannot be used for the Earth's polar regions due to amplified distortion. Let us now examine UTM's corresponding system that focuses on theses polar regions—the Universal Polar Stereographic.

The Universal Polar Stereographic

Serving as the polar version of the UTM, the Universal Polar Stereographic (UPS) system uses a universal polar stereographic projection to transform the three-dimensional polar regions into a two-dimensional system. The UPS takes over where the UTM projection distorts, which is defined as above 84° north latitude and below 80° south latitude, but also includes an additional 30' of latitude, extending into the UTM grid for a small degree of overlap between both systems. Figure 10.6 portrays the approximate combined geographic coverage of Earth through the UTM and the UPS systems.

As depicted, the UPS system has two zones, namely, the north and south polar zones. Like the UTM, each zone has its own grid structure and coordinate system. Northings and eastings are used to characterize coordinate positions for each zone and are subsequently calculated using a polar aspect stereographic projection. Figure 10.7 presents a polar aspect stereographic projection.

Similar to Figure 10.7, the UPS system employs a conformal map projection that is free of angular distortion. The projection retains a constant scale along the parallels and is true scale at 87° 7′ north and south. As with the UTM, the U.S. military utilizes a gridded version of the UPS system in which each grid block is identified with a distinguishing two-letter combination (e.g., ZA, where the easting coordinate is defined by Z and the northing coordinate is defined by A).

Overall, the UTM and UPS systems are complementary to one another and combined provide a whole flat view of Earth. The zoned, multigrid approach offers a wonderful positional mapping capability to cartography and surveying, while the minimized distortion provides a near true-to-life representation. In short, the UTM-UPS combined system is a good way to characterize the Earth as a whole and to lay a foundation for both coordinate representation and measurement.

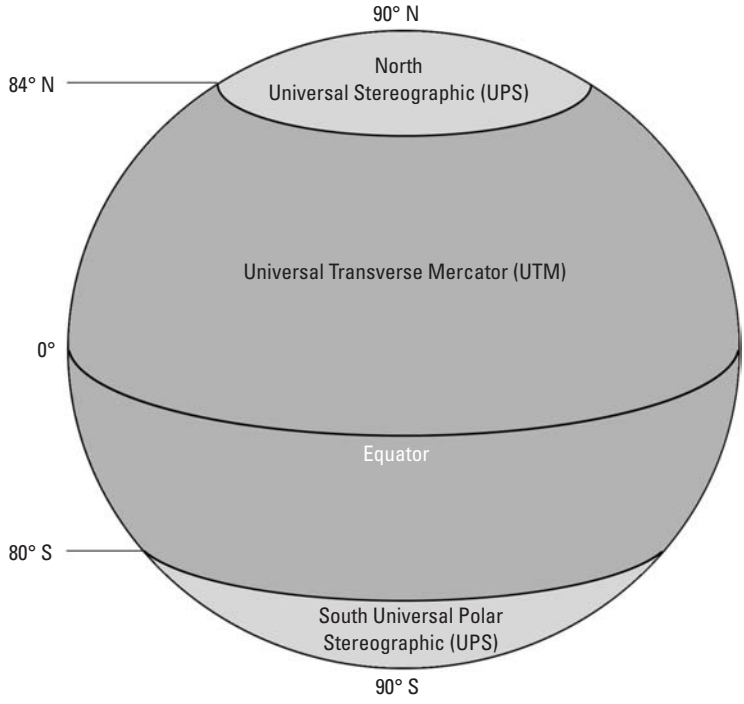

Figure 10.6 The UTM-UPS global coverage.

The State Plane Coordinate System

The State Plane Coordinate System (SPCS) is a zoned grid system that divides all 50 United States into more than 120 numbered zones. The SPCS was first introduced in the 1930s by the U.S. Coast and Geodetic Survey to serve as a common reference for cartographers, surveyors, and engineers. The SPCS is used only in the United States and allows coordinates from an entire state or portions of a state to be transformed into planar (rectangular) coordinates on a single grid. The SPCS was developed to have even greater precision than the UTM, with its maximum scale distortion at just 1 part in 10,000.

Unlike the UTM system that covered both sections of the northern and southern hemispheres within one zone, SPCS zones are bounded by state borders. Smaller states are divided into one or two zones, while larger states are divided into as many as six zones. Each zone has its own origin, central meridian, and standard parallel which often follow state county boundaries. Additionally, for easy identification, each zone has its own assigned code.

Figure 10.8 illustrates the SPCS used in Arizona. It is important to recognize that the state is divided into three zones, which are attributed for their

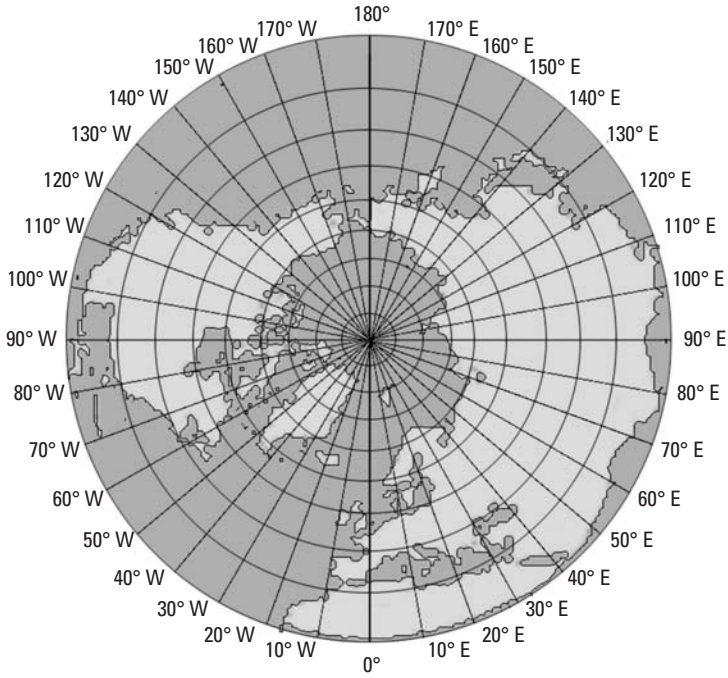

Figure 10.7 A north polar aspect stereographic projection of the Earth.

spatial location within the state: Arizona West, Arizona Central, and Arizona East. Each zone is assigned a unique four-digit code encompassing a common state prefix 02 and an incremental two-digit zone suffix. As illustrated, Arizona's zones follow the state's county lines.

The original SPCS was developed using the standard national datum NAD27 (North American Datum of 1927). Appropriately called the U.S. State Plane Coordinate System of 1927 (SPCS27), this early version references the Clarke 1866 ellipsoid and creates a set of local grids for each state. Like NAD27, the SPCS27 system is based on the foot measurement—a U.S. standard that has since changed.

After NAD27 was superseded by the more accurate NAD83, the SPCS was revised. The new system, similarly called the U.S. State Plane Coordinate System of 1983 (SPCS83), is based upon the latest national standard horizontal datum (NAD83). SPCS83 moved away from the antiquated foot measurement to the U.S. standard, the meter. Due to its NAD83 foundation, SPCS83 offers greater geodetic control and cross-links to the GPS-based GRS80 datum.

The SPCS is based upon two map projections: the transverse Mercator and the Lambert conformal conic. For states that are elongated north to south,

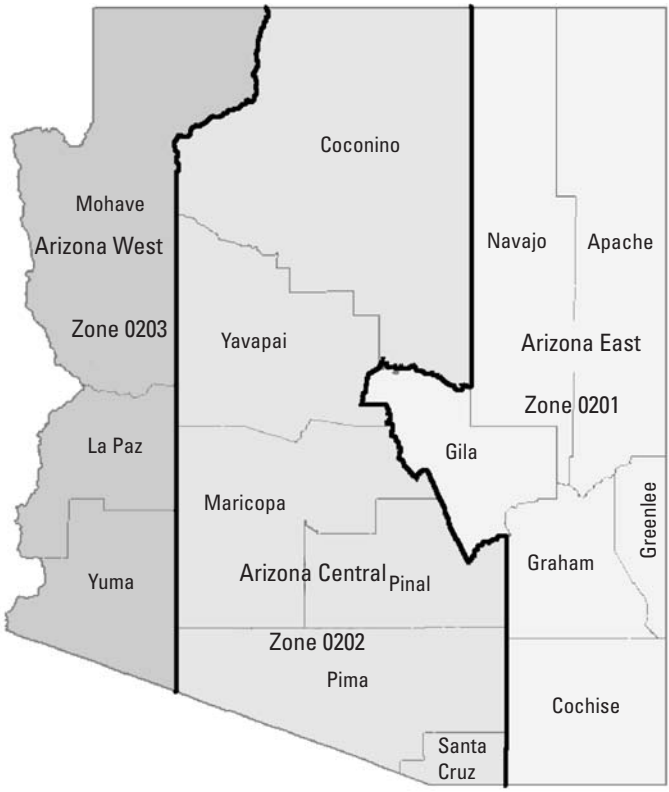

Figure 10.8 The State Plane Coordinate System in Arizona.

such as California and Florida, the SPCS utilizes the Lambert conformal conic for minimal projection distortion. For states that are elongated east to west, such as Pennsylvania and New York, the SPCS utilizes the transverse Mercator.

The SPCS also utilizes the northings-eastings method of coordinate identification. Like other planar coordinate systems, false northings and false eastings are used to keep coordinates positive for every zone. Since every zone is slightly different, each has its own values for false northing and false easting. Overall, the SPCS system is an exceptionally precise and easy system to employ throughout the entire United States.

Coordinate System Implementation in GIS

Coordinate systems play an important role within GISs. They are used throughout every form of geodetics from geographic information referencing and vector

feature geometry to geodetic map projections and datums. The coordinate system forms the definitive core of GIS and serves as the primary tool for modern geodetics.

It is important to understand that the implementation of a coordinate system in a GIS enables geographic data to be defined by vector data. The positional accuracy of vector data on a coordinate system allows for real-world features to be precisely represented in the GIS, as well as on the ever-important geographic information products. Vector data also enables feature topology and its resulting, advantageous efficiency. In short, GIS accuracy and vector data availability are both direct products of utilizing a coordinate system.

Another beneficial effect of coordinate system implementation is that geodata from various (different) sources can be used with one another through layering techniques and coordinate system transformations. By knowing the source data's reference system, feature coordinates can be converted to a single, uniform GIS coordinate system. With all the data sources converted, the information can be manipulated on the same grid, and associations between sources can be made. It can be noted that without the implementation of a coordinate system, a GIS would remain just a database.

Part III:
GIS Applications and Environments

Geographic Data for Analysis and Presentation

11

Thematic Mapping

In his published anecdotes, Samuel Johnson, noted eighteenth-century writer and philosopher, wrote, "The use of traveling is to regulate imagination by reality, and instead of thinking how things may be, to see them as they are." We are those travelers in that, throughout this book's final part, we will be traveling from GIS's theory into the territories of true GIS products and real-life applications. As part of this demystification of GIS, we will depart from discussing how information products should be (imagination) to how they really are (reality).

We already know that in order to produce useable geographic information products, the user must manipulate geodetics through the selection of a standard ellipsoid and datum for their particular focal area. We also know that, once selected, a beneficial map projection must be chosen and applied upon a defined coordinate system. After these elements are set, valid geographic information products can be created and analysis can be conducted with a degree of quantified certainty.

One of the most common and valuable products a user can produce with GIS is a map. Some map products depict pure cartographic information. These products include road maps, subway maps, and the like. Other map products offer a mechanism for comprehensive geographic data analysis and, as such, are typically more valuable. These specialized maps utilize user selection and the benefits of a GIS to offer a unique, yet comprehensive, description of the focal geographic terrain. This specialized map product is called a *thematic* map.

The Need for Thematic Mapping

We have all seen and used a thematic map of some sort. Think of any major city subway or bus map with the stations or stops depicted, or of a TV weather map with temperatures and high- and low-pressure areas represented. Well, the stations, stops, temperatures, and highs and lows are all attributes of geospatial data. These dataset attributes are called themes, and subsequently the subway, bus, and weather maps are all variations of thematic maps.

A thematic map is defined as a specialized map that depicts the spatial distribution of one or more explicit themes. These map themes portray dataset attributes and can detail anything quantifiable, such as population density, income distribution, crime, natural resources, water distribution, pipelines, and disease occurrence. Since GISs are used to manipulate, analyze, and convey geospatial information, thematic maps offer the GIS user a better way to understand the geographic area in focus, as well as an excellent means to inform others.

Now, just imagine how difficult it would be for the user if the bus stops were identified in a data table rather than graphically on the map or if the temperatures for 20 neighboring locations were spoken by the broadcaster and not represented on the map. It is quite possible that some commuters would miss their stops, while the comprehension of temperatures for 20 locations would become an exhausting test of mnemonics and listening. Without thematic, visual indicators, the delivery of this data would be less than effective.

Thematic maps offer a means to define data attributes in a way that is not fully available from a data table. In fact, thematic mapping offers the GIS user a better instrument to convey geographic information and geospatial data that is relative to their information objectives. This, in part, provides a greater means to analyze data sets and find trends and spatial patterns that may remain hidden in data tables. Figure 11.1 offers some insight into how a data table from the U.S. Census Bureau can be interpreted differently when portrayed as a thematic map.

As demonstrated in Figure 11.1, the data table containing household and county information for the state of Florida "hides" the housing trends that the map freely depicts. One definitive trend, in particular, is the state's household per county ratio, whereby the highest ratio is in southeastern Florida and the lowest ratio in northern Florida. The thematic map helps visualize these trends and spatial patterns, while the data table, although informative, seemingly obscures Florida's popular household areas within its data.

Thematic maps offer a bird's-eye view of a particular attribute within the context of a geographic area. As such, they can provide either qualitative information or quantitative information. Examples of qualitative information are vegetation types, soil conditions, and land use categories. Quantitative information includes such attributes as number of Hispanic homeowners, carbon

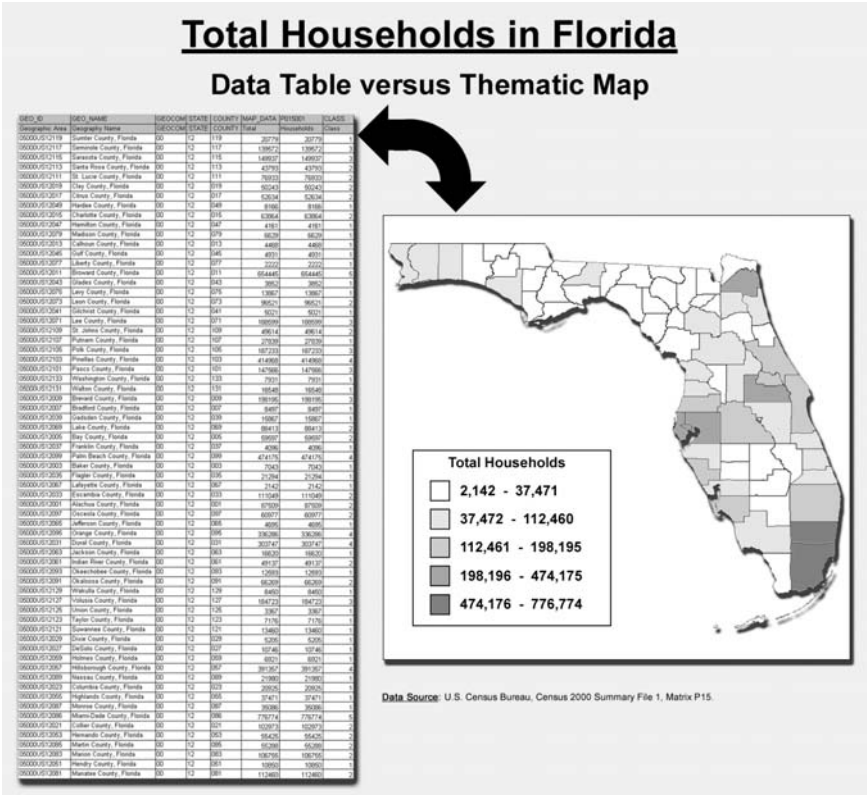

Figure 11.1 A data table versus a thematic map.

monoxide emission measurements, and soil depths. The thematic map can depict both qualitative and quantitative data only if two or more themes are used in tandem.

In the end, the absolute need for well-designed thematic maps becomes apparent whenever medium to complex attribute analysis is undertaken. Since users have inherent limitations to their mental acuity, visual models are necessary for enhancing data comprehension and vitalizing the data's analytic potential.

Manipulating Thematic Layers

A GIS offers users an easy method to manipulate specific data attributes through the application of thematic layers. A layer is a set of theme-based data that is described and stored in a map's data library. Layers do not contain geographic

data, per se, but are georeferenced to geographic data. Additionally, layers complement geographic data through a basemap or satellite image, or such information as roadways, pipelines, soil sample locations, soil types, vegetation types, and water distribution. Layers can be turned on or off in a GIS and can be ordered relative to viewing priority. For instance, a higher priority theme would be placed atop a less important theme, such as a railroad track layer atop a background map of the area.

Figure 11.2 offers a good, visual explanation of thematic layers. The composed thematic map is a combination of five thematic layers: cities, railroads, interstates, major roads, and states. These layers are logically ordered for best overall viewing, with the attribute layers overlying the background layer (states). If the states layer had the highest priority for viewing, then it would block the other themes from showing through. Therefore, part of mapmaking with a GIS is both realizing the importance of logical layer order and keeping data conveyance at a premium.

For GIS users, thematic layers prove to be incredibly useful when developing information products. What makes thematic layers so advantageous is the fact that they provide data attributes in the form of features and surfaces that are uniquely linked to the geography. These features and surfaces are layered and georeferenced to help advance the overall understanding of the terrain and offer insight into what objects affect the landscape, and to what degree. Incidentally, this forms the foundation of thematic mapping's enhanced geospatial analysis.

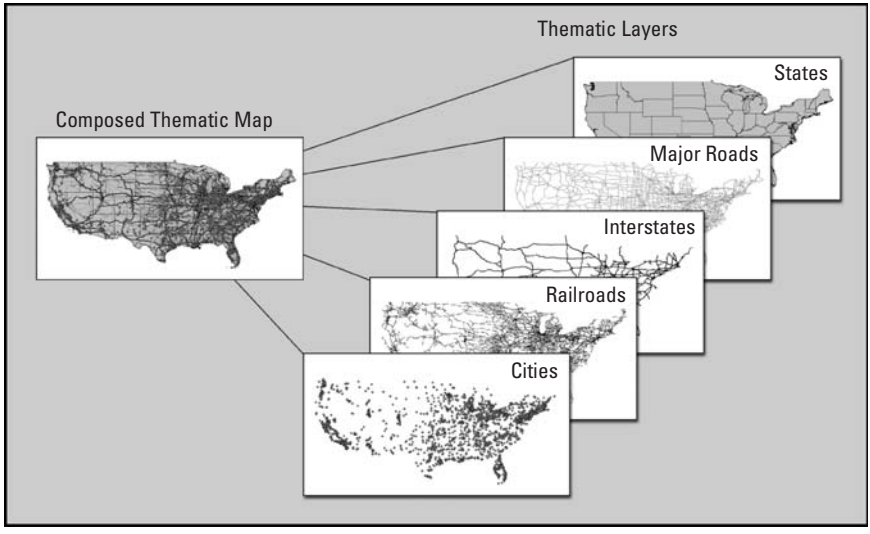

Figure 11.2 How thematic layers constitute a thematic map.

Thematic layer *features* are either natural or manufactured objects that are present or exposed to the terrain, either above ground or below ground. Thematic features include natural objects, such as wetlands, mudflats, and hydrology, or manufactured objects, such as pipelines, roadways, and electrical distribution lines. Each map feature has a defined geospatial position, shape (i.e., point, polygon, or line), and identifier (or symbol) that represents one or more of its characteristics.

Thematic layer *surfaces*, on the other hand, are slightly different and offer a different type of information. These layer surfaces offer a perspective to the terrain in terms of specific characteristics. Examples of thematic surfaces include elevations, soil density, temperature, pressure, precipitation, and flooding. Unlike features, surfaces do not always have defined shapes.

Proper thematic mapping involves a certain level of user discipline relative to thematic layers, as well as a consistent layering scheme. For effective GIS use and map control, layers should be consistently named, with easily identifiable labels. These layer names should suggest the layer's function and indicate some type of hierarchy. Suppose you are entitling a thematic layer of regional streams. A title such as "rty65sc" would make a poor thematic layer name, since it is not easily ascribed to streams or anything else. A better choice would be "Streams001" since it is obvious and has a method to define a stream hierarchy.

Now imagine having 20 different thematic layers for a particular region, including seven stream-related layers, six soil-related layers, and seven layers defining various utilities (gas, electric, and so forth). Which label nomenclature would you rather use? What if you had to produce 22 multithemed maps of that region for a client? Without a disciplined approach to layer taxonomy, this thematic mapping undertaking can rapidly become an onerous task.

As with everything in GIS, there is no single correct way to manipulate or display thematic information. GIS is all about personal choice, creativity, and user flexibility. As such, GIS offers various thematic mapping types from which to choose. We will take a closer look at each thematic map style to understand how and when each is appropriate.

Types of Thematic Maps

GIS offers a fair degree of flexibility and choice when it pertains to what geospatial information is used, how it is used, and the manner in which it is presented. Similar control is offered when depicting attribute data in a thematic map. Consequently, there are numerous ways thematic information can be portrayed over a geographic region. Depending upon the particular data portrayal or analytic objective, the GIS user has a certain amount of freedom over the mapping design.

Given the widespread implementation of thematic mapping, four prominent map types have surfaced. Each offers a particular analytic benefit and, as mentioned previously, can depict qualitative or quantitative data. These four primary thematic map types are choropleth maps, graduated symbol maps, dot density maps, and isopleth maps. Let's examine each one.

Choropleth Maps

Perhaps the most prevalent type of thematic map, the *choropleth map* offers a definite method of portraying ratios, densities, or proportions aggregated within a specific region. These regions are defined by bounded areas, such as census tracts, counties, states, or countries. Choropleth maps, also known as *graduated color maps,* depict thematic information in these bounded areas through color shading and color/value attribution.

Figure 11.3 provides a good example of a choropleth map and illustrates how state median age data can be portrayed in grayscale. The map quickly offers spatial patterns associated with age and individual states that would have been nearly impossible to discern from the data alone. Notice how the eastern states have a higher median age, while the central states hover closer to the middle of the age spectrum. It is easy to visually identify that Utah has the lowest age group (youngest median population).

A choropleth map assigns a value or range of values (called *data classes*) to a specific color or shading. In the figure, the data classes were assigned to five different shades of gray. Hence, the figure has five data classes. For best results,

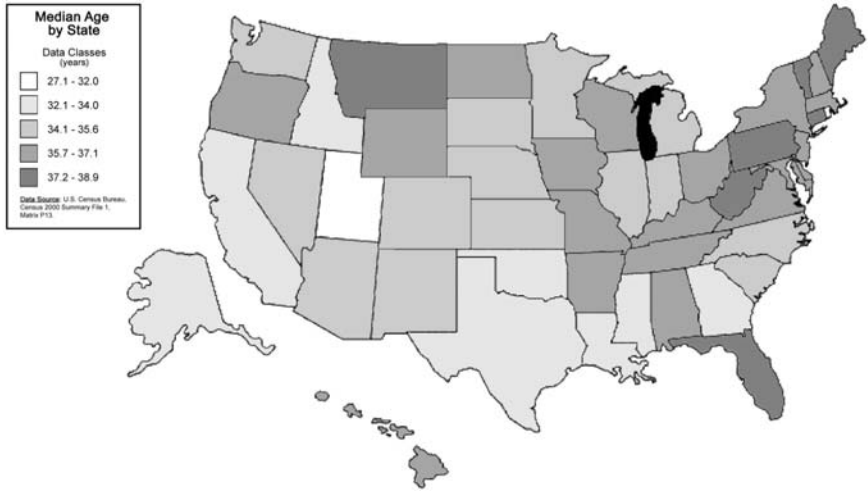

Figure 11.3 A choropleth map of the U.S. census data on median age by state.

choropleth maps should utilize no more than eight data classes since most individuals have a hard time distinguishing between many subtle variations in colors.

Choropleth maps work best with discrete data over defined, bounded areas. Problems arise when choropleth maps are detailed with too many unique values attributed by unique colors. In such cases, the map turns into a geographic rainbow and loses its analytical worth. Poor map designs lead to spatial patterns and communal trends that get lost in the sea of differentiated color.

Choropleth colors for data classes follow particular conventions, whereby the rule of thumb is: The lighter the color, the smaller the value; the darker the color, the greater the value. In the median age map (Figure 11.3), the color white indicates the youngest age range (smallest value), while the darkest gray indicates the oldest age range (greatest value). These maps are portrayed in grayscale or color, typically using a predefined color scheme called a *color ramp.* The grayscale colors in the figure form a predefined color ramp. Users also have the option to bypass the color ramp scheme to define their own color-data class attribution. Whatever color scheme you use, the overall objective is to provide choropleth maps that are simple to understand and offer the greatest potential for spatial trend analysis.

Graduated Symbol Maps

The second type of map is the *graduated symbol map,* which is similar to choropleth maps in function but uses symbols (typically a circle or dot) instead of a color fill. Graduated symbol maps are highly beneficial when indicating quantity or magnitude of a certain phenomenon in relation to geographic positioning. These thematic maps indicate positional data and attribute values through a common symbol of varying size. As the choropleth had a rule for its colors, graduated symbol maps have a similar rule of thumb: The smaller the symbol, the smaller the value; the larger the symbol, the larger the value. Figure 11.4 offers a sample graduated symbol map that details total population by U.S. state.

In Figure 11.4, state populations are shown in relative approximation using various sizes of dots. Each size is assigned a specific value (e.g., 1 million) and is placed in the appropriate states. You can easily recognize a pattern for the country's population through this particular map type, with the east coast having more states with a greater populations than the west coast.

Aside from the "standard" graduated symbol map, a few variations exist for enhanced data portrayal. One variation is called the proportional circle map, wherein the map symbols (graduated dots) are proportionally sized according to their represented value. For example, a proportional circle map of the national population (i.e., Figure 11.4) would perhaps have a miniature dot to represent 1

Figure 11.4 A graduated symbol map of U.S. state populations.

million people, a dot that is 4.5% larger to represent 4.5 million, and another dot that is 10% larger than the miniature dot to represent 10 million people. Value and symbol size are duly proportional.

Another variation is the pie chart map, wherein the symbol used to represent data is a proportional pie slice. This type of map depicts two pieces of discrete data for each bounded region (e.g., state). Last, a third variation similar to the pie chart map is the bar/column chart map. This map portrays bar graphs as a symbol for each region or state and, like its pie chart counterpart, offers a way to depict two forms of discrete data. Ultimately, the most popular of all the variations of graduated symbol maps is the "standard" version.

Dot Density Maps

Often, there is a need to show theme concentrations over a defined region. Choropleth and graduated dot maps are ineffective in the conveyance of thematic densities when they apply to specific geographic locations (as opposed to aggregate areas). For these instances, a *dot density map* is the choice. As the name implies, dot density maps depict spatial densities of particular thematic elements or events.

These specialized thematic maps are excellent for discerning area-theme relationships and can provide insight into the concentrated patterns of a bounded area (e.g., a state). Dots on the map are always uniform in size. Unlike other thematic map types, each dot (indicator) on the map represents a defined number of thematic elements for a specific geographic position.

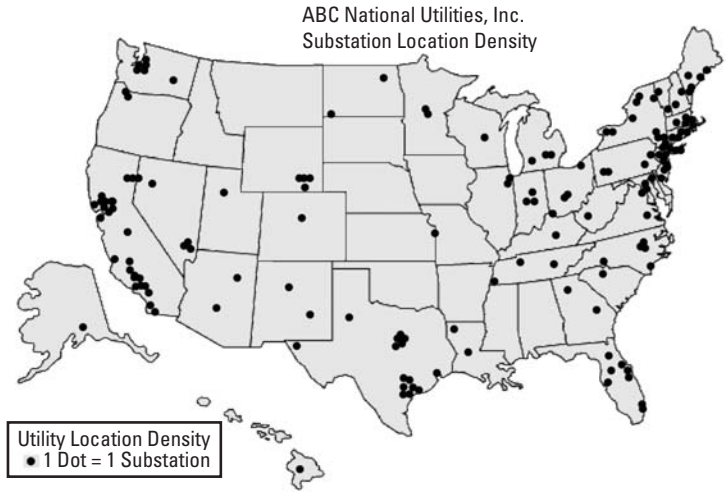

Figure 11.5 Dot density map.

The dot density map portrayed in Figure 11.5 offers an example of a typical theme density map and a perspective on how the thematic densities assist dataset analysis. Just glancing at the map provides the user with important substation concentrations throughout the United States. Ideally, it could help ABC National Utilities understand where it has an abundance of utility facilities and where it has few or none. Each dot represents one substation and provides an approximate position within each state.

Dot density maps are sometimes problematic relative to understanding exact numbers or precise coverage. In areas of abundance, such as the New York City–New Jersey–Connecticut area on Figure 11.5, the dots occupy a good portion of the map space. Since New York City is completely covered with black dots, it can be mistaken as meaning hundreds of substation locations rather than the actual, much smaller amount. In addition, dot density maps could give the wrong impression of an overabundance in a region when the amounts are adequate for the given population and area.

Aside from these few inequalities, dot density maps offer an excellent way to depict attribute densities throughout a geographic region. They are simple to understand and effectively represent concentration patterns and spatial trends across the entire mapped terrain.

Isopleth Maps

The last type of thematic map we will discuss is called the *isopleth map.* Known also as an *isoline map,* isopleth maps visually depict continuous or nearly

continuous data in contiguous patterns of color or shading. Like choropleth maps, values are broken down into data classes and are represented by a color ramp (or user-defined ramps). Isopleth maps connect same data classes together with lines that form the perimeter to same data class areas over the geographic region. The resultant map of same value areas presents a sophisticated view of the spatial patterns in the region, as well as a means to define regional trends.

Due to the manner in which continuous data are represented, isopleth maps are frequently used by scientific, environmental, and meteorological professionals. Typical continuous data mapped with isopleths includes temperature, emissions, precipitation, rainfall, elevation, and contamination. Isopleth mapping can depict a variable data feature within a thematic map or as part of a topographic map (isoline). As an example, Figure 11.6 represents a real-world isoline map created by the U.S. National Atmospheric Deposition Program (NADP) to depict the country's total precipitation in 2004.

In Figure 11.6, the continuous data has no inner boundaries other than the perimeters defined by the explicit data classes. The precipitation trends for the country are well documented in that two "hot" precipitation zones are identified: the southeastern states (i.e., the Louisiana–Alabama region) and the immediate northwest (i.e., the Washington–Oregon region). Because there are 11 colors in the color ramp, particular data points are indicated within the map to facilitate the overall data representation.

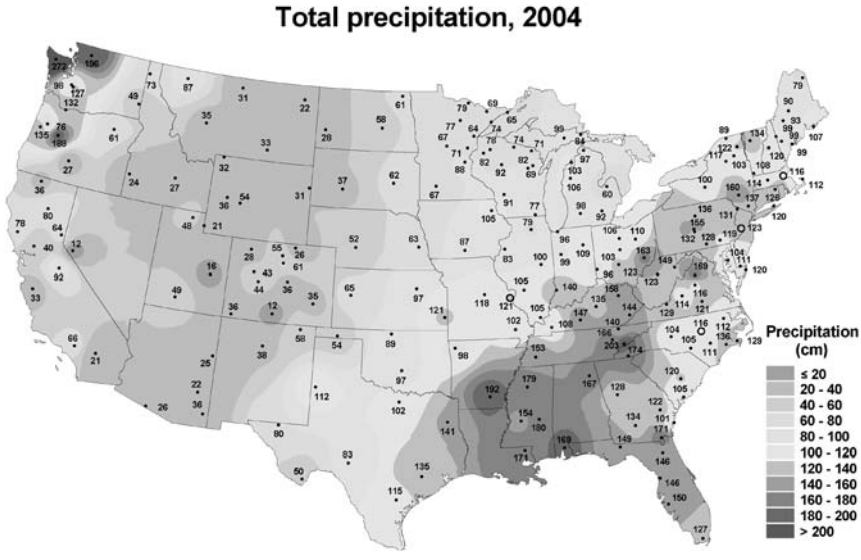

Figure 11.6 An isopleth map of the total U.S. precipitation in 2004. (*Source:* National Atmospheric Deposition Program (NRSP-3), 2005. Reprinted with permission.)

The NADP's isopleth map is used by various professionals to understand not only national precipitation trends but also where precipitation could pose problems. Suppose you were a manager for a major national lumber company and were responsible for picking the location of a new facility. One specification for the facility is that it would need five acres of open land for drying and storing wood. NADP's isopleth map would certainly help minimize the potential effect of rainfall and moisture on the open-air wood storage, and, ultimately, help distinguish good facility locations from poor ones.

Aside from the professional realm, isopleth maps are commonplace in television and published weather reports. Temperature belts and pressure bands are typically illustrated with isopleth maps and high-contrast color ramps (i.e., red means hot and blue means cold). Just imagine how much harder it would be to understand these weather reports if broadcasters used choropleth maps or, even worse, graduated symbol maps. The successful use of isopleths, as with the other map types, is defined by the data being displayed, as well as the anticipated use of the map.

Mapping Data, Classification, Portrayal, and Distinction

Thematic maps, by design, fortify attribute data dissemination and promote analysis not readily obtainable through data tables. These theme-based representations offer highly useful information only if the information being presented is organized logically. Effective thematic mapping involves understanding the data to be presented, a sensible breakdown of that data, selection of a proper map appearance, and well-defined map features. Let us briefly discuss these important thematic mapping elements.

Counts, Rates, and Densities

As discussed, each type of thematic map has its own characteristics as they apply to the data representation. Thematic data can be quantified and represented as numeric counts, rates, and densities. *Counts* are real, whole numbers that represent distinct data entries. Examples of count data include population, number of facilities, and total soil samples. Individual counts are typically represented by a symbol for each item counted. If the counts are too large or exact locations are indeterminable, then one symbol can represent a group of count data (e.g., "one dot represents 100 people").

Rates are a proportion between two counts and are devised by dividing one count by another. Rates are mapped to illustrate how an attribute has changed over time for a specific region or to show the relationship between two

attributes. Rate data includes percent of the total and percent change. Choropleth maps are primarily used for rate data mapping.

Densities are similar to rates in that they show a relationship between two counts; however, densities are intimately related to the geographic region. One count in a density is an area of the geographic region where the second or other count was conducted. Densities include persons per square mile and concentrations per square foot. As with rates, a choropleth map is the superior mapping method for density data.

Data Classification

Data classification can determine whether a thematic map is effective. Data classes were briefly mentioned during the map type discussions, though we must now examine the different methods of determining proper data classes. There are four primary methods for data classification: equal interval, quantile, standard deviation, and natural breaks.

The *equal interval* method is self-implied: It breaks the data into classes of equally distributed intervals. For instance, town population data can be broken into equal intervals of 1,000 people, such as class 1 equals 0 to 1,000, class 2 equals 1,001 to 2,000, and so on. Equal intervals offer an unbiased yet simple way to break represented data.

The *quantile* method divides data into classes having equal amounts of features. For example, if a thematic map had 100 attribute features, you could use five data classes with each representing 20 features. Data are ordered by rank in the classes and, as such, the quantile method proves excellent for maps with ranked values. However, one potential disadvantage to the quantile classification is that it distorts the natural distribution of attribute data and may skew the overall attribute data analysis.

Unlike other data classification methods, there is a defined nomenclature associated with quantile maps. For instance, maps with three classes are called *tertile,* maps with four classes are called *quartile,* maps with five classes are called *quintile,* and so on. Additionally, due to the same number of features per class, quantile classifications often produce visually pleasant maps.

Standard deviation classifications create classes that represent standard deviations from the average (mean) attribute value. Typically, the standard deviation method requires an even number of data classes so that there are an equal number of data classes above and below the mean attribute value. This data classification offers simple comparisons between above-mean and below-mean data. One disadvantage to this classification is that a level of statistical understanding is needed to fully interpret the resultant map.

Finally, the *natural breaks* method recognizes that the breaks in distribution may be directly related to the characteristics of the theme being mapped.

GIS mapping software is able to search for these natural breaks in the charting or histograms of the data using a statistical equation called Jenks method. The natural breaks classification maintains uniformity throughout the entire thematic map and avoids any obviously saturated data classes. For example, a choropleth map with 49 out of the 50 United States in one color offers no real analytic advantage. This method of data classification would find minute differentiations in the data and adjust the data classes accordingly, thus producing a more useful analytical map.

Projection and Scale

The topics of projection and scale have been discussed throughout this book because they are, among other things, functional map essentials. Thematic mapping requires the designer to judiciously select elements and features that promote understanding and efficacy. To do this, map designers utilize both map projections and scale to present the data in the best light, so to speak. As we know, map projections are selected to best highlight the region being mapped through minimizing unwanted distortion. Each projection type has variations that may or may not affect the mapped region. Careful consideration must be applied when selecting the best projection, based on an understanding of the desired properties you want to exhibit.

Working in tandem with a projection is map scale. Depending upon the level of attribute data refinement, map scale may be manipulated to best depict the available data. For instance, a total population count of each U.S. state would be best scaled on a nationwide level, rather than state or county level. However, if population data were available for Michigan's counties, a state-level map of Michigan may be warranted if applicable to the user's mapping objectives.

Both scale and projection are wholly user defined and, if used right, can be significant in transforming a data set into a highly useable geographic information product.

Legends, Color, and Symbols

A legend is a map reference that lists and distinguishes various map colors, lines, shapes, patterns, symbols, and annotation. Often, the legend highlights other map-related information such as the scale, source, and projection. Symbols defined in a map legend are assigned to particular data attributes or themes within the map. Map colors, on the other hand, distinguish between similar legend elements and symbols (e.g., colors can distinguish different soil characteristics). Legends, colors, and symbols, when used together, give the user total

disclosure of the relevant information needed to discern spatial trends within the data set.

An interesting and important aspect of these mapping elements is that they compose the geographic product's metadata. Back in Chapter 4, metadata was discussed at length. The map legend elements, such as map scale, title, and classification, make up the metadata used to catalog the geographic product within a GIS or other database management system. The more information provided in the map's legend, the greater the document's access and searchable data.

Figure 11.7 offers a sample thematic map legend from a wetlands inventory. Notice that there are very distinct elements within the wetlands inventory legend that define distinct forms of data within the map. We have the map title and/or identifier that label the map for the user and distinguishes the map's purpose. Under "Area Transportation" there are different symbols used for various transportation-type elements. For instance, a thick multishaded line is used for an interstate highway, solid colored lines are used for roadway features, and roadway sign symbols are used for roadway identification. You should also recognize how different colors are used to differentiate between the various features (i.e., state road, streams, and so on). Under "Wetlands" in the legend, color fills distinguish attributes among the various wetland types.

Figure 11.7 also highlights other important map elements such as the county identifier, map scale, map number in the series, and date of creation. These tidbits of information add to the user's scope of understanding and enable universal use.

In short, the sole purpose for legends, color, and symbols is to enable anyone with any background to pick up a map and understand, at least on a minimal level, what information the map is conveying.

Common Cartographic Elements

Before closing the topic of thematic mapping, we must examine the cartographic elements that frequent and add dimension to maps. Thematic maps have two basic separations: the data frame and the map information frame. The data frame is the actual thematic map with themes overlying a basemap. The map information frame is the area of the information product that contains cartographic elements. Figure 11.8 offers an advanced view of the most common map elements

The elements depicted in Figure 11.8 are typical features that are found alongside or below a thematic map (data frame). Since proper map identification is needed for user comprehension, thematic maps utilize a map title block and a more detailed map identifier. The map's title block typically contains the company responsible for the map, as well as the type of thematic map (e.g., a

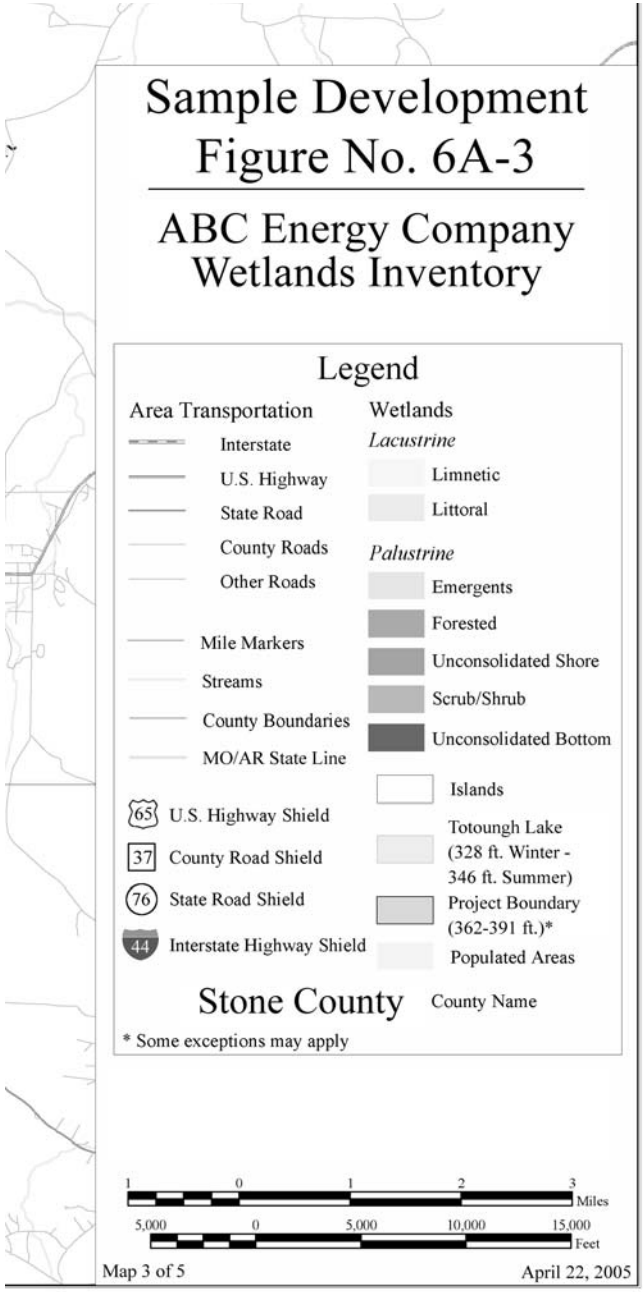

Figure 11.7 A sample thematic legend.

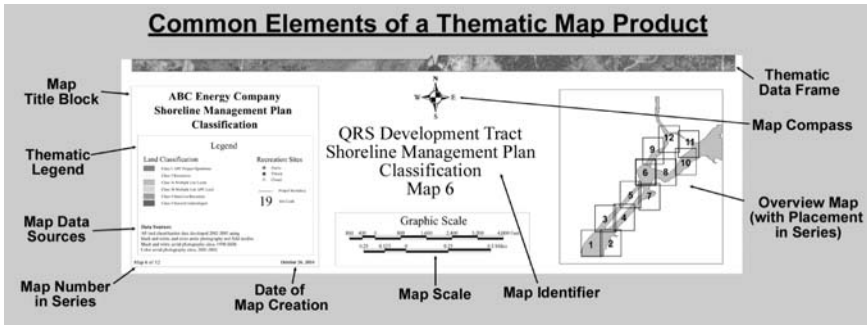

Figure 11.8 Common elements of a thematic map product.

shoreline management plan classification). The map identifier highlights the land involved, the nature of the theme involved, and the map's position (number) within the grouping of area drawings.

As discussed in the previous section, a common element found on a thematic map is a legend. The map legend offers the user a pure "nuts and bolts" understanding of the map's thematic phenomenon. The figure's legend contains an assortment of data class information, with color fills used for land classification and dot/line symbols for recreational sites.

The map's legend may also contain more background information, such as data sources, a textual description of the map's number in the entire series (if applicable), and the official date of creation. This background information will serve as a key component in useful information products.

Any cartographic product utilizes both a map scale and a map compass. The map scale, as previously discussed, helps present the attribute data in as much detail as possible. In fact, scales can be manipulated to portray a larger region of focus, as well as aid in the recognition of actual feature size. The map compass has a simple function: It signifies the true direction of north. Often, the map compass is just an arrow pointing north, while other times (as in Figure 11.8), the map compass is more elaborate.

Another common cartographic element employed is the overview map, which graphically illustrates the individual map's placement among the entire series of maps. For instance, the ABC Energy Company's map was map 6 in a 12-map series. The overview map shows the arrangement of the maps, with map 6 highlighted. As you can imagine, this map element supports user understanding of the region depicted in the data frame and offers insight into how it relates to both the landscape and the other maps.

Overview maps enable individual maps to retain a high level of detail and portray the focus region in an easily viewable format. Just think how ineffective

and small featured a thematic map would be if it had to represent all 12 maps in one data frame.

Overall, no matter which cartographic layout and elements are used to describe the attribute data set, the mapping must be consistent, well detailed, and easy to read. These GIS end products are ultimately used by interested people engaged in a solution. It is always important to remember that when the thematic maps are of good quality, the GIS and support efforts are held in high regard. An ineffective or poorly executed thematic map will, subsequently, mar geographic information efforts and vandalize the data credibility of the GIS.

12

GIScience, Engineering, and Related Applications

Up until now we have discussed geographic information systems on a basic level, describing the *what* of GIS with some of the fundamental elements that make the spatial technology tick. Now we must tackle the reasons why a GIS would ever be needed on a project and the advanced, innovative ways GIS is being used today.

As stated earlier, GIS is used in many different industries for a wide range of reasons. This chapter, as well as the next two chapters, attempts to clarify some of the *whys* of GIS with a compendium of different and viable real-life applications.

Using GIS for Technical Applications

In *The Quest for Certainty*, John Dewey, a prominent American philosopher and educator, wrote, "Every great advance in science has issued from a new audacity of imagination." GIS is clearly such an "audacious" technology. Within its short existence, GIS has proved itself an excellent analytical tool and a leading pathway to innovation. GIS's architecture, unlike any enterprise database system, is well designed for the widely diverse implementation field.

Even more dramatic is GIS's usefulness in highly technical and specialized arenas, such as the sciences, engineering, and technology. With these and other technical applications, GIS has helped companies stay one step ahead of competition, while emblazoning their technological contributions and advances. Many of the world's largest and most successful technological companies and agencies use GIS as a means to centralize their information, automate their analytical processes, and analyze the current and future markets.

In tandem with the scientific and engineering advances, GIS helps companies enhance their business operations from financial endeavors to marketing and potential use analysis. GIS's inherited automation offers the opportunity for higher efficiency over time while keeping procedures consistent and information available. The following discussions cover general science and engineering applications, while offering some perspective on the business end of the technology.

GIScience: Principles and Applications

Geographic information science (known as GIScience) is the study of geographic concepts, such as places, things, and phenomena on the Earth's surface, using GISs. GIScience is concerned not only with where objects are on the Earth's surface but also what these objects are and their relationship to other entities. Through GIScience, GIS becomes both an information technology and an Earth science. With its innovative software technologies, GIS showcases information about the Earth's surface (and other celestial bodies) with geographic data and, in turn, offers the visually gratifying form of geographic features. These features supply the specific knowledge about where things are in the world (their locations) as well as what they are (their attributes).

GIScience also provides nearly effortless analytic methods for describing spatial autocorrelation, or the spatial relationships between geographic features. Geographic data are diverse in character. Some data sets are very detailed and contain volumes of attribute information, while others are restricted and modest in size. All of these elements define the broad interpretation of GIScience.

Though GIS is most commonly classified as a computer or physical science, GIScience opens the gates for the infusion of sociology, the empirical social sciences, and history. GIScience is now used for geoarcheology, psychological analysis, social services, and historical analysis. Additionally, this trend of interdisciplinary applicability is most closely echoed by the field of geostatistics, a discipline offering a synthesis between two disciplines: traditional statistics and geospatial interfaces.

Make no mistake, the definition of GIScience is very broad and the proverbial ground it covers will grow exponentially as object-oriented geospatial functions and techniques become ever more important.

Case Study: Using GIS to Study Relationships Between Bedrock Geology and Subtle Topography

GIS plays a vital role in the geosciences and is increasingly becoming a source for revolutionary scientific analysis. One such study involved the definitive quantification of relationships between bedrock geology and topography, where the

bedrock contained sandstone and shale, and the topography involved a subtle but well-defined surface. The study area was in Oklahoma in the United States and contained geology fractured by area drainage. The researchers used GIS, importing a digitized basemap of Oklahoma's bedrock geology and a topographical map. Unfortunately, topographical maps prove difficult for detailed evaluation of landforms over large areas and small reliefs, or elevation differentials. The researchers decided to use a digital elevation model (DEM) for a more precise analysis of the study area's subtle topography.

Ultimately, by using GIS the researchers were able to distinguish that the study area's topographic variations rely heavily upon the ratio of sand to shale in the bedrock in areas where sand overwhelmingly exceeds shale. Sandstone was found to be thicker in higher relief areas and thinner in lower relief areas. Additionally, the researchers found that there was no real difference in geology bulk density within these variant regions. Without GIS, these relationship findings would not have been made or determined easily. GIS enabled the researchers to easily quantify the subtle differences in local topography within the different bedrock geologic units—an onerous feat using conventional field techniques. The study has afforded future research and quantifiable topographic studies a viable basis for better land use and an enhanced understanding of subtle topographies.

Engineering Applications

As mentioned previously, the field of GIScience is broad in its interpretation and crosses borders with other applicable disciplines, such as the environment, conservation, mathematics, and engineering. More specifically, the physical sciences have long shared common ground with the engineering discipline in such areas as natural resource design, feasibility studies, and environmental impacts from engineering applications.

Similar to GIScience, the engineering industry has maintained its own history of geographic techniques. From the early days to the present, drawn maps and plans have played a huge role throughout the wide stretch of engineering applications. Amongst the civil, structural, environmental, transportation, industrial, aerospace, mechanical, and electrical industries, for instance, engineers regularly use site maps and plans to depict the proposed scope of work, particular designs, and the proper implementation of such designs in a defined geographic space. Old hand-drawn prints and layout designs showcased early geographic mapping techniques perfectly and provided engineers with a planning foundation. These painstaking hand drawings became extinct with computers and computer-aided design programs. Today, engineers are supplementing CAD with the dynamic drawing accessories offered by GIS.

Today's geospatial standards in the engineering industry are actually inherited from the days of plan views in black pen on a Mylar transparency, displayed through an overhead projector in a dimmed conference room. Black pen markings on the site plan can now not only be accurately scaled and drawn using CAD but can also be geospatially defined in real time and geocoded within GIS. The engineering industry has readily embraced this conjoining of CAD with GIS and has realized GIS's positive impact on company bottom lines, project budgets, quality assurance, safety, and the project schedule.

But GIS goes well beyond engineering site plans and geographic products; engineers use GIS for various engineering applications, such as property delineations, conduit/transmission runs, pipeline siting, marine science, surveying, engineering scenario planning, terrain analysis, and traffic accident research. GISs, for example, help utility companies define their electrical substation placement among distribution networks over entire coverage areas. As another example, oil companies use GIS to pinpoint offshore drilling locations, hyperlinking drilling reports and detailing product quantities for these particular geographic locations.

Some of the more effective engineering applications are oil and water pipelines. The pipeline industry's use of GIS is highly progressive and embraces a wide range of disciplines and engineering methods. Typical pipeline projects involve, to some degree, surveying, GPS and remote sensing, pipeline siting, vegetation mapping, wetlands delineation, natural river/waterway channel analysis, parcel delineation, slope analysis, and defining existing pipe locations. In fact, the pipeline industry has moved in the direction of *trenchless mapping,* or full data collection and scenario planning before construction starts. GIS proves exceptionally advantageous in gathering all data, defining construction scenarios, conducting analysis, and detailing the entire project in one effort without breaking ground. GIS-based trenchless mapping helps the pipeline constructors understand the situations they will face while minimizing expensive project changes, enhancing their public outreach programs, and keeping the risk for litigation at bay.

We could review each engineering discipline and highlight literally hundreds of valid, real-life applications where GIS is used and has made a positive difference. There are many available publications and periodicals that solely detail variant and innovative applications. For this discussion we will take a look at one specific application, New Jersey Natural Gas' Transmission Line Parcel Delineation, whereby the critical GIS functions used are representative for many engineering and utility projects.

Case Study: New Jersey Natural Gas Transmission Line Property Delineation

To prepare for law-mandated public and emergency notifications, New Jersey Natural Gas (NJNG), a utility provider in central New Jersey, required an

accurate record of existing properties within 700 feet of its underground gas transmission lines. These central gas lines service a massive area that covers Ocean, Middlesex, Passaic, and Morris counties. NJNG quickly realized the absolute complexity of such a large-scale property (parcel) delineation effort. Accordingly, the New Jersey utility turned to a local geospatial and engineering firm, T&M Associates, Inc., to manipulate the existing data and develop the necessary GIS backbone for the project.

The geospatial system was built upon ESRI's ArcGIS 9 environment. Existing digital parcel information was initially obtained from the state and other sources and imported into the system. Original tax Mylar sheets were scanned into a raster image and consistently referenced with existing tax file naming conventions. This scanned raster image was then rectified with New Jersey's high-resolution orthoimagery (from 2002) and digitized. The digitalization process defined lot lines, boundary lines, and roadways and streams. The outer edges of primary building rooflines (or *footprints*) within the project area were also delineated. The lots created from individual tax sheets were saved as a merged geodatabase file, with adjacent sheets edge matched as necessary. A best-fit approach was used to create the overall parcel layer.

Finally, the parcel layer and subsequent feature attribute table was linked with New Jersey's tax list database, called MOD IV. Unique identifiers and quality assurance protocols were used to facilitate the joining of information, preventing data duplication and parcel ownership errors. In the end, the parcels 700 feet to each side of the transmission lines were successfully delineated and a base GIS was developed for future NJNG efforts.

Marketing and Financial Applications

Aside from the purely technical aspects of the engineering and scientific communities resides the ever-important business bottom line. No matter how advanced a company is or how many innovations a firm has brought to the market, bottom line profitability is the true make-or-break for any business venture. To stay successful, business managers must understand the needs of their market while staying abreast of new potentials. These endeavors take resources: people, time, and money.

The keystones to business bottom line profitability and industry success prominently include business marketing and financial stability. To help managers with their market and financial analysis, business managers are reaching out to new technology and industry trends (i.e., Six Sigma quality discussed previously). In recent years, GIS has played a huge role in conducting valid business sustainability analysis while offering managers an amazing tool for understanding business shortcomings.

GIS offers business marketers the valuable capability of real-time market analysis and customer profiling. Customers can be researched through demographics and purchase histories so that marketing can be redirected (if needed) and the precise customer reached. Some firms advertise GIS-based marketing services that are geared for medium to large businesses of any venue. Internal marketing departments have teamed with in-house or outside GIS consultants to target their market campaigns. In the end, this business marketing strategy has a complementary effect on the fiscal end of the business.

Business financial departments are using GIS to model sales patterns and market histories while aiding in the discovery of profit model inefficiencies. GIS can help accountants prepare or conduct company audits, as well as handle the overwhelming requirements of state- or country-imposed fiduciary regulations. Sometimes, GIS is used for combined marketing and financial analysis when product areas or markets have drastically decreased in sales or new services have proved unprofitable. Commonly, marketing and finance go hand in hand to keep businesses profitable and in touch with the markets. The following case study melds both business ends together through the investigation and interpretation of a rapid chain store closure.

Case Study: Analyzing the Rapid Closure of a Cincinnati-Based Office Depot

In mid-2001, Office Depot, a major chain store for office supplies and equipment, opened a new branch in an eastern suburb of Cincinnati, Illinois. After just six months of operation, the new store closed. Was it a failure in marketing? Was competition surrounding the store too harsh? How could a formidably successful chain have such a fiscal miscalculation? These questions prompted a retail marketing study using GIS analysis tools to offer insight as to the reasons for the store closure.

The branch in question (Beechmont Avenue) was a sister store to five other Office Depots and had competition from five Office Max stores and nine Staples stores in the greater Cincinnati area. The researchers decided to focus on geographic location, since location impacts sales potential and the closure of the Beechmont Avenue branch was related to its low sales potential. The researchers developed a sales potential model within GIS based upon a retail industry standard (D. L. Huff's sales potential model) to evaluate the store's overall performance.

GIS analysis constituted the known spatial distribution and spending habits of potential customers in coincidence with the store's overall highway accessibility, square footage size, approximate travel time, and distance. These characteristics were diagnosed against preopening and postopening data from the Beechmont store, the other greater Cincinnati–based Office Depots, and the area competitors. Through GIS analytical tools and the Huff-based sales model, the

researchers were able to ascertain that one reason the store was underperforming was poor customer accessibility. Closing the branch may have been more cost effective than keeping the failing store open, although as noted in the study, if this type of GIS-based analysis had been conducted before opening the branch, management would have saved a great deal of time and money.

13

GIS and the Environment

Since the world's conscience about the Earth's resources began to peak in the mid-1970s, there has been increasing public concern and interest in environmental issues. Lead-based paint, asbestos-containing materials, PCBs, mercury, underground storage tanks, and chlorofluorocarbons (CFCs) have been just a few of the many environmental issues holding public scrutiny throughout the years. However, environmental concerns migrate well beyond hazardous materials and manufactured contaminants. In fact, a cavalcade of public and governmental issues have addressed environmental conservation and those arenas governed by Mother Nature. Animal habitat preservation, deforestation, endangered species, geology, floodplain analysis, water resources, and mining are just a handful of the myriad areas where the public, environmental agencies, and nature convene.

With this ever-growing and substantial public inquiry, state and governmental agencies need accurate information at their immediate disposal that can be quickly discriminated, analyzed, and conveyed to the mass public. To this extent, GIS has become the tool for both the field scientist and the desktop environmentalist.

Using GIS for Environment Applications

Environmental issues became vividly clear to the public in August 1978 when the small, populated community near Niagara Falls, New York, filled headlines. The community was called Love Canal. Hidden underneath this 15-acre neighborhood was a former chemical landfill. After reaching maximum capacity in 1953, the landfill was closed and covered under layers of dirt. Buried within the

soil were metal drums that, throughout the years, began to rot, causing hazardous chemicals and wastes to leak into the soil. By the mid-1978, the leaking drums became horribly evident when hazardous wastes began percolating to the surface of Love Canal's backyards and cellars. It was later reported (in November) that 200 tons of dioxin, a lethal chemical, and more than 200 chemical compounds were buried in the canal.

In 1978, the Love Canal neighborhood included approximately 800 single-family homes and 240 low-income apartments. Three schools also graced the Love Canal parcel, of which the 99th Street Elementary School was built almost directly above the former landfill's epicenter. A posttoxic release study revealed a high rate of birth defects and miscarriages among Love Canal families throughout the years and offered documented claims of birth deformities and pregnancy-related problems within the community. Ultimately, the Love Canal incident remains one of America's worst environmental disasters and one of America's most remembered tragedies.

Beginning in the 1990s, GIS has grown as a chief facilitator for major environmental efforts. This technical evolution was inevitable since most environmental efforts are deeply entrenched within the fabric of the land and hold geographic importance. GIS is used for hazardous material issues and natural occurrences alike and has now become the popular instrument for land disputes and owner delineation lines. Researchers are now applying the tool to past contamination for further analysis and understanding. In fact, the U.S. Environmental Protection Agency (USEPA) has reprised analysis on the Love Canal incident using GIS so that environmentalists, agencies, scientists, the public, and the victims have a heightened clarity as to what really happened and a sharpened view of every angle of which people were affected.

The following sections detail common GIS applications as they relate to environmental issues and conservation, though in theory GIS can be used for analysis in many environmental situations. Although cost and feasibility are typically the prohibitive factors for GIS in many environmental decisions, when GIS is applied, the results are sound, intrinsically useable, and many times astounding.

Managing Natural Resources

Natural resources are said to be the Earth's wondrous gifts to humanity. The soil upon which we walk, the vegetation we utilize, the animals with whom we coexist, and the water we drink are all innate elements to life and the recognized gifts of our planet. Natural resources can be considered the prize possession of all humans, although, throughout the ages, humans have neglected to care for these gifts.

There is not a day that goes by without our hearing or seeing examples of human neglect, such as the greenhouse effect, air pollution, toxic emissions, hazardous waste, oil spills, corroding shorelines, and endangered species. During the past two decades, a new surge of environmental conservation of the Earth's resources has surfaced and caught the eye of the public. The management of these natural resources has become the breeding ground for conservationists, public outcry, activism, and lawsuits. This surge has evoked many ideological and creative uses for GIS.

Natural resources encompass rivers and streams, lakes and inlets, landforms, geology, forests and woodlands, mines, wildlife habitats, and ecosystems. The management of these natural earthly gifts involves a deep understanding of each system and a proactive plan for these resources to remain unharmed. Natural resource management covers a large platform for potential analysis, from reclaiming brownfields and facilitating wildlife habitat protection to defining oil spills and delineating land classification. GIS is used by conservationists of all types to define potential infringements upon the resources from nature, as well as any residential, commercial, or industrial imposers. It helps form a stable cadre of geographic information and analysis from which to solidify environmental campaigns or to cast the proverbial stone. Conservationists look toward GIS for the position they need in the fight against combatant corporations, developers, and residents.

But GIS doesn't satisfy just the conservationists; it holds valid analytical and environmental defense support for those on the other end of the conservation fight (i.e., the corporations, developers, and residents). For instance, GIS may be used by a developer to show the self-benefiting, attractive results of little or no intrusion against the natural aesthetics of a lake. Dam owners may use GIS to show how a dam removal would positively affect the area, while not disclosing the owner's high-yielding advantages. Whatever side you are on, GIS proves to be a magnificent propaganda tool.

Many times GIS is used toward natural resources when there is no head-to-head fighting at all, but just as a way to quell rising public concern or help with preemptive actions as to appropriate for the specific natural resources. Energy companies tend to use GIS to explore the impacts of operational by-products, such as the impact of rising waters on wildlife, and uses analysis from the GIS products to determine if actions are warranted.

Case Study: Lebanon Natural Resources Management with Participatory GIS

Entrenched within the Mediterranean, Lebanon boasts a diverse socioeconomic society throughout its relatively small population (4.1 million people). Remarkably, Lebanon is a war-torn land. By 1991, 17 years of war ended, leaving Lebanon overwhelmingly disabled. Its once profitable agricultural industry was

deteriorating, and the country looked toward its natural resources for help. However, after years of brutal war, Lebanon's resources were unmanaged and in disrepair.

The Environmental and Sustainable Development Unit (ESDU) at the American University in Beirut took notice and began a series of research programs that meshed technology with community support. The ESDU developed the "participatory GIS" or PGIS, whereby the community provided participatory research, land data, and information for a GIS. The program approach proved highly successful, evidenced by the fact that the ESDU utilized PGIS from 1995 to 2003.

A participatory GIS is a fresh approach to getting relatively accurate measurements and geodata for areas that are hard to measure. The nature of participatory GIS offers many incentives to native volunteers to measure and register land-based and geological features. Such incentives include comprehensive area resource identification and profitable agricultural analysis. In exchange for these incentives is the ability for a highly customized and unique data set. Participatory GISs are gaining popularity in underprivileged communities worldwide and within the GIS community.

Lebanon used PGIS for various natural resource management applications, such as to delineate indigenous agro-ecological zones, plan orchard development, delineate poorly or inappropriately used land, plan rainwater harvesting reservoirs, and develop georeferenced databases for the study area.

Ultimately, PGIS served Lebanon well, providing accurate georeferenced land information that has proved invaluable to researchers, developers, communities, and land stakeholders alike. The participatory GIS information products have given Lebanon a new lease on their natural resources and a feasible approach for socioeconomic growth.

Case Study: Community-Based Natural Resource Management Program in Namibia

In Namibia, Africa, GISs are playing an important role in supporting community decisions as they relate to the management and use of Namibia's natural resources. Namibia's communities are using GIS information products, particularly printed geographic maps, to manage the natural resources on an individual community level. Namibia's Community-Based Natural Resource Management (CBNRM) program involves participants in every community to encourage the proliferation of sustainable development. Namibia's community-based program is very similar to Lebanon's participatory GIS program, but with a heavier focus on natural resources.

The CBNRM's use of geographic data and information is distinct, primarily land-use planning, resource conservation, game and wildlife monitoring, tourist and commercial development, and communication. One of the chief

activities threaded throughout the various GIS uses is boundary delineation, especially for conservancy and land development.

Namibia's community GIS program relies heavily on an intercommunity sharing of geographic data, information products, and tools. The program runs on a needs-based approach and involves dedicated community field users who trust the accuracy of the GIS information, have fostered a set process to delineate community needs, and have built a reservoir of information to ensure the program's longevity.

Environmental Investigation and Remediation Applications

A continuously growing area for intensive GIS use is in the hazardous waste arena. With the uprising in brownfield redevelopment, environmental impact statements, building toxics, and hazardous material remediation, GIS has become the premier project database, saving companies and agencies substantial amounts of money over long-term projects.

Interestingly enough, the USEPA is the largest user of geospatial information as it relates to the environment. The USEPA Web site, http://www.epa.gov, boasts a fully hyperlinked and geospatially coded (or *geocoded*) mapping tool, whereby any user can search a U.S. location and retrieve graphically enhanced maps depicting all recorded environmental concerns. The Web site provides a wonderful example of GIS use in an environmental application.

Hazardous materials come in many forms and can infiltrate the human ecosystem in an innumerable number of ways. Just a sampling of the possible environmental episodes include leaking underground storage tanks; toxic releases; the presence of volatile organic compounds (VOCs) and semi-volatile organic compounds (SVOCs) in soils; and micro-fiber silica and polycyclic aromatic hydrocarbons (PAHs) in the air. As with the USEPA site, GIS can and is being used to geographically reference release locations for various agencies and private firms.

GIS has made an indelible mark on the way sites are remediated and monitored. In particular, heavily contaminated sites such as the USEPA superfund sites and chemical dump sites use GIS to track soil boring locations, with hyperlinked sampling results. For environmental site assessments, GIS is used to organize Sanborn maps (historical site characteristic maps) that detail site history, to depict locations of potential contamination, to hyperlink sample analysis, and to represent underground structures, such as storage tanks, and known soil contamination.

On asbestos and lead-based paint contaminated sites, GIS is sometimes used for large contaminated buildings and facilities, whereby asbestos "hot spots" and known lead-based paint locations are meticulously defined in the

system. Sample analysis, air-monitoring results, abatement information, and containment locations are delineated, and sample chain-of-custody information is accurately tracked.

Case Study: Illinois Underground Storage Tank Monitoring and Inspection Program

Within the United States, Illinois has more than 28,000 facilities with underground storage tanks (USTs). These facilities range from industrial to commercial uses, though many are simply gas stations. USTs hold petroleum or other forms of fuel in metal-encased tanks. These systems are well built, but after years of neglect and metal shell deterioration, fuel can leak from the storage tanks into the soil. This causes severe human health issues. Every state in the United States requires owners to report USTs.

Illinois needed a comprehensive yet efficient way to manage the locations and information associated with its USTs statewide. Many former gas station sites still have USTs below ground with newer building structures above. These USTs are of greatest concern since they may not have been drained and closed properly, or residual fuel may have leaked into the soil during tank closure. Fuel-laden soil creates VOCs and SVOCs that are known carcinogens. To help accurately monitor and inspect USTs throughout the state, Illinois's Office of the State Fire Marshal (OSFM) turned to GIS.

The use of GIS virtually reinvented the way OSFM handled USTs, from the everyday monitoring and inspection to the data retrieval and data quality. Before GIS, the field inspectors carried boxes of files with them and had to complete nearly 20 different forms to collect the necessary tank inspection information. They then had to mail these forms to OSFM headquarters for processing and entry into the database. Now that GIS has been implemented, the field inspectors need only their laptop computer and GPS receiver. Tank information is entered directly into the computer and the once-tedious forms are quickly completed. Sites get geocoded with the collected information, forms, and GPS location data. Field inspectors can create maps to locate tanks and facilities, as well as perform spatial queries on facilities. In the end, GIS has made Illinois's UST program highly efficient, flexible, and accurate.

Case Study: The USEPA's Disaster Dioxin Air-Monitoring GIS System

After the September 11 terrorist attacks on the World Trade Center in New York City, the world became horribly familiar with air carcinogens and how latent environmental hazards can become time bombs to human health. With the Trade Center disaster, large, concentrated amounts of dust were propelled throughout the Lower Manhattan area, reaching upper Manhattan and parts of Brooklyn, Queens, and Staten Island. Within the fine dust were varying levels of

carcinogens such as asbestos and silica fibers. In Lower Manhattan there were many other elements of potential concern, such as fiberglass, mercury, PAHs, PCBs, lead dust, dioxins, and trace metals. The collapse of the building structures caused the material to granulate and become extremely fine dust, an ingestible state that proves most dangerous.

The USEPA used GIS to assist in the analysis of the laboratory results and the field samples. The USEPA set up fixed air-monitoring stations throughout New York City, with a concentration of stations in Lower Manhattan. These stations produced results that were fed into the GIS, from which environmental exposure trends were determined. The GIS information products were used to disseminate accurate, up-to-the-moment results to the public through USEPA's Web site and media presentations.

The GIS products served the numerous environmental agencies and scientists with an accurate geodatabase of sampling results that were at their proverbial fingertips, while offering the nonenvironmentalists a visual depiction of the concentrations and areas where environmental exposure was greatest. The USEPA response was a marvel in the way geographic information and environmental analysis can collaborate to serve a wide range of applications for a much greater array of users.

Shoreline Management Systems

GIS use with shoreline management has provided owners and conservationists a stable repository of geographic landform data and a tool to provide environmental impact analysis. A shoreline management system is a proactive structure by which a shoreline is planned, managed, and/or delineated, with potential human and natural encroachers easily determined. Coastal planning, shoreline planning, and wetlands management are popular topics for a wide range of individuals, including developers, environmentalists, regulators, and lawyers. All three shoreline systems are linked in scope and audience, as well as through their proclivity for dispute and participant division. GIS helps all participants understand the overall scope of the effort in dispute and offers GIS information products (such as maps and land classification charts) to help end these disputes through information.

Environmental regulators use GIS to legally validate their shoreline and coastal management planning efforts, while conservationists use GIS to aid their efforts to preserve natural areas. Developers typically use GIS to further communicate their project's scope to residents and community groups while facilitating the evaluation of the potential area impacts.

GIS information products result from careful shoreline management planning efforts that can lend tremendous credence to any environmental

management undertaking and potentially influence political opinions or legal decisions. You might be asking yourself, "How does GIS really do this?" GIS increases the visibility of the effort and showcases facts to substantiate claims, ideas, or complaints. The ability of GIS to utilize plentiful, accurate, and freely available geographic data can be the "equalizer" in big business or bureaucratic environmental litigation. Any users with modest GIS knowledge and desktop computer proficiency can build a system to "make a case" for their shoreline, coastal, or wetlands management cause.

In the United States alone, shoreline, wetland, and coastal management planning is truly big business. Management planning is backed by the government through enactments to state and federal law, including the USEPA's Coastal Protection and Management Act of 1995 and Coastal Protection and Management Regulation 2003, the U.S. Geologic Survey's Shoreline Management Act of 1971, and the USEPA's Wetlands and Watershed Act of 1997.

Case Study: The Coosa/Warrior Shoreline Management GIS—Alabama Power Co.

As a direct result of the U.S. Federal Power Act of 1935, the Federal Energy Regulatory Commission (FERC) was granted the right to regulate nonfederal hydroelectric projects. Owners of hydroelectric facilities must periodically relicense their facilities with the government in order to reap governmental aid and receive revenue from their hydroelectric enterprise. These relicensing efforts are time consuming and costly and must meet FERC and local agency requirements. Requirements are strict, cover various areas of importance, and usually involve the management and planning of impacted shorelines and owner-occupied coasts.

As part of Alabama Power Company's relicensing efforts, a geospatial database was developed to help facilitate the relicensing of seven major hydroelectric facilities on the Coosa and Warrior watersheds in Alabama and Georgia. The project involved spatial database design, spatial analysis, image processing, environmental shoreline management, and land classification.

A complete Shoreline Management Plan (SMP) system was developed for Alabama Power's work at the sites, classifying more than 3,000 miles of shoreline and project areas. With the application of GIS, the SMP mapping effort consisted of more than 150 map layouts that were developed for public presentation and project team analysis.

Other Environmental Applications

The list of geospatial environmental applications is far more extensive than the popular areas discussed in this chapter. You can say that the list is virtually ever

growing. Through user creativity and out-of-the-box thinking, GIS has reached the small corners of the environmental industry and instilled renewal into the traditional project management controls. Areas such as pollution prevention, groundwater modeling, environmental compliance, and water resources (among others) have gained new life through GIS and as a result have promulgated higher efficiency rates for technical analysis and the dissemination of information.

By its very nature, GIS is fully migratory within the industries and, as such, has shifted into firm practice worldwide. Whether because of its power of efficiency or its sheer management capabilities, GIS has proved itself an incomparable project tool. Realizing this, many large consulting firms and organizations now have in-house GIS capability and thus offer geospatially based solutions as part of their core environmental offerings.

14

GIS and the Public

Since the advent of the Internet, more and more people, whether they know it or not, use GISs on a frequent basis. Although the Internet and GIS are separate systems, some Internet sites offer GIS-processed information, such as turn-by-turn driving directions or up-to-the-moment weather information. The public has the ability to search neighborhoods for health and safety hazards, search communities for public notifications and alerts, or even find out the air quality index for that specific day in any defined location. The general public relies on these sites for free, quick information, though the users rarely understand that the information they are manipulating is supplied from a GIS or that they comprise the majority of Internet-supported GIS users.

The general public is also the largest group uniquely affected by GIS technology. Information systems have infiltrated everyday life, from tangible products, such as news and home electricity, to abstract products, such as emergency 911 system routing and port vessel tracking. The reality is that GIS and the public are intertwined, and as the technology grows in use, the number of ways one person is affected by GIS becomes incalculable.

A Public Need for Information

Without question, it is vital that the general public have a source or group of sources that provide accurate information. A means to easily distribute geographic information to the public can sometimes mean life and death. For instance, during the September 11 attacks in New York City, the NYC Police Department used GIS to maintain public safety, control Lower Manhattan access, and disseminate community information. Through various state and

federal Web sites, the public had the comprehensive ability to access area maps, timetables for redirected traffic patterns, rescheduled public transportation, information about community meetings, and results of air quality samples. This intrinsic use of GIS helped maintain control of a very unstable situation while keeping the public well informed. During the emergency, the public demanded accurate information quickly and continuously, and a GIS proved to be the most comprehensive and easily implemented of solutions.

This need goes much further than just community safety, disaster, and emergency situations; the need resonates throughout public schools systems, public transportation systems, and within the policies and regulations that govern facilitation. To this end, GIS has infiltrated the populace as a subtle but powerful information medium. It can be suggested that the immediacy of GIS information products, in tandem with an Internet delivery, makes daily newspapers and the evening news seem like "pony express" reporting.

Nevertheless, immediacy is not always the main propellant for GIS use. Many times the public user requires the power of the information database rather than data immediacy, since it offers immense public documentation catered to a specific application. For instance, school principals can monitor crime statistics in a school's district, and social service providers can tap into local demographics and social structures. These types of public applications necessitate accurate, time-nurtured data rather than up-to-the-moment data.

Similar to the other disciplines of GIS (i.e., education, business management, environmental, and so forth), public praxis is evolving and is limited only by user creativity. The following sections highlight typical applications for the public's use of GIS and information management. As you will quickly realize, the general public comprises a very diverse suite of users that viewed macroscopically is wide ranging and viewed microscopically is highly user particular.

Managing Public Health and Safety

Public health and safety have always been subjects of debate, interest, and downright concern. From the early days when there was minimal medical knowledge and no technology, people with a communicable disease such as tuberculosis could infect the neighborhoods or towns where they lived. News of a new case would send fear racing throughout the communities. Neighbors would inform others of new cases. People fearful of infection would stay indoors or somehow try to hide from the disease. Invariably, others would be infected. The end limits to any disease management efforts would be to either quarantine and treat the infected or wait for their death.

Nowadays, medical knowledge is painstakingly sophisticated, and the once dreaded communicable diseases are fervently managed by professionals. The

public fear of such community-infectious diseases has tapered to mere interest. However, the concern about deadly new outbreaks has not diminished. As in the days of old, public information remains the first and best barrier to a total outbreak, and new technology provides a second barrier for professional analysis and understanding. As you can imagine, GIS plays an integral part within both barriers and the meticulous spatial tracking and management of disease.

Disease management is not the only public health and safety issue where GIS plays a management role. Scientists and medical professionals use GIS to spatially analyze areas for air contaminants and toxins, higher rates of miscarriage and birth defects, spikes in asthma and other respiratory stressors, proficiency in child inoculations, increased worker safety concerns, and occurrence of repetitive motion injuries, just to name a few. GIS aids in public awareness programs, offering accurate information online while providing health and safety analysts a compendium of source data.

The process of managing public health and safety is imperative to lessen human loss or injury when outbreaks and emergencies occur or as an ongoing medical prevention program. GIS is used to inform the public of "hot spots," or places to avoid, while indicating information for preventive measures and locations for proper treatment. Many governmental and state public health agencies use GIS technology to identify or defuse a potential health safety threat, conduct communal human health risk assessments, make better decisions in terms of public safety, or just stay ahead of area health trends. The superfluity of demographics, client data, and resource distribution is among the greatest reasons why a GIS is used.

Case Study: Detailing Areas at High Risk for Elderly Fall Injuries to Enhance Injury Prevention Programs in Alberta, Canada

Researchers from the University of Alberta's Division of Emergency Medicine, the Health Surveillance Branch of Alberta Health and Wellness, and the British Columbia Rural and Remote Health Research Institute conducted an investigation detailing the geography of fall injuries in the elderly within Canada's Capital Health Region in Alberta. The researchers used GIS to analyze the spatial character of fall injuries within the study area in an effort to enhance fall prevention methodologies. The data set for this particular study comprised Alberta residents greater than 66 years of age who visited an emergency department for a fall. Postal codes from emergency vehicle and department reports comprised valid location data.

Using GIS, spatial analysis was completed to identify general fall injury patterns and high-incidence areas in both Alberta proper (such as rural and medium-population areas) and within a domicile (such as on a stair or off a ladder). The researchers relied heavily on geographic information products, such as

empirical Bayes estimate maps of incidence data. Empirical Bayes estimates invoke British mathematician Thomas Bayes's theory of statistical sampling, which states that a probability distribution can be assigned to an unknown parameter in a statistical problem. In this application, the researchers assigned an underlying probability distribution to the fall incidence ratio. In the end, the researchers proved their argument: that fall injuries in the elderly occur in distinguishable areas, making region-specific fall prevention programs possible and definitively beneficial.

Disaster: Planning, Response, and Recovery

We have already discussed in some detail how a GIS can be used for information distribution in emergencies or for analysis in the wake of a disaster. However, there are additional functions relevant to natural and human-made disasters that we have not covered, namely disaster planning, response, and recovery.

As a result of the recent natural events and terrorist activities, the need for a heightened focus on disaster planning is sobering. Property owners, bankers, insurance professionals, and state and federal agencies have taken preliminary steps to increasing their disaster preparedness, while being proactive toward disaster response procedures and the minimization of lost business days during recovery. As you might guess, GIS has been playing a greater role in these areas.

Disaster planning involves understanding historical events, analyzing each historical event's "before" and "after," and learning to better deal with a similar situation. Field- and satellite-based GIS data in time-lapse maps are used to study events ranging from the levels of floodwaters and the nature of particular tornado damage to past errors in fire safety and building collapse characteristics. Disaster planning highlights offsets to catastrophic ruin and ways to back up current systems. Overall, disaster planning covers a wide ground, but it can be reigned in through the analytical and database power of GISs.

Disaster response goes hand in hand with planning, but with a deeper focus on past response–related errors. The main purpose of a response is to lessen the amount of loss, be it human loss or material loss. Every past error indicates how a response should not be conducted, while highlighting those areas where additional planning is needed. A well-planned GIS can help route emergency personnel to the correct area or alert them of the correct protocol, transplanting accurate data for potentially fatal guesswork. A GIS can calculate the best route, querying the most recent street-position data, construction detour data, and traffic information. Using a GIS for disaster or emergency responses can be the time-saver needed to save critical material or to save a person's life.

This leads us into disaster recovery, which is the readjusting of a disaster event to a level of normality or stability. For example, banks implement offsite

data recovery stations, where vital financial information is transmitted and can be instantly recovered in the event that the origin bank is incapacitated. Disaster recovery goes much further, such as in the reoccupancy of buildings or the desperate search for human life in a building's rubble. GISs are used to inform (once again) rescuers and emergency personnel of vital location data, such as the number and identity of building occupants from an electronic security badge database or maps of predisaster floor layouts. The main purpose for disaster recovery is to minimize loss while stabilizing the situation in a timely manner.

Transportation and Information

Public transportation systems have always been a natural candidate for embracing GIS and the geographic information products the technology offers. Subway maps, bus routes, highways and public access roads, and ferry paths have historically involved graphical street maps overlaid with route paths, route numbers, and legend symbols. Maps offer the general public an easy-to-understand bird's-eye view of the entire transportation system and engage the simple human task of recognition. There are no in-depth text instructions to comprehend or composed tables to siphon through in order to find the desired information. Just graphics, labels, and overlays: the basis for GIS.

With the use of geographic information products, public transportation and the distribution of transportation-related data are much more efficiently facilitated. Transportation GISs not only can map routes for the public user but can also detail construction locations, alternate routes and reroutes, city gridlock areas, and sites of heavy congestion. These systems help keep the public commuter well informed while offering a means of informed transportation choice. This side to GIS use in transportation is extremely visible to the public user.

There is another side to public transportation that is less visible to the end user and much more instrumental in application. GISs are used to maintain subway tracks and roadway, maintain transportation fleets and equipment, identify system faults, route emergency vehicles, pinpoint accidents, and make immediate changes to information products. These applications, of course, are just a sampling of the copious functions that public transportation managers, engineers, and operators require.

Going one step further, transportation planners and engineers use GIS to better analyze particular traffic situations in any study location. These professionals use spatially defined or geocoded data to help discern the causes and effects of the particular situation, while the information gained from this type of geospatial analysis aids in the development of a practicable, cost-effective solution. A GIS enables transportation professionals to build upon existing transportation network data, update information with GPS, and easily integrate spatially referenced attribute data.

You need not look too far from your own town or nearby city to fully observe the power of GIS in relation to public transportation and information dissemination. Visible to the public or not, many of today's smaller public transportation systems (and almost every large public system) are now spatially enabled in some fashion. Check out a transportation Web site for a local agency for indications of geospatial data. If you want to grasp how completely public transportation and GIS can meld, take a look at Portland, Oregon's TriMet interactive system map at http://www.trimet.org.

Case Study: Portland's TriMet Transit Tracker Online

Portland's TriMet system offers its public ridership real-time bus information and train (TriMet's MAX trains) arrival data through an ESRI ArcInfo-backed system called Transit Tracker. The real-time information is accurate wherever the user may be. The system works off GPS mobile tracking, wireless technology, and a GIS. Transmitting sensors on the public buses send location information to the Transit Tracker system database, while sensors built within the train tracks transmit train speed and sensor location. The system displays actual bus locations and calculates an estimated arrival time for MAX trains based upon transmitted information. Public users can access this data wherever they are through handheld devices, the Internet, or telephone.

TriMet's interactive system map uses a high-resolution aerial photograph in conjunction with bus and train data layers. Maps highlight bus stops, MAX stations, points of interest, and park-and-ride locations. As with any GIS map product, map views can be zoomed in and out, information can be retrieved about stops, stations, and routes, and specific locations can be searched and viewed. An interesting feature to TriMet's system is their MAX train "up-to-the-minute arrival time" window that displays train arrival countdowns. Portland's use of an online GIS for public transportation is highly progressive and will set the path for future public transportation information systems.

Homeland Security's Third Eye

Although we have discussed GIS's role with disaster planning, not a day goes by when the phrase "homeland security" is not heard, along with the notion that something more is needed for terrorist events than pure disaster planning. In these undetermined times, the subject of national security is of great importance to both the government and the public. Governments want to maintain a status quo on threat control and homeland sustainability, while the public wants full information disclosure and a stable sense of life safety. Security analysts and managers now use GIS in conjunction with other in-place protocols for threat

and vulnerability assessments; security control procedures; sea craft and aircraft tracking systems; surveillance, detection, and intelligence gathering; data sharing; and overall preparedness.

The interesting aspect about using GIS with domestic security is that typical security projects meld the public applications just discussed: public safety, disaster planning, and transportation systems. Its use with public safety is seemingly obvious. GIS offers a means to identify safety concerns and areas for potential vulnerability, whereby officials can close off these vulnerable areas to the general public. GIS products enable agencies to identify and subsequently control public access areas to help maintain public safety and enhance early threat detection.

GIS offers powerful capability in understanding how a safety plan will work in the event of a disaster or terrorist situation. The technology helps security analysts detail the best areas for a rapid mass public exodus from any area, as well as defining the easiest paths for emergency personnel. GIS proves to be most useful with interagency information sharing, in addition to serving as a central repository for information-gathering exercises. This single system, single data methodology may be the deciding factor in preventing a terrorist attack or in maintaining control during a sudden, disastrous event.

The transportation portion of domestic security revolves around mass public threats and evacuation protocols. Because transportation systems handle a large, diverse ridership, with people looking over unknown faces every day, the importance of early detection is critical to human safety. GIS and GPS are used to monitor train and bus locations and can help officials identify any abnormalities with service. These abnormalities can act as the early detector in public safety concerns or hostage and terrorist situations (on September 11, planes had abnormal flight patterns). Additionally, GIS can collect ridership data for any given moment, which can aid in vulnerability analysis and rescue/recovery initiatives.

Traditionally, in mystical circles a person's "third eye" was considered the eye that saw the unseen and invoked a person's extrasensory perception. GIS is quickly becoming the third eye for worldwide homeland security protocols, since it helps analysts "see" what is not readily obvious and helps keep agencies one step ahead of terrorists. In reality, the technology's automation is its greatest asset to these security professionals, while the data's accuracy and consistency enables more concentrated and successful threat mitigation measures.

Public Education Applications

GIS technology has become the newest tool for public education analysis and proliferation. GIS is now used in tandem with teaching curricula to enhance a

student's ability to comprehend lessons and perform hands-on problem solving for complex problems. Science, physics, mathematics, Earth studies, and chemistry are among the major subjects most positively affected by GIS, though the scope of in-class analytics is wide. The information products form intriguing, exciting manipulatives that tend to engage students and help progress their understanding of the topic.

Teachers are not the only educators using the information technology; school officials, principals, district leaders, and superintendents have begun using GIS to better understand their district's or school's demographics. Educators and school officials can evaluate their school system occupants through a mix of demographical data that ranges from racial background and economic status to familial situations and standardized test scores. GIS offers a new level of detailed analysis that helps educators and officials pinpoint where deficiencies lie and successes hide. When used correctly, a GIS can be a potent facilitator for a better school system.

The power to conduct accurate educational analysis through information sharing between districts/schools is far more effective than with past methodologies. A GIS, by default, becomes a central clearinghouse for school data, which aids in quantitative and qualitative educational understanding. School officials can precisely rank their schools with other same-level schools, district leaders can compare their successes with those of other districts, and superintendents can monitor the overall effectiveness of their public education domain.

Using GIS in tandem with education helps students and educators become community aware and more firmly involved with the events and activities around the school. This interchange of information breaks the spatial barriers of traditional learning and gives everyone involved a refined vision of data exchange while making each user aware of their community's spatiality.

Aside from the educational advantages of GIS, school facility managers can implement a Web-based GIS for campus/school facility information. Students and educational personnel alike can easily access real-time campus maps, building information, campus activities, and community notifications. Facility managers can use such a system for building inventories and utilities, as well as to dispense facility closure and emergency evacuation information.

In the same vein as facility information, the campus community can use the technology to tap into available neighborhood information for identification of potential threats, to learn about local evacuation procedures, and to realize areas of caution. Some district police departments conduct spatial crime analysis through geocoding community felonies (i.e., turning crime addresses into grid coordinates) to keep neighbors, neighborhood watch groups, and officials informed of local incidents. The availability of neighborhood data depends upon the capabilities and funds of the particular community. Nevertheless,

through GIS, public education participants have a viable means of being zealous in their community while encouraging active learning and participation.

Redefining Public Policy

The field of public policy remains one of the most radical arenas for GIS implementation. That stated, one reason for its radical prowess is public policy's diverse and ever-changing atmosphere. Public policy covers every agreeable public domain, spreading from education and the environment to social services and international applications. If that weren't diverse enough, public policy initiatives involve the lawmakers in government, the decision makers in industry, and the eventual public end users. In short, public policy GIS applications cover every niche we have discussed so far in this book.

Since public policy's applicatory enormity can be overwhelming, let me define its common scope for spatiality. Typically, GIS is used to help secure governmental financing, define public issues to the legislators and voters, determine the effectiveness of current policy, help streamline new and existing governing protocols, and identify voids in foreign policy.

Governments finance various efforts, such as agency requests (e.g., war analysis and border patrol), industry innovations (e.g., power generation and aircraft development), and public needs (e.g., public assistance programs and education). Consequently, a deeper understanding of such financial distributions and contributions is required, and the overall effects of these fiscal changes must be adequately assessed.

To simplify fiscal assessment, GIS maps have become the popular tools of public policy applications. Maps can provide straightforward graphical depictions of current policy and highlight the advantageous elements of proposed policy changes. Color scale maps tend to be the presentation of choice for policy makers, since the graphical displays are easy to understand and can be manipulated for any specific purpose. For example, a request for additional fiscal allotment to the U.S.'s Women, Infants, and Children (WIC) program can be proved to be warranted with the help of a needs evaluation map using a confirmed data set and a differentiated color scale. The shades of color can signify increases or ranges in a target need and give a visual, easily distinguishable peek at how an allotment of funds can fill the understood needs.

Going beyond fiscal analysis and the definition of public issues, GIS has been a proponent of public policy education. Many times agencies need to educate the public on their current policies to enhance public awareness of active programs, prevent misunderstandings, and diminish unnecessary outcries for policy reform. GIS can play and has played a huge role in public policy education through detailed maps, explanatory literature, and online information

depots. With GIS-enhanced policy education programs in place, the general public is better informed, and ultimately, the policy making process is progressively focused and successful.

Case Study: Public Policy Education in Gaston County, North Carolina

In 1988, the Quality of Natural Resources Commission (QNRC), a committee of appointed citizens in Gaston County, North Carolina, was chartered to identify the county's air, surface water, and groundwater environmental concerns. A substantial portion of QNRC's work was to recommend policy changes or new policy to protect Gaston County's natural resources. Early in the project, the committee was faced with incomplete and fractured data, as well as data too technical for effective policy making. The QNRC's work progress quickly became stifled, at which point a multidisciplinary group from North Carolina State University (NCSU) stepped in to help. The group undertook a two-phase approach to the study, wherein the first phase highlighted a countywide environmental assessment and the second phase involved refining that assessment and developing a public policy education program with educational materials.

Throughout both phases of the work, the NCSU-QNRC team used geographic information systems. In phase one, GIS was used to help the research team analyze the nature and impact of Gaston County's environmental problems. In phase two, GIS was used in a more educational function, with information products being developed and used for policy education tasks. GIS maps highlighting hazardous waste sites, community well locations, water supply intakes, and surface water quality monitoring sites were among the various types of public materials created. These maps were implanted within educational literature and distributed to the public.

The NCSU group developed a public policy education program that piggybacked the publicly distributed educational materials and helped in policy evolution. Geographic information products aided the NCSU group and QNRC to realize the extent of environmental problems within Gaston County, locate the faults within existing public policy, and portray their findings to the public in a wholly comprehensible manner. In the end, NCSU and QNRC met their charter and created an environment whereby Gaston County's natural resources are protected.

15

Getting Started with GIS—An Overview of Environments, Tools, and Data

As we now understand, GIS, by its very nature, caters to visual understanding. A well-planned information product captures the important elements of the location like a snapshot captures moments and delivers it in a digestible format. Individually, text and graphical representation offer essential information for any need, but together, a whole story is told.

The same premise goes for the discovery, demystification, and total comprehension of GIS itself. A textual description of GIS and its many elements such as this book can only deliver a theoretical understanding of the science and systems. The learning of GIS demands interaction and hands-on use for a true and total grasp.

We are now at that crossroad where the essential theory has been discussed and the hands-on portion must commence. This chapter is designed to get you up and running with GIS and to pinpoint key data and software destinations on the Web for you to explore. As you work more with a true GIS environment, the theory will coalesce and an advanced understanding will form.

Getting Yourself Up and Running with GIS

Up until this point you have been armed with GIS theory and are now likely eager to start using a geospatial environment. Like an athlete mastering his sport, the GIS novice must practice in a GIS environment for the theory to fully make sense. But how can you move past the theory if you own no such GIS software and have no data with which to practice?

You can purchase the required software; however, the overall expense may be too great for someone just learning the craft. To gain experience quickly, a more practical solution (at least in these beginning stages) is to try out the free GIS software made available through various outlets in the geospatial and GIS communities. Some of the software offerings have been around for many years, while others are relatively fresh in the field. The array of available programs includes complete GIS environments, component software, basemaps, and geospatial data.

Before moving too far, we will take a brief look at the leading geospatial systems on the market that are considered the industry "standards." Once we examine what is available for purchase, we can set our sights on the easy-to-acquire free programs. Bear in mind that these systems are somewhat scaled-down environments. However, some free GIS environments, such as GRASS (discussed later), are comprehensive and are used as the sole systems in many agencies around the world. With only modest use, you will gain an appreciation of the power and functionality of this available software.

Leading For-Purchase GIS Environments

GIS is a hot commodity in the technical world. Many engineering, environmental, and technology firms use GIS regularly and subscribe a sometimes sizable budget each year for upkeep on the latest and greatest GIS environment. Luckily, today's market is highly competitive and, as such, offers an excellent array of GIS packages from which to choose. As with many software niches, there are many software packages offered, but only a handful are true benchmarks.

The GIS industry has many comparable packages available to the public. Table 15.1 lists diverse GIS environments available for purchase. However, within this listing there are seven GIS environments that lead the pack in terms of package features, flexibility, overall use, and cumulative sales throughout the industries. These systems are ESRI's ArcGIS, Intergraph Corporation's G/Technology, General Electric's Smallworld, Clark Labs' IDRISI Kilimanjaro, Autodesk's GIS Design Server, DeLorme's XMap, and MapInfo.

Although these leading software packages are considered popular and are being discussed within this context, I encourage you to examine the whole range of available GIS environments to identify the right software for your need. All of the software packages on the market are quite similar, but each offers particular variations to define functional autonomy. Equally, every GIS user has a different prerequisite and need, and to select software based on popularity may, in the end, shortchange efforts and minimize project goals. Keeping that in mind, let us take a brief look at these leading geospatial environments.

XMap	http://www.delorme.com/professional/xmap

ESRI's ArcGIS is by far the most popular geospatial environment available. The Environmental Systems Research Institute is an offshoot of the U.S. Geological Survey (USGS) and has grown in popularity since its inception in 1969. Due in part to its ties with USGS, ArcGIS has become the favored system for many U.S. and international agencies. The ArcGIS environment encompasses an integrated set of geospatial products that, grouped together, form a powerful enterprise GIS environment.

ESRI's ArcGIS suite is designed for the private and public sectors alike, making available software for desktops, laptops, tablets, servers, and mobile devices. The GIS software enables users to analyze, manage, and map geographic information and can be deployed throughout an organization by Internet and intranet connections. Users can install plug-ins, called *extensions*, to add functionality to their GIS viewing package. ESRI also offers ArcExplorer, which is a free GIS data viewer that allows basic mapping and spatial querying. Overall, given their solid industry presence, ESRI's GIS suite has remained a strong leader in the GIS software market.

Another strong leader in overall use and popularity is Intergraph's G/Technology and GeoMedia program suites. Intergraph's packages offer powerful analysis, management, and design tools geared toward users in virtually every business sector. Intergraph's G/Technology suite of programs offers specialized industry-specific data models for the various utility, pipeline, water, and communications industries. Intergraph boasts that G/Technology addresses the

best practices for cost containment, process improvement, systems integration, customer base retention, and new service opportunities. Additionally, the software was designed as an Open GIS and can subsequently work with many different GIS formats.

Intergraph's GeoMedia software suite provides user flexibility through strong, quality-focused programs designed for efficient map design, presentation, and sharing. GeoMedia allows users the flexibility of desktop, laptop, and enterprise-wide compatibility. Additionally, Intergraph offers GeoMedia Viewer, a free GIS viewer geared toward desktop geospatial viewing and the distribution of data. The combination of G/Technology and the GeoMedia software suites proves a formidable GIS environment.

General Electric's Smallworld suite offers a fresh "feel" to GIS through its advanced spatial technology and seamless existing system integration. The Smallworld suite encompasses a selection of powerful geospatial programs, including Smallworld's Core Spatial Technology, Spatial Intelligence, Enterprise Integration Tools, and Design Manager. Smallworld's program suite is designed for desktop, laptop, and Internet interoperability.

GE's software architecture is somewhat different from ESRI's all-purpose design and Intergraph's general and specialized software programs. Unlike the broad focused programs, Smallworld's design centers upon engineering, scientific, and business-oriented applications. Like its competition, GE's flexible GIS platform is an exceedingly capable geospatial environment.

In an industry with so many competing environments, a good many users prefer user simplicity and image workability over an abundance of functions and project-specific decision-making. For this, Clark Labs offers IDRISI Kilimanjaro, a widely used raster-based GIS and image processing environment. IDRISI was developed as part of an academic research program and has been designed (and redesigned) to stay user friendly and highly accessible, while serving as a benchmark in geospatial standards.

IDRISI Kilimanjaro offers the same advanced GIS and image functions as the other leaders, such as GIS modeling, database querying, spatial data development, and geostatistics; however, the software uses advanced object-oriented development tools that are especially suited for focused research and environmental modeling. Aside from its raster-based functionality and ease of use, its low cost has maintained IDRISI as a viable competitor among the GIS leaders.

No discussion about GIS environments should exclude Autodesk, a strong software company in the engineering and technical fields for many years. Autodesk is best known for its impressive AutoCAD software and has now grown its technical market to include GISs and mapping, since CAD and GIS are complementary. Autodesk Map is the company's GIS environment that is built around AutoCAD and, as such, invokes user comfort through its widely familiar AutoCAD "feel."

Autodesk Map offers the user flexibility in designing, maintaining, and producing maps and geographic data. The software's geospatial capability is solid and acutely comparable to the competition. The program suite supports desktop, laptop, tablet, mobile, and enterprise systems and has a huge following. Through their enterprise GIS system, called GIS Design Server, Autodesk offers easy data integration with reliability and security. Although the user can work on various GIS file types through the software, the most seamless of file exchanges are with files that were originally designed in an AutoCAD environment. That being said, with functionality excellence, user trust, and an already familiar program exchange, Autodesk Map proves itself a GIS forerunner.

Taking the route of minimized expense, maximum function is mapping giant DeLorme's XMap software. XMap is a relatively low-cost, full-featured GIS environment that offers GIS and GPS mapping capabilities. XMap uses a modular design for expandability, interoperability, and enhanced functionality. XMap also supports Open GIS and most GIS data formats. DeLorme's software offers a less expensive alternative for quality, but standard, GIS capability.

This leads us to MapInfo's suite of GIS software, led by their MapInfo Professional program. MapInfo Professional is a popular GIS environment that is comparable to the other leading systems in terms of geospatial capability, analytical tools, and add-ons.

MapInfo's development side is where this software package shines, through MapX, an Active X component that enables alternative software embedding. What this means is that developers can embed mapping applications within other applications, such as Microsoft Word and Excel, Lotus 123, and others. This specific capability added to the suite of other GIS analytic capabilities has made MapInfo highly attractive to business developers and users. Incidentally, MapInfo's product uniquely exemplifies how geospatial environments differ, each offering advantageous characteristics amenable to particular goals.

Now that we have examined the most popular for-purchase environments, let me just reiterate that for-purchase systems require available funding and, as with any purchase, should not be chosen by text alone. You would never dare purchase a new car without taking it out for a test drive. Identify the software packages you are interested in and examine functionality, cost, and file interoperability. Then take your GIS test drive by downloading demos of the software and discovering which software meets your needs and which fall flat.

GRASS and Other Free GIS Environments

To many GIS novices, the thought of spending hundreds, even thousands, of dollars on GIS software is alarming. What may be even more disturbing is the fact that comprehensive software is ultimately needed to provide the user with

the full functions, science, and geospatial mechanisms of GIS. As mentioned previously, the proper learning of GIS requires theory intermixed with hands-on use. Without access to GIS software, the latter part of the learning equation is undermined.

Past users have been in a similar situation of learning on a budget or staving off expensive software purchases until project requirements and full system benefits became apparent. The need for inexpensive or totally free GIS software surfaced in the early 1990s, and over the many years a catalog of quality, free GIS environments developed. In many cases, the free GIS software, called *freeware*, is a scaled-down version of the more popular fee-based software. These scaled-down versions are sometimes as basic as GIS viewers and ESRI-based shapefile editors, while other versions are fully functional base GIS systems. Both forms of freeware offer the novice GIS user a surefire means to gain the hands-on skills needed for proper understanding without a hefty monetary investment.

Answering this call for a free, fully functional GIS environment is GRASS, one of the oldest and most recognized GIS software applications available. GRASS, which stands for Geographic Resources Analysis Support System, was originally developed by the U.S. Army Construction Engineering Research Laboratories (USACERL), a branch of the U.S. Army Corps of Engineers, in 1982 as a military tool for land management and environmental planning. The USACERL maintained and revised the software up until 1995, at which time the software was deemed well developed and suitable for a wide range of applications. Today, GRASS is maintained by Baylor University in Waco, Texas, and has various mirror sites throughout North America and Europe.

By design, GRASS is a raster and topological vector-based GIS that supports image processing, geographic data management, spatial modeling, map and graphics production, visualization, and geospatial analysis. The software, with its straightforward functions and solid architecture, has gained wide appeal throughout the industry, whereby users have chosen GRASS over one of the more popular for-purchase GIS environments. The software contains more than 350 programs that offer add-on functions, such as raster/vector manipulation and enhanced mapping capabilities.

The GRASS GIS environment is used for academic and commercial applications worldwide by public and private organizations alike. In fact, the software is used by the National Aeronautics and Space Administration (NASA), National Oceanic and Atmospheric Administration (NOAA), U.S. Department of Agriculture (USDA), National Park Service (NPS), U.S. Census Bureau, and USGS. With wide industry use and public domain status, GRASS proves to be an excellent starting point for beginning GIS users.

As previously indicated, all types of skill sets have turned to GRASS and other free packages to produce viable GIS products. The demographics for

system development and use are interesting. Free GIS software packages have been developed by university researchers, programmers, philanthropists, geospatial organizations, governmental agencies, and private developers since the 1980s. As with any mass assortment of developed software, a large number of the available titles were created to serve specific roles, either in application (e.g., mining and business statistics) or in function (e.g., file format conversions and image analysis). Beyond these specific titles are the base geospatial environments (such as GRASS) and standardized software that enable users on all platforms and of all skill sets to develop, manage, analyze, and map geographic data.

To guide you in this maze of freeware, Table 15.2 offers an abridged listing of popular free GIS environments, viewers, and shapefile editors available. More comprehensive listings of geospatial freeware exist on the Web through FreeGIS.org (http://www.freegis.org), GIS Lounge (http://www.gislounge.com), and the Open Geospatial Consortium (OpenGIS; http://www.opengis.org). You will be amazed at the amount of free GIS software available. In fact, be prepared when you visit FreeGIS.org; the site is astonishingly broad and has a cavernous array of good GIS software links.

The quality of freeware ranges from the very good to the moderately bad, which really means from high operability to difficult to use. Since GIS outputs

are directly related to the geodata entered and not the system per se, quality really can be judged only on ingrained capability and functionality.

GIS Component Software

Once you begin using GIS software, whether free or purchased, you will soon realize that the software has limits. Most times the software will be satisfactory within these limits; other times you may want more. Perhaps the limit breaker is a data set that is in a different format that will take twice as long to integrate into your system or maybe a specific map analysis function that currently doesn't exist in the software. When more is desired, you have two options: Work around the limitations of your GIS environment or turn to GIS component software.

GIS component software is a building block that, when added to GIS software, forms an enhanced, personalized environment for the user. A mix of component software will make any GIS environment distinct for that user—making the environment the user's own. GIS component software allows the user to go far beyond the base system boundaries, limited only by a user's ability.

Component software is analogous to an office work desk. The actual furniture is like your GIS environment software—solid structure, yet standard for a multitude of users. The user's belongings—family pictures, reference books, or project paperwork—relative to the desk, just like component software to the GIS, make it the user's own. When used correctly, these belongings (components) add to the overall experience, use, and personalization of the desk (GIS environment) for a distinct user.

GIS component software comes in many variations, including specific function programs or user development software. Specific function components perform a dedicated task that adds to the GIS environment's tools. Such components include data format converters, flow data analyzers, and image processing software. User development software, on the other hand, is a development toolkit that enables the user to program components to perform specific functions. Say, for instance, you need to embed maps into a particular non-GIS program and there is no predeveloped component for your raster-only GIS. Developable component software would be the likely choice, especially if this operation is to be done numerous times. Simply put, component software helps save user time and automate redundant functions.

If component software interests you, there are many excellent products on the market. Perhaps the most popular component software available is Geotools (http://www.geotools.org), an open source GIS development toolkit that is freely distributed. The software is Java based and offers users the ability to develop OpenGIS-compliant products. OpenGIS is dedicated to developing

and standardizing geospatial and geoprocessing specifications. What makes Geotools attractive to users is its modular design, which allows easy installation and removal of components. The software works well with the major fee-based and free GIS environments mentioned previously.

There are various component software and development toolkits available. Table 15.3 lists a variety of useful component software links for you to explore. Sites involve fee-based and free software. Care should be taken when selecting components to download, since not all components work with every GIS environment.

Once you get hands-on familiarity with a GIS environment and are comfortable with the base functions, you should try a component. Test out a few different components to decide what these building blocks can do for your efficiency and total GIS experience. In the end, only you can decide what (or if) components are right for you. Sometimes it depends just on the objective of a project. But as with your office desk, only you can decide what you need within arm's reach.

Geospatial Data Clearinghouses

It can be said that a GIS system is only as good as the user's ability and the data set used. No discussion on how to get started with GIS should dismiss the acquisition of geospatial data. There are fundamentally two ways to obtain geospatial data: creating it yourself or acquiring previously developed data sets. Creating a quality data set is neither simple nor cheap, as one would expect. Quality dataset development requires, at a minimum, field visits and/or field personnel, satellite image analysis, aerial image analysis, GPS coordinate attainment, geospatial data entry, preexisting dataset investigations, and any existing basemaps. The effort expended on creating custom data sets can be arduous and expensive; therefore, often firms or individuals creating the data set sell their product on the market or create a geodata "bi-product" to sell. You can refer to our discussion on data bi-products in Chapter 2.

Acquiring a previously developed data set is frequently more practical and, as such, the path most GIS users take. You can acquire much needed data instantly over the Internet either at a price that is far lower than creating the data set yourself or through freely distributed data sets. For specific data sets, perhaps the 2005 bushfires in Yellowstone National Park, previous data sets may not be available and the burden of creating it is on the user.

Previously created base and bi-product data sets are distributed primarily through geospatial data clearinghouses, data warehouses, and data depots. The terms *clearinghouse, warehouse,* and *depot* are nearly synonymous with each other. For our purposes, we will view them similarly, as collections and collaborative sources of geospatial data sets. These clearinghouses sell for-purchase data sets as well as distribute free data sets under a public domain license. Easier-to-obtain datasets, such as satellite-based data, are distributed free and less available data, such as detailed bi-products about specific areas, are often fee based.

Geospatial data clearinghouses are widely used throughout the numerous industries using GIS. As a learning GIS user, you should visit these clearinghouses quite frequently and obtain free data sets and metadata with which to hone your GIS skills. Advanced users frequent these clearinghouses regularly for their project maps and geographic information products, as well as for background metadata. Whatever the purpose, these data clearinghouses are among the best places to obtain viable geospatial data and metadata.

Table 15.4 details only a small handful of international data clearinghouses. All of these sites have free data sets, and some, such as the Data Depot, are totally dedicated to free data and metadata. Bear in mind that these are just a selection of the many hundreds of available clearinghouses. For a more comprehensive listing of data sites, refer to the University of Edinburgh-Association of Geographic Information's GIS Resource list (http://www.geo.ed.ac.uk/home/giswww.html) for links to several hundred U.S. and international GIS data sites.

Proper use of free (or any) geospatial data sets is essential for attaining effective and accurate GIS products. Users must carefully consider and understand the guidelines about how the data were obtained and how they should be used. This information lies within the data set's geospatial metadata, which we discussed back in Chapter 4. No matter whom the data comes from or what typical parameters are normally used, each data set is individual and should be treated as such for the sake of your product's quality and applicability. Assume nothing and keep the data quality bar raised.

At last, you are ready to turn theory into practice within the world of geospatial information and GIS. With the mystery and uncertainty about GIS removed by understanding, you are well on your way to creating geospatial answers to today's worldwide geographic questions. Armed with these discussions and the starting knowledge of the available GIS environments, you can keenly get yourself started with GIS.

Afterword

The Future of the Growing GIS Technical Revolution

It is hard to believe that GISs have been around for more than four decades. Within this time frame, the world has experienced rather turbulent and exciting times, wherein society has dealt with human inequality issues, a superpower Cold War and escalating world unrest side by side (almost hand in hand) with the proliferation of the Internet, powerful microprocessors, and terrestrial and extraterrestrial exploration. Today, the thought of GIS as a "fresh" technology still exists, but in reality it has been reinvented and revised so many times that it now appears as something much different from its original form.

The first 40 years of GIS have proved that the core theory has remained unchanged, but the method and functionality of manipulating this theory and producing informative products have drastically changed. When GIS first came into being, it was developed and used primarily for land use issues. Its simple database structure offered a repository of land-based information and analysis. Through the years came the availability of satellite imagery, relational databases, desktop computers, powerful software, and world data infrastructures, just to name a few. Add these innovations with users who are better educated and have a multidisciplinary interest and the sum is an established, reinfused technology.

You may be asking yourself, "Where does GIS go from here?" or "How can this already established technology survive in the years to come?" Every user most likely has a personal opinion as to the future of GIS. In fact, there has been a good amount of print and online space dedicated to the dissemination of opinion and prediction.

A common theme throughout many opinion papers is the belief that history is the best indicator for technological evolution, since it reconstitutes in

continuous yet variant forms. I hold this same belief. Consequently, if history proves a valid gauge for GIS, then the technology will ultimately survive through further revision and enhanced redirection. Although this sounds as generic a prediction as a newspaper horoscope, the mere fact that GIS still exists today and is a developed technology adds value to this claim.

Let us move beyond today's version of GIS and postulate about the direction it is going. For this, I have developed what I call a GIS compass. This GIS compass (and this entire discussion for that matter) represents my own personal musings as to the direction of GIS. The following compass directions are selections of real issues that, to me, may influence the course of GIS's evolution.

The Developing GIS Compass

A compass is a worthy instrument, used to navigate terrains and help the user get from a point of origin to one of destination. It also helps the user discern what direction he or she is going. Understanding the value of a compass and the need to gauge the GIS industry's direction, I created the GIS compass. My objective was to help convey a selection of emerging terrains for GIS and identify the chief directions that I believe the industry is currently moving. Figure A.1 depicts the developing GIS compass.

As evident through today's GIS use, the industry is quickly moving in four distinct and primary directions. I define them as:

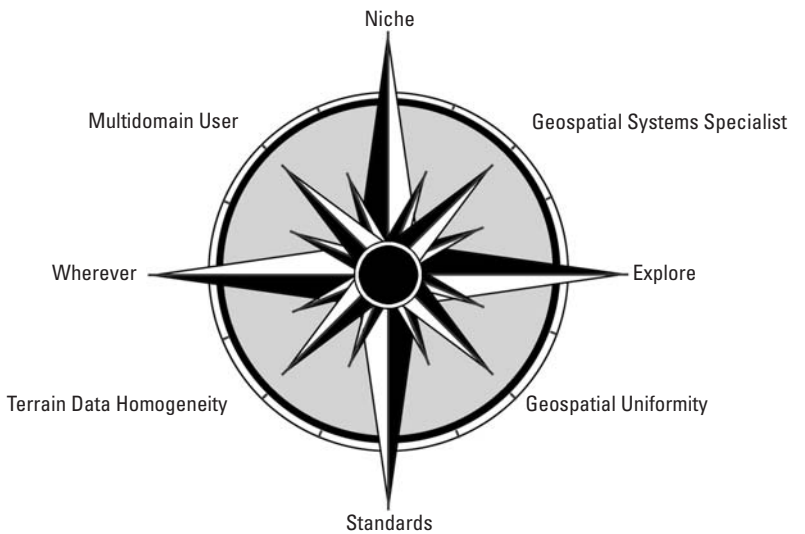

Figure A.1 The GIS compass.

- *N for niche.* Moving from the present-day GIS professional to an information technology niche field;
- *E for explore.* Moving from a geodatabase to enhanced geospatiality by exploring the increasing geospatial landscape;
- *W for wherever.* Progressing from the Earth to other topographies (both macroscopic and microscopic), such as interstellar terrains and inner body mapping;
- *S for standards.* Developing universally respected global standards.

These primary directions are speculative in nature and were determined through my interactions in the industry. User types are diversifying, applications are broadening, and the knowledge that any mapable surface can be geospatially coded is spreading. Among these primary directions are meldings in between that, I believe, will ultimately form the specifications to industry survival. Let us now take a brief look at these key pathways.

Niche

The GIS professional was always just that, a professional dedicated to GIS. These dedicated persons form the core staff responsible for (and knowledgeable about) spatially enabled geodatabases. Typically, they are the project members who provide the geospatial grunt work, such as uploading basemaps and data, validating data, geocoding resources, troubleshooting geospatial inaccuracies, and producing specific information products. They are the dedicated professionals for GIS.

With greater interest and better software abounding, it appears that today's GIS professionals are sometimes sidetracked by GIS do-it-yourselfers or project managers who skimp on their budgets. It is not out of the ordinary for GIS professionals to be tasked with other non-GIS project responsibilities. Most commonly, the GIS professional is slated as the information technology (IT) specialist, wherein the workload consists of both geographically based and general information–based system tasks. It has been my experience that the GIS professional's role also involves the actual IT hardware configurations.

This leads us to our first GIS direction: niche. I believe the future GIS professionals will not be GIS professionals per se but IT specialists with a GIS or geospatial niche. The need for a dedicated geospatial person, at least in the engineering and technological fields, is already being thwarted by minimized budgets and a push for multitasking. This is not the case for every company. Many large companies have teams of GIS professionals providing services that have sustained over time, and for federal and local agencies, the need for dedicated GIS professionals will undoubtedly remain.

Like everything else, only time will determine to what extent and in what sectors the industry will go in this direction. One thing is clear, though: that the upcoming GIS professionals will need to diversify their capabilities in order to remain valid in the marketplace.

Explore

As GIS moves toward and into every feasible technical and nontechnical crevice, the understanding (even enlightenment) of geospatiality continues to occur. When GIS began, it was a geographic database; today it is a geospatial data infrastructure. The idea that environments can be geospatially linked to other information is exciting to most, especially when it offers forms of analysis that never existed before. We have school systems exploring the geospatial terrain in their districts, such as crime statistics, neighborhood demographics, district and nondistrict school information, and more. Today's industries are just beginning to understand the absolute value of geospatial data and how they can use that information to make better decisions and grow their businesses.

Agencies have traditionally been the geospatial leaders and are continuing to broaden their range of analysis. GIS has progressed from land use applications to such exciting applications as geospatially referenced rainforest inventories. Homeland security has emerged in the geospatial realm, using available and project-acquired data to ensure public safety, while remaining a few steps ahead of the malcontents.

Exploring the geospatial landscapes involves increased knowledge of how to use and manipulate data. Geospatial training is already a large market in today's marketplace and, I trust, will likely grow into a huge on-demand market. More firms and agencies will likely continue to invest money for geospatial awareness training, since the potential cost savings and advantages to proprietary information are great.

Wherever

Similar to GIS's "explore" direction is a trend that is voraciously gaining speed: moving from Earth's immediate surface to diverse terrains and topographies. GIS has traditionally been applied to Earthbound geography, but in past years GIS has emerged as the system of choice for various different topographies. For instance, NASA has used GIS to precisely map and conduct unique analysis of the Moon's surface characteristics and, with the aid of its two robotic Martian rovers, has geospatially mapped the surface of Mars.

This "wherever" direction is not necessarily macroscopic or solely applicable to extraterrestrial landscapes; it also applies to landscapes too small to see. The medical industry is in its infancy in using GIS technology. I'm not talking

about disease tracking and prevention analysis, but rather the inner landscapes of the body, such as geocoding a map of the human brain or the human body's constituents.

The scientific community is progressing with GIS, as well. The potential for a union of underwater microscopy and GIS has only begun to be explored. I foresee GIS being used to monitor and analyze the various life forms and living structures on Earth's declining coral reefs. The absolute potential for once unimaginable analysis is made available through geospatial technology.

But more must be done to move farther in this primary direction. As stated previously, training will play a giant role in progressing industry understanding. The medical and scientific fields are just two of the myriad disciplines GIS can benefit. The tricky part, however, is getting GIS integrated within these sectors. If that weren't complicated enough, professionals must work "outside the intellectual box" and be creative with their applications in order to expand the overall system benefits. Now, I agree that GIS may not prove to be the be all and end all tool, but I do think it will play a growing role in many fields new to GIS. As with any technology, the overall efficiency and usefulness of the technology is intimately dependent upon the user's capability.

Standards

An area where there is presently the greatest amount of activity and conflict is with GIS standards. Today's GIS industry presents numerous and varying standards that are supported by some organizations and disputed by others. The procedures, protocol, format, and implementation of various GIS elements, such as metadata, are continuously experiencing change and redirection. In fact, there are some geospatial standards prominent in the United States that differ from the prominent standards in Europe and Australia.

As a promising pathway for geospatial consistency, some globally focused organizations are gaining the support and validation needed to create new standards and fluid interoperability. In recent years, the Open Geospatial Consortium has made great strides in creating the OpenGIS, a global system dedicated to universal GIS compatibility. I recognize that defining global standards will afford all GISs and geospatial data sets a method to seamlessly interoperate with each another.

Similarly, there are numerous metadata formats that are progressing toward global standardization, such as the FGDC, Dublin Core Initiative, and ISO efforts. The Open Geospatial Consortium has even posted guidelines for metadata, which has proved to be one stepping stone for international metadata standardization. With each metadata schema, there are very different minimum requirements, in addition to differing metadata semantics and syntax. I foresee this direction progressing further.

Even though great strides have been made through the ISO metadata efforts, I sense that global standards may never occur, simply because it would require a good many organizations worldwide to buy into the structure, discipline, and protocol of a specific standard. If these universal standards are achievable, it will most likely be countless years before global standards truly manifest and get approval by the whole GIS community. That being stated, if this direction's destination is reached, it has the potential of redefining the way GIS is done in the years to come.

All Directions in Between

The GIS compass is unique in that between my primary anticipated directions (refer to Figure A.1) there are meldings—geospatial systems specialist, geospatial uniformity, terrain data homogeneity, and multidomain user—that offer likely products. The geospatial systems specialist, for instance, is a melding of two directions—a niche IT person specializing in all things geospatial. Likewise, geospatial uniformity, to me, involves a melding of geospatial exploration (all things geospatial) and standardization.

Terrain data homogeneity melds the idea of any terrain (on or off the Earth) with standards and homogeneous use of the data. The multidomain user direction melds the notion of using GIS wherever necessary with specialized (niche) yet multidisciplinary users.

As you may have realized already, it is my opinion that the progression of the four primary directions can be met through creative combinations of each. These combinations are manifesting today worldwide and, as a guess, will increase in both occurrence and availability. It will not be too long before doctors and building managers alike are using GIS to conduct business tasks, or geospatial products from different continents are cataloged the same exact way throughout the world. Apparently, there will also be a time in the not too distant future when GIS systems will read all formats without fail. Right now, these aspirations are in process and remain to fully manifest. I feel, given time, they will. You can say they are whims of fancy and hold no certainty as yet; however, one thing is definite: that GIS remains a true technical revolution.

Appendix A: Reference Ellipsoid Parameters

Considered a worldwide ellipsoid, WGS84 is one of the most widely used reference ellipsoids available. However, there are several major ellipsoids that are focused to specific areas and more locally used. Table A.1 highlights key reference ellipsoids and provides the associated semimajor axis (equatorial radius), semiminor axis (polar radius), and inverse flattening parameters. Please note that semiminor axis constants were calculated using the following formula:

$$Semiminor\ axis = Semimajor\ axis \times \left(1 - \frac{1}{Inverse\ flattening}\right)$$

Table A.1
Reference Ellipsoid Parameters

Appendix B: Worldwide Geodetic Datums

Using geodetic datums correctly is an important part of working with GIS and producing accurate information products. Although similar, geodetic datums are distinct, having unique geodetic characteristics. Therefore, conversion between datums is needed. To convert from one datum to another, specific conversion parameters and the three-dimensional coordinate shifts between both datums must be known. In more complex conversions, where coordinate axes are not parallel and/or scaled, coordinate axes rotational parameters and a scale difference factor must be known as well.

Since the World Geodetic System 1984 uses an Earth-centered, Earth-fixed coordinate system, it is a highly used, worldwide datum (and reference ellipsoid). In fact, GPS is based upon WGS84. Due to its worldwide appeal, many applications require local datums to be converted to WGS84. As with any simple geodetic datum transformation, basic datum transformation parameters must be known.

Table B.1 contains a brief listing of geodetic datum transformation parameters relative to WGS84. It highlights some of the more conventional datums used throughout the world, but by no means is it a comprehensive listing of available datums. Further information and more complete local listings are freely distributed through the datum sources cited.

The following base parameters were used to create Table B.1:

$$WGS84 \ semimajor \ axis = 6{,}378{,}137$$

$$WGS84 \ flattening = 0.003352811$$

Table B.1

Glossary

absolute accuracy Map accuracy based on geographic coordinates and specific to an object's geographic location in relation to its true location on the surface of the Earth.

active pages Web pages that offer full user interaction, whereby the user can request information, as well as make changes to and manage the database.

aspect The relative orientation of the projected plane and the ellipsoid of revolution with respect to the location of an observer.

attributes Columns in a relational database management system (RDBMS) that contain distinct field data.

axis A line of symmetry within a shape.

axis of revolution *See* axis of rotation.

axis of rotation An axis upon which a two-dimensional shape is rotated to form a three-dimensional shape. For instance, an ellipse is rotated upon its major axis to form an ellipsoid.

azimuth The horizontal component of a line's direction, measured in degrees clockwise from the baseline; the baseline is typically the vertical axis (*y*-axis), and both the line and the baseline share a common center point.

azimuthal projection — *See* planar projection

bar scale — *See* graphic scale

bi-products — Developable information products formed as a result of a specific application data process.

Cartesian coordinate system — A two-dimensional, planar coordinate system, where horizontal and vertical distances are measured as *x* and *y* coordinates.

cartography — The organization, design, collection, portrayal, and reproduction of geographically based information in various formats, such as on graphic maps or within digital formats.

Cassini, Jean-Dominique (1625–1712) — An eighteenth-century patriarch of a renowned French geodesic family who erroneously concluded that the Earth pointed toward the poles and flattened at the equator. Cassini's Earth model was a prolate ellipsoid and resembled an egg shape. It was the favored model among the French geodetic community until the French Academy of Sciences proved him incorrect in 1745. Cassini was born Giovanni Domenico Cassini in Genoa, Italy, and after moving to France changed his name to Jean-Dominique.

centroid — The center of an area, region, or polygon represented as discrete *x-y* coordinates.

circle — A symmetrical two-dimensional shape in which any point on the outer shape is a set distance (radius) from a center point.

client-server system — A relational database type that is designed to effectively handle with speed and efficiency the many users accessing the central database at one time. This system uses a network to connect the user workstations (called clients) to the central database residing on a file server.

Codd, Edgar F. (1923–2003) — The author of "A Relational Model of Data for Large Shared Data Banks," who detailed a new method of simplifying database management using relational algebra for straightforward database functions. He is considered the forefather of the relational database management system. *See* Relational database management system (RDBMS)

compensatory scale factors Variant scale factors that compensate for one another to preserve a projection's area characteristic. These scale factors are typically greater than 1.0 in one direction and less than 1.0 in another direction. In equal-area projections, using compensatory scale factors will project a circle on a globe as an ellipse on a plane surface.

computer-aided design (CAD) Computer-based design software used to produce various technical and design drawings, specifically in the engineering, architectural, and environmental fields.

conformal projection A projection classification that maintains the shape and angles of a small area while minimizing distortion. As regions become larger, projections and area shapes become more distorted.

conic projection A type of map projection in which the globe is represented at an exact scale along a particular parallel (standard parallel) between the equator and a pole. Distortion increases away from that standard parallel. It can be envisioned that this map projection is made by projecting the features of the Earth onto a conic wrap (like a birthday hat) then cutting it to make a flat map.

continuous data A numeric form of data usually associated with the physical measurement of boundaries that are not well defined.

coordinate A number set that represents a specific location within a reference system. An *x-y* set is used in a planar coordinate system and an *x-y-z* set is used in a three-dimensional coordinate system.

curvilinear surface A surface consisting of or bounded by curved lines.

cylindric projection A type of map projection where the globe is represented by equidistant, parallel straight lines that intersect one another at right angles. The projection is true at the equator and increases in distortion toward the poles. It can be envisioned that this map projection is made by projecting the features of the Earth onto a cylindrical wrap then cutting it to make a flat map.

database management system (DBMS)	A program or collection of programs that enables the user to save, modify, classify, select, and extract information from a central database. DBMSs are used throughout the world and throughout almost every industry for the purposes of centralizing information and automating processes.
datum	Any set of numeric or geometric parameters used to accurately measure or define another quantity.
developable projection surfaces	A shape that can be flattened as a surface without any residual distortion. Predominant shapes include cones, cylinders, and planes.
digital elevation model (DEM)	Digital terrestrial or terrain elevation data that is typically defined by *z*-values and referenced to a common datum.
digital terrain model (DTM)	A digital, three-dimensional model of the Earth's surface. DTMs are typically used to define terrain and landform reliefs.
discrete data	Data about geographic features with well-defined boundaries that are represented by points, lines, or polygons.
distortion	The warping of shape, direction, scale, or area on a map projection or image in relation to real-world measurements.
distortion magnitude	The amount and density of distortion in a projection.
distortion pattern	A discernible pattern in a projection's distortion, such as the misrepresentation of landforms near the poles or distortion of areas.
dynamic pages	Web pages that offer some user interaction, whereby the pages display the most recent or dynamic database information as defined by the user.
Earth model	A physical shape that wholly represents the Earth and is used for mathematical and scientific purposes.
Earth-Observing Satellites (SPOT)	*See* Satellite Pour L'Observation de la Terre.
Eccentricity	An ellipse-specific constant that measures the degree of flattening as the relationship between the focal radius and the semimajor axis.

ellipse A two-dimensional shape that is flattened on one axis. The shape resembles a flattened circle and consists of a major and a minor axis.

ellipsoid A three-dimensional shape that is flattened on one axis. The shape resembles a flattened sphere and is formed from an ellipse rotated around an axis (axis of rotation). Like the ellipse, it consists of a major and minor axis.

ellipsoid of revolution An ellipsoid that revolves around a major axis. *See* axis of rotation

enterprise system A system that supports a wide variety of users having different functional requirements over an entire organization.

equal-area projection A projection classification determined when the relative sizes of all features on a globe are maintained during the projection process. An equal-area projection vigilantly retains area properties of the ellipsoid on the plane surface through the use of compensatory scale factors. This projection classification may distort shape, angle, and/or scale.

equator An imaginary line that covers the widest circumference on Earth. It is indicated as 0° latitude.

equatorial Relating to or dependent upon the equator.

equidistant projection A projection classification determined when scale is true along at least one line (a focal line) or from one or two points (focal points) to all other points on the projected surface.

Eratosthenes (276–194 B.C.) An innovative third-century B.C. Greek mathematician who made a nearly accurate calculation of the Earth's circumference using base scientific understanding, crude measuring instruments, and meticulous observation. His observations occurred in Egypt, within his home town of Syene (now Aswan) and at Alexandria, a town roughly 500 miles away.

feature file A file that contains geographic object feature information, such as representative point, line, and polygon information.

file-based system The simplest of relational database types that uses a single file for the database tables, queries, security information, and forms/reports.

finite Within a limit or set parameter.

first eccentricity *See* eccentricity.

flattening A measurement of axial compression in an ellipse that is directly related to the differences in both the semimajor and semiminor axes.

focal radius The distance from the center point to the foci (i.e., F_1, F_2) in an ellipse.

geocode Geospatially coded information products.

geodesy The division of science associated with the measurement and portrayal of the Earth. Geodesy, known also as geodetics, is intimately concerned with the determination of the size and shape of the Earth, as well as its elements. These Earth-based elements include its terrestrial gravity, magnetic field, tides, geologic and crustal movement, and polar motion.

geographic coordinate system A geographic reference system that uses latitudal and longitudal measurements to define point locations on a sphere or ellipsoid.

geographic data Geographic-related information about a map's features, including point locations, shapes, and descriptions.

geographic information *See* geographic data.

geographic information system (GIS) A collection of computer hardware, software, and geographic data for capturing, storing, updating, manipulating, analyzing, and displaying all forms of geographically referenced information. GIS is, in essence, a central repository of geographic data collected from various sources, including satellites, the global positioning system (GPS), and topographical maps.

geography The study of the Earth's surface that furnishes information about the Earth and distinguishes how features upon the Earth correlate with one another. It is the founding science to GISs.

geoid An exacting model of the Earth defined by the mean sea level. The model continues through the continents and is not defined by true topological heights or standard shape references.

geomensuration The measurement of the Earth as a whole, such as on a global level, that offers credible measurements useable toward precise geodetic positioning, surface shape, and size.

geometric A term that represents the spatial relationship between features and objects.

geometric deformation indicators The circular or elliptical indicators on an indicatrix. A circle represents conformality (no distortion in shapes), while an ellipse represents local distortion at the intersection where the object is plotted. These circular or elliptical objects are fixed at a finite scale with explicit locations in the projected surface.

geoprocessing The fundamental process of creating a derived set of geographic data from various existing data sets using operations such as feature overlay and data conversion.

georeferencing The process of referencing images, spatially transforming them into a defined coordinate referencing system, and integrating and overlaying them in a GIS environment.

geospatial analysis The process of analyzing and interpreting geospatial models.

global positioning system (GPS) Handheld and mobile devices that communicate with a system of satellites orbiting the Earth to record *x*, *y*, and *z* coordinates and calculate precise positional data. GPS devices are used for a multitude of applications, including surveying, mapping, hiking, and navigation.

globe A scaled, physical representation of the Earth.

graphic scale A map scale that depicts a bar of a certain length to represent a distance length. Graphic scales are commonly called bar scales and enable the map user to visually recognize distances with relative ease.

graticule A basic grid of meridians and parallels.

hemisphere One-half of a symmetrical shape, such as an ellipsoid or sphere. Earth is divided by its equator, forming a northern and a southern hemisphere.

horizontal control datum Any datum that serves as a geodetic reference for a precise northerly or southerly location (latitude) and easterly or westerly location (longitude).

index file A file that contains unique identifiers that comprise more detailed product information and help speed spatial feature queries.

indicatrix A visual distortion analysis tool that depicts a projected graticule as a distortion graph and shows distortion as circles or ellipses at the specific intersections in the plane.

inverse flattening The reciprocal of flattening used to minimize human error and help simplify conveyance.

irregular triangular surface model *See* triangulated irregular network.

isarithms *See* isoline.

isoline A line on any surface that connects points of equal value.

large-scale A project or map signifier that refers to applications involving small areas of focus, such as a community, a city block, or a university campus. A typical large-scale representative fraction can be assumed to be anything less than 1:50,000.

latitude The distance along a meridian that is either north or south of the equator. Latitudes are measured in degrees and are commonly called parallels.

layer A set of theme-based data that is described and stored in a map's library. Layers may contain a basemap or satellite image or can include such information as roadways, pipelines, soil sample locations, soil types, vegetation types, and water distribution.

legend A map reference that lists and distinguishes various map colors, lines, shapes, patterns, symbols, and annotation. Many times, the legend highlights map scale, source, projection, and other information.

light intensity detection and ranging (LIDAR) Remote sensing tool that uses a laser to precisely measure distances to various surfaces and terrain.

linked attribute table A matrixed table that contains explicative attributes for a group of spatial features.

longitude The angular distance between a target meridian and the prime meridian (0°). Longitude lines converge at the north and south poles, with measurements typically expressed in degrees, minutes, and seconds.

major axis A line of symmetry that passes through the widest portion of a shape. In an ellipse, the axis passes through both foci.

map projection A process that transforms a three-dimensional object, such as the Earth's globe, into a two-dimensional format. Some projections preserve shape; others preserve the accuracy of distance, area, or direction.

map scale The relationship between a distance on a map and its corresponding distance on the ground. It relates the size of map-based features with their actual, real-world size.

map space A platform for geographic data in depicting Earth features on a distinct coordinate system.

meridian A vertical line extending from the north pole to the south pole. Locations along the same meridian are said to have the same longitude.

metadata Information about a specific data set, including the geographic data's source, resolution, scale, and proper use.

mid-scale A project or map signifier that refers to applications that are not overly large or small, but rather fall right in the middle. A typical representative fraction ranges from 1:50,000 to 1:500,000.

minor axis A line of symmetry that passes through the shortest portion of a shape. In an ellipse, the minor axis passes through the center point and is perpendicular to the major axis.

multitier system A relational database type that functions similarly to the client-server system, except that there are middle servers, which contain software to perform certain tasks and process transmitted data. *See* three-tier system.

natural resources Natural elements of the Earth, such as rivers, streams, wetlands, and landforms.

natural scale *See* ratio scale.

Newton, Sir Isaac (1642–1727) Considered the father of modern mathematics, his gravitational theory published in *Philosophiae Naturalis Principia Mathematica* became the backbone for Britain's Earth model. The British model was an oblate ellipsoid—grapefruit-shaped and bulging in the middle. In 1745, the French Academy of Sciences proved the British model was correct and, subsequently, validated Newton's theory.

normal aspect A projection aspect based upon a standard line along which distortion is minimized. The farther you move away from the standard line, the greater the distortion.

oblate ellipsoid A grapefruit-shaped ellipsoid that bulges in the middle and is flat on top and bottom.

oblique aspect A projection aspect used when the axis of the Earth and the axis of the projection are oriented in an arbitrary manner. This aspect type is uniquely suited for geographic areas that are centered along lines that are neither meridians nor parallels. Consequently, this aspect type tends to be directed northwest, northeast, southwest, or southeast.

orthomorphic projection *See* conformal projection.

orthophotography The photographic process by which aerial photographs are rectified to produce an accurate image of the terrain. The process removes the Earth's tilt and any land relief displacements that occurred at the time the photo was taken.

parallel Two or more lines wholly separated by a constant distance. Geographically speaking, latitude lines, such as the equator, are in parallel with one another.

photogrammetry The process of identifying objects and measuring their true physical dimensions from photographs.

planar projection A type of map projection that is an azimuthal orientation of a projected surface. This projection type is true only at the center point and protects the integrity of azimuths, bearings, and directions from a central point to other more remote points in the plane. It can be envisioned that this

	map projection is made by projecting the features of the Earth onto a flat, touching plane, like a piece of flat paper touching a globe.
planar space	A map space utilizing a horizontal (*x*) and vertical (*y*) axis.
planar surface	A two-dimensional surface defined by an *x-y* coordinate grid.
plane coordinates	Positional measurements from the origin (0,0) in a planar coordinate system. Coordinates are typically represented by an *x-y* pair.
plane of the ecliptic	The imaginary line that defines the elliptical path the Earth takes as it orbits the Sun.
polar aspect	A projection aspect that centers on a single point, either the north pole or the south pole. This aspect retains symmetry about any meridian and distorts between them.
poles	The points where the axis of rotation intersects the surface of a three-dimensional shape.
primary key	A unique attribute in a relational database management system (RDBMS) that distinguishes each record. They can be sequential record numbers or user-defined values that are unique and, thus, not duplicated anywhere within the same attribute throughout the records.
prime meridian	A reference longitudal line that flows through Greenwich, England. The prime meridian is typically called the Greenwich meridian and is located at 0° east and west.
projection aspect	The relative orientation of the projected plane and the ellipsoid of revolution with respect to the location of an observer.
projection type	A term that relates to the distinct types of map projections available for use on the projected plane, such as the cylindric, conic, and planar types.
prolate ellipsoid	An egg-shaped or elongated ellipsoid that is flattened in the middle.
quadrangle	A map that defines a focal area's topography within latitude and longitude lines. It usually refers to the U.S. Geological Survey's 7.5-minute series or 15-minute series.

raster data Spatial data represented as a grid of valued pixels or cells. Each cell contains an attribute value and positional coordinates. These positional coordinates are wholly associated with the grid and its defined order.

ratio scale A map scale that reduces a map's distance to 1. One unit on the map corresponds to a distance in the same units on the ground. In a typical 30-minute series topographic map, the representative fraction is shown as either 1/125,000 or 1:125,000, whereby the 1 and 125,000 are the same unit of measure. A ratio scale is more formally known as a representative fraction and less formally as a natural scale.

reference ellipsoid A standardized ellipsoid with officially proved and measured parameters. The reference ellipsoid enables GIS to define point locations with regional accuracy.

region of interest The area where focus has been placed.

relational database management system (RDBMS) A program or collection of programs that enables the user to build data relationships to efficiently save, modify, classify, select, and extract information from a central relational database.

relative accuracy Map accuracy specific to an object's geographic location in relation to the true location of other objects on Earth.

relief map A map detailing the elevations and depressions of the Earth's surface with contour lines, shading, and digital terrain modeling. Relief maps are and appear to be three dimensional in nature.

remote sensing Any form of distance-based or remote viewing, observation, and measurement of the Earth. Typical forms include aerial photographs, satellite images, global positioning systems, LIDAR, and sonar.

representative fraction *See* ratio scale

resolution A measurement of image sharpness, usually indicated by pixels per line or dots per inch.

Satellite Pour L'Observation de la Terre (SPOT) A series of Earth-observing satellites that offer the ability to observe the whole Earth (minus a strip over the equator) in a single day. These satellites are part of a remote sensing program first designed by France in partnership with

	Belgium and Sweden. Current satellites include the SPOT1 and SPOT2 units. Use of the SPOT3 satellite ceased in 1996.
scale reduction	The process of proportionally reducing actual dimensions into much smaller, more convenient dimensions.
second eccentricity	An ellipse-specific constant that measures the degree of flattening as a relationship between the focal radius and the semiminor axis.
semimajor axis	Equal to one-half of the major axis.
semiminor axis	Equal to one-half of the minor axis.
sidereal day	A true day measurement, with a length of 23 hours, 56 minutes, and 4.09 seconds.
sidereal year	A true year measurement, with a length of 365.2564 days.
Six Sigma	Stands for six standard deviations from the mean or average and involves a measure of quality that strives for near perfection. This quality protocol is a disciplined, data-driven methodology for eliminating shortcomings and deficiencies in any business process.
small-scale	A project or map signifier that refers to applications involving relatively large areas, such as a map of the world, the continent of Australia, or the city of Rome, Italy. A typical small-scale representative fraction can be assumed to be anything greater than 1:500,000.
Snow, John (1813–1858)	A British physician who mapped all cholera deaths on a hand-drawn street map of a London neighborhood and helped end the epidemic of 1854.
spatial	A term used to describe anything located within a space that has physical, measurable dimensions.
spatial analysis	The study of geographic feature locations, attributes, and spatial dimensions and the relationships between each.
sphere	A symmetrical three-dimensional shape, in which the distance (radius) from the surface to a common center point is identical anywhere on the object. It can be thought as a circle rotated around an axis.
spheroid	*See* ellipsoid

standard axis *See* axis

standard line A line of exact scale that is represented by a true scale factor value of 1.

State Plane Coordinate System A two-dimensional, planar coordinate system established by the U.S. government to define positions on, above, and below the Earth's surface by *x-y* coordinates.

static pages Web pages that display database-driven information that cannot be changed, altered, or modified by the user.

Structured Query Language (SQL) A relational programming language used in complex database management systems. It is pronounced "Sequel."

Summer Solstice The longest day of the year, which occurs when the Sun is farthest north. In the northern hemisphere, the day is around June 21. In the southern hemisphere, the day is around December 22.

surveying The measurement of individual parts on the Earth's surface that offers credible measurements useable toward precise geodetic positioning of surface shape and size of the ever-changing physical terrain.

tagged-image file format (TIFF) A standard raster data file format that supports black-and-white, grayscale, limited color, and true color images.

thematic mapping The process of creating specialized maps using select information (i.e., a basemap) relating to one or more explicit themes. Themes include such information as roadways, pipelines, soil sample locations, soil types, vegetation types, and water distribution.

thick clients Users with a majority of processing capabilities in a relational database management system (RDBMS), such as is in the client-server and file-based relational database systems.

thin clients Users with reduced processing capabilities in a relational database management system (RDBMS), such as in the multitier relational database type.

three-dimensional Term pertaining to a spatial object or phenomenon dealing with three physical dimensions, typically *x*, *y*, and *z*.

three-dimensional mapping Spatial mapping that is detailed against three spatial coordinate planes, usually *x*, *y*, and *z*. Sometimes the *z* plane is substituted for an *m*, *n*, or k plane.

three-dimensional space A map space utilizing a horizontal (*x*), vertical (*y*), and perpendicular (z) axis.

three-tier system A relational database setup involving three distinct tiers: the client or user tier, the application tier, and the development tier. *See* multitier system.

Tissot indicatrix A helpful tool for visually modeling distortion and for graphically analyzing the distortion properties in a projected surface.

Tissot, Nicolas Auguste A nineteenth-century cartographer best known for his groundbreaking approach to distortion analysis, known now as the Tissot indicatrix, in his *Memoire sur la Representation des Surfaces et les Projections des Cartes Geographiques.* His indicatrix became a helpful tool for visually modeling distortion and for graphically analyzing the distortion properties in a projected surface.

Tobler's First Law of Geography A fundamental law of geography that states that things close together in space tend to be more alike than things that are far apart.

topographic map *See* quadrangle

topography A definition of the terrain's shape or configuration, typically represented in map form by layered contour lines.

topology The spatial relationships between contiguous or adjacent geographic features.

transformation The conversion of map or image coordinates from one coordinate system to another. Standard transformation techniques include rotation, skewing, shifting, and scaling.

transverse aspect The projection aspect when a standard line (normal) aspect is rotated 90°. This transverse aspect projection minimizes distortion along meridians and can have azimuthal or equatorial alignment.

triangulated irregular network (TIN) A network or series of continuous, nonoverlapping triangles used to define elevation data over a focus area. These

	triangles are used for surface representation and display, sometimes called an irregular triangular surface model.
true scale	A scale that is devoid of distortion, represented by a scale factor of 1.
tuples	Rows in a relational database management system (RDBMS) that contain the individual records.
two-dimensional	Term pertaining to a spatial object or phenomenon dealing with only two physical dimensions, typically *x* and *y*.
two-dimensional space	*See* planar space
UTM coordinate system	A two-dimensional, positional coordinate system based upon the Universal Transverse Mercator (UTM) map projection. The UTM system partitions the earth's surface into 60 zones wherein each zone (cell) is roughly 6° east to west and 8° north to south.
vector data	Spatial data expressed as an ordered list of coordinate points (*x-y* coordinates) to represent geographic features with associated attributes. Geographic features are represented by points, lines, and polygons.
vector space	A platform for geographic vector data, which use *x-y* coordinates with lines and shapes to depict Earth features. It stores nontopological coordinate geometry and attribute information for spatial features.
verbal scale	A map scale that expresses the map-to-ground relationship in words, such as "One inch represents 75 miles" or "One inch equals 75 miles."
vertical control datum	Any datum that serves as a geodetic reference for elevations or height above and below the reference shape, be it a geoid or standard ellipsoid.
Winter Solstice	The shortest day of the year, which occurs when the Sun is farthest south. In the northern hemisphere, the day is around December 22. In the southern hemisphere, the day is around June 21.
zenithal projection	*See* planar projection

About the Author

Stephen R. Galati is the Northeast proposal manager for TRC Environmental Corporation. With more than 13 years of experience in technical writing, engineering, and proposal management, Mr. Galati's work centers upon environmental, marketing, and GIS applications throughout the United States. He has written numerous articles for industry periodicals.

Mr. Galati holds a B.S. in electrical engineering from Pratt Institute and an M.A. in English from the College of Staten Island–City University of New York. He is a member of the American Society of Photogrammetry and Remote Sensing, the American Geophysical Union, and the New York City Chapter of Geographic Information Systems and Mapping Operations (GISMO), as well as a GeoData Alliance Affiliate.

Contents

Foreword *ix*
Ron Furness and Andy Sherin

Preface *xiii*
Darius Bartlett and Jennifer Smith

Contributors *xv*

Chapter One *1*
Coastal Spatial Data Infrastructure
Roger A. Longhorn

Chapter Two *17*
Bridging the Land-Sea Divide Through Digital Technologies
Simon Gomm

Chapter Three *27*
A Comparative Study of Shoreline Mapping Techniques
Ron Li, Kaichang Di and Ruijin Ma

Chapter Four *35*
Monitoring Coastal Environments Using Remote Sensing and GIS
Paul S.Y. Pan

Chapter Five *51*
Spatial Uncertainty in Marine and Coastal GIS
Eleanor Bruce

Chapter Six *63*
New Directions for Coastal and Marine Monitoring: Web Mapping and Mobile Application Technologies
Sam Ng'ang'a Macharia

Chapter Seven *77*
Exploring the Optimum Spatial Resolution for Satellite Imagery: A Coastal Area Case Study
Chul-sue Hwang and Cha Yong Ku

Chapter Eight 95
Visualisation for Coastal Zone Management
Simon R. Jude, Andrew P. Jones and Julian E. Andrews

Chapter Nine 109
Application of a Decision Support System in the Development of a Hydrodynamic Model for a Coastal Area
Roberto Mayerle and Fernando Toro

Chapter Ten 125
Decision-Making in the Coastal Zone Using Hydrodynamic Modelling with a GIS Interface
Jacques Populus, Lionel Loubersac, Jean-François Le Roux, Frank Dumas, Valerie Cummins, and Gerry Sutton

Chapter Eleven 141
Towards an Institutional GIS for the Iroise Sea (France)
Françoise Gourmelon and Iwan Le Berre

Chapter Twelve 153
Culture Intermixing, the Diffusion of GIS and its Application to Coastal Management in Developing Countries
Darius Bartlett and R. Sudarshana

Chapter Thirteen 165
The Use of GIS to Enhance Communications of Cultural and Natural Resources and Contamination
John A. Lindsay, Thomas J. Simon, Aquilina D. Lestenkof and Phillip A. Zavadil

Chapter Fourteen 181
GIS Applications in Coastal Management: A View from the Developing World
Peter C. Nwilo

Chapter Fifteen 195
High-Resolution Elevation and Image Data Within the Bay of Fundy Coastal Zone, Nova Scotia, Canada
Tim Webster, Montfield Christian, Charles Sangster and Dennis Kingston

Chapter Sixteen 219
Mapping and Analysing Historical Shoreline Changes Using GIS
Courtney A. Schupp, E. Robert Thieler and James F. O'Connell

Chapter Seventeen *229*
GIS for Assessing Land-Based Activities that Pollute Coastal Environments
J.I. Euán-Avila, M.A. Liceaga-Correa and H. Rodríguez-Sánchez

Chapter Eighteen *239*
Applying the Geospatial Technologies to Estuary Environments
David R. Green and Stephen D. King

Chapter Nineteen *257*
A Territorial Information System (TIS) for the Management of the Seine Estuary – Environmental and Management Applications
Jean-Côme Bourcier

Chapter Twenty *269*
Developing an Environmental Oil Spill Sensitivity Atlas for the West Greenland Coastal Zone
Anders Mosbech, David Boertmann, Louise Grøndahl, Frants von Platen, Søren S. Nielsen, Niels Nielsen, Morten Rasch and Hans Kapel

Chapter Twenty-one *281*
Environment Canada's Atlantic Sensitivity Mapping Program
André Laflamme, Stéphane R. Leblanc and Roger J. Percy

Epilogue: Meeting the Needs of Integrated Coastal Zone Management *295*
Jennifer L. Smith and Darius J. Bartlett

Index *301*

Foreword

The material presented in this volume comprises updated and edited presentations first made to the CoastGIS'01 Conference conducted in Halifax, Canada between the 18th and 20th June 2001 together with chapters commissioned by the Editors.

The CoastGIS series of conferences have been the outcome of a fruitful collaboration between the International Geographical Union's Commission on Coastal Systems and the International Cartographic Association's Commission on Marine Cartography. Generally entitled "International Symposium on GIS and Computer Mapping for Coastal Zone Management" we have seen five successful CoastGIS conferences held over this decade-long collaboration.

These conferences were held in Ireland (Cork, 1995), Scotland (Aberdeen, 1997), France (Brest, 1999) Canada (Halifax, 2001) and Italy (Genoa, 2003). A closely allied CoastalGIS conference was conducted in Wollongong, Australia in July 2003. Future conferences are planned for Scotland, Australia and Barbados.

At the first meeting in Cork, we had the honour of being addressed in a keynote presentation by Lord Chorley, who referred in his address to the House of Commons Environment Select Committee's 1992 Report on coastal zone protection and planning. Reflecting on the findings of that Report, Lord Chorley was then struck by three main points.

"First, it is only in recent years that the coastal zone has been recognised as one important topic in its own right. Second, the huge range of relevant aspects or considerations. (Thirdly): the huge number of agencies involved, often with overlapping and perhaps incompatible responsibilities, jurisdictions and objectives."

These themes have recurred throughout the conferences that followed.

Halifax 2001

CoastGIS'01 was convened in Halifax, Canada, at Saint Mary's University between 18th – 20th June 2001. The conference attracted over 150 delegates from the Americas, Europe, Africa, Asia and Australia who presented 36 oral presentations and live demonstrations in a single stream format and 50 posters. The theme selected by the 2001 Science Committee was "Managing the Interfaces," a theme with a multitude of possible interpretations. Overall, the shift in emphasis towards *integration* of systems for coastal management and the

growing interest in coastal spatial data infrastructures were especially in evidence at this meeting. So too was the international dimension of coastal GIS.

Notably, for the first time, financial assistance from the Canadian International Development Agency and the Geomatics Association of Nova Scotia permitted CoastGIS 2001 to fund ten delegates from the developing world to participate in the conference. Two chapters in the book result from this initiative (those by Nwilo and Euán-Avila *et al*.).

CoastGIS 2001 also instituted demonstrations of live GIS systems. Three chapters in this volume arose from this innovation (Laflamme *et al.,* Mosbech *et al.* and Bourcier). There were field trips to Nova Scotia Community College's Centre for Geographical Sciences in the Annapolis Valley and to the Bay of Fundy, where we considered the coastal issues facing a region that experiences the highest tides in the world.

This setting drove home the dynamic nature of the coastal zone interface of land, sea and air. Within this framework, several of the conference presentations that evolved into chapters in this volume deal with the dynamics of the coastal zone, while others address approaches to bridging the land-sea divide.

Many presentations at the Halifax gathering focused on the need for an effective interface amongst the range of participants and stakeholders involved in coastal management. The chapters in this volume that describe applications and case studies and those that include traditional ecological knowledge demonstrate the impact of effective communication between these parties.

The use of increasingly advanced technologies in the coastal zone (notably remote sensing, web mapping and mobile application technologies, visualization techniques, and LiDAR) to support research and management was a highlight of the conference and is detailed in several chapters.

The reader will no doubt be well aware of the amazing developments of GIS capability over the last decade in particular. Nonetheless, the development of standards, formats and data models together with the sheer genius of GIS technological developments and ultimate cost effectiveness are perhaps still hampered by the paucity of available data sets. At CoastGIS 2001, the development of spatial data infrastructures was highlighted. Susan Lambert, then the Executive Director of the Kentucky Office of Geographic Information and now with the United States Geological Survey, presented a keynote lecture on the development of the GeoData Alliance, a nonprofit organization open to all individuals and institutions committed to using geographic information to improve the health of our communities, our economies and the Earth. A presentation was also made on Canada's Marine Geospatial Data Infrastructure. The Editors of this volume invited Roger Longhorn to summarize the progress in the development of coastal spatial data infrastructures for this volume.

Genoa 2003 and beyond

One advantage the authors have in writing this Foreword is being able to do it immediately after the successful conclusion of this successful conference, which ran from October 16 to 18, 2003. Exploration of the SDI theme continued at the 2003 CoastGIS conference held in Genoa, Italy. At this gathering emphasis was placed upon many of the non-science and non-technology issues that continue to adversely impact the success and long-term sustainability of many coastal zone projects and wider coastal zone monitoring initiatives at national and regional levels due to barriers to the access to data and information.

In summarizing the outcomes of the Genoa conference on behalf of the Scientific Committee, Roger Longhorn noted that virtually all presentations had covered coastal zone research, monitoring or management work in a *single* nation, often in a single sub-national region. Very few therefore faced the added difficulties that can arise when trying to locate, access, understand and agree on the usage and dissemination terms for data from owners outside not only one's own discipline, but outside one's national legislative infrastructure for information use. The ocean, as Longhorn pointed out, has a "nasty" way of connecting one piece of coastline to another, and neither the ocean nor the physical coastline show any respect for national boundaries and differing jurisdictions.

Some of the key points highlighted by different members of the Scientific Committee at a meeting held on the last day of the conference included the following:

1. We need political champions to help guard our interests in seeing that coastal information needs are not forgotten as larger national and regional (trans-national) spatial data infrastructure (SDI) frameworks are created.

2. GIS in the coastal zone is certainly about supporting "science work", but there are also non-scientific and non-technical issues to be considered, hence the need for a policy level of collaboration.

3. Data usability is a key concern and continues to require both research and information management focus for continued development of ways to harmonise data for wider use.

4. Information infrastructure developments are needed that permit easier discovery of existing data and use of data once located, in a variety of forms, from multiple data owners or custodians.

5. We need to find ways to engage stakeholders (data creators, custodians and users) even more widely in the data management and access issues.

With the launch of the EU Water Framework Directive in 2000, to be fully implemented by December 2003 in all EU Member States, we have seen the first institutionalized, regional (trans-national) legal requirement that GIS be used in

monitoring the implementation of a major EU policy, and one of extremely high importance on a global level - i.e., maintaining good quality water resources in river basins, groundwater, coastal zones and the off-shore transitional waters leading to the coastal zone. In all likelihood this is only the first such legal requirement that we will see coming from major international institutions for use of spatial information and GIS tools for planning and monitoring purposes.

Therefore, coastal GIS practitioners need to address their next efforts towards effective usability of coastal knowledge (not just coastal data) as a major contribution to regional planning and monitoring, even at transnational level. In regard to this perceived need, two issues arise:

1. The landscape/seascape paradigm offers a comprehensive perspective of both the physical and human/cultural aspects and their interaction, defining the present state and heritage. At the European level, the European Landscape Convention (2000) may be assumed as a reference for Coastal GIS attuned for Administration in the governance, planning and design phases. Definition of relationships with non-European landscape policies should be sought.

2. The operation of data, jointly with the implementation of data infrastructures, may be regarded as a chief subject for GIS optimisation. It is hoped to create a link with the running global and pan-European initiatives and/or policies by offering a contribution for Data Infrastructure Profiles suitable for coastal GIS and or promoting these achievements towards non-GIS and non-ICAM specialists, addressing the concerned stakeholders in public administration and industry.

The legal requirement to use GIS for monitoring the Water Framework Directive, and the implied directive to use GIS to monitor the EU ICZM Recommendation both focus on primarily physical data, i.e., coastal or benthic flora and fauna, geomorphology, etc. Yet for wider planning and monitoring purposes, many administrative and non-physical data sources will be needed. These must somehow be accommodated by the evolving coastal SDI.

As we write, it is fairly clear that CoastGIS as a gathering will be around for the foreseeable future. Perhaps the main intangible, but nonetheless very real, benefit from the series of gatherings has been the camaraderie and consequent networking of many of the main contributors. However, as researchers and practitioners we all need more tangible records of these significant events. We trust that the presentation of part of the ongoing record in this volume will contribute to the development and improvement of coastal zone management around the globe.

Ron Furness *– Chair, International Cartographic Association Commission on Marine Cartography*
Andy Sherin *– Chair, CoastGIS 2001 Science Committee, Co-chair of the CoastGIS 2001 Organizing Committee and Coastal Information Specialist, Geological Survey of Canada*

Sydney and Ottawa, 13th November 2003

Preface

Darius Bartlett and Jennifer Smith

This book has arisen out of a decade-long collaborative initiative between the Commission on Marine Cartography of the International Cartographic Association and the Commission on Coastal Systems of the International Geographical Union, and manifested in the series of conferences known as the CoastGIS Symposia. The first CoastGIS meeting was held in Cork, Ireland, in February 1995. Since then, successive events have taken place in Aberdeen, Scotland (1997), Brest, France (1999) and Halifax, Nova Scotia (2001). The majority of chapters presented in the pages that follow had their origins in papers presented at the Halifax meeting, supplemented by a selection of additional contributions commissioned by the editors specifically for this volume.

Previous volumes have focused on GIS research in the marine and coastal realms (Wright and Bartlett, 2000) and on the application of GIS to oceanography and fisheries (Valavanis, 2002). The current volume is, to the best of our knowledge, the first to focus specifically on the role of GIS in integrated coastal zone management. We hope it will provide guidance, inspiration, encouragement and, where merited, a degree of caution, for all those tasked with the stewardship of the world's coasts, as well as for those whose interests are more academic and research-oriented.

The wide diversity of perspectives that can and must be brought to bear on the challenge of coastal zone management is reflected in the range and organisation of chapters in this book. Thus the opening chapters focus on technical issues, ranging from the incorporation of GIS within wider information infrastructures to techniques of visualisation, the importance of error and uncertainty in coastal databases, and the interfacing of GIS with simulation and process models. This is followed by a number of chapters that step back from technology, and which seek to put coastal zone GIS into a more human context, particularly through examination of cultural issues and exploration of techniques for incorporating traditional ecological knowledge within GIS-enabled coastal management regimes; and, finally, attention focuses on the use of GIS to historic shoreline change analysis, the application of geomatics to estuary management,

and to better understanding and management of environmentally sensitive shorelines.

We are particularly delighted that contributions to this volume have come from each of the inhabited continents of the world, namely from Africa, Asia, Australia, Europe and North and South America. The diversity of perspectives on coastal management arising from the cultural and professional backgrounds of the authors, and also from the range of geographic locations used in the case studies and applications reported on, underscores the truly international dimension of coastal management today.

As always, compilation of an edited collection of papers depends on the support, encouragement and assistance of a vast number of people who have worked "behind the scenes." It is, of course, a pleasure to thank the authors who have contributed chapters to the book, and who have borne with cheerful patience the many demands – some reasonable, some perhaps less so – of the editors. We also acknowledge with gratitude the support of the International Geographical Union and the International Cartographic Association.

On an individual level, to merely "thank" Ron Furness and Andy Sherin seems woefully inadequate: it is no exaggeration to say that, without the sustained friendship and cheerful encouragement of both these gentlemen, this volume simply would never have seen the light of day. No less valued was the encouragement of our friends and colleagues on the International CoastGIS Scientific Committee, past and present.

Closer to home, Darius Bartlett wishes to thank friends and colleagues within the Geography Department and the Coastal and Marine Resources Centre at University College Cork; his postgraduate students for their lively discussions and thought-provoking questions; and, above all Mary-Anne, Becky and dog Jessa for putting up with my irregular hours, my absences from home and my all-too-frequent neglect of domestic duties and responsibilities. For her part, Jennifer Smith would like to thank Andy Sherin and the Canadian CoastGIS committee who facilitated her involvement in this project.

Finally, both authors acknowledge with gratitude the assistance, support and guidance of Tony Moore at Taylor & Francis in London and Randi Cohen and Jay Margolis at CRC Press in Florida, who helped steer production of this volume from conception through all stages of publication to its final appearance on booksellers' shelves.

Darius Bartlett first encountered GIS as a postgraduate student at Edinburgh University in about 1982, and has been researching and writing on conceptual, institutional and related issues arising out of coastal zone applications of GIS since the mid-1980s. More recently, he has started investigating the incorporation of marine and coastal areas into SDI initiatives, issues surrounding the diffusion to and use of GIS in the Developing World, and use of GIS by community groups, voluntary organisations and Non-Governmental Organisations (NGOs). An avid traveller, he has so far visited over 65 countries around the world, and looks forward to visiting the remainder in due course. He is a Member of the International Geographical Union's Commission on Coastal Systems; and was one of the founder organisers of the CoastGIS series of biannual conferences.

Jennifer L. Smith
World Wildlife Fund Canada, Atlantic Office, Suite 1202, Halifax, Nova Scotia, Canada, B3J 1P3. Phone: (902) 482-1105; Fax: (902) 482-1107; e-mail: jsmith@wwfcanada.org

Jennifer Smith manages the application of GIS in conservation planning for World Wildlife Fund Canada’s Marine Program. She holds an Honours degree in Geography from McGill University, Montreal. Her interests in work and studies have focused on environmental monitoring, change in ecological systems, seagrass ecosystems, developing areas and GIS-based decision support for protected areas network design.

THE AUTHORS

Roger A. Longhorn
ral@alum.mit.edu

Roger Longhorn is an independent ICT policy consultant who holds B.Sc. and M.Sc. degrees in Ocean Engineering and Shipping Management from M.I.T, Cambridge, MA, USA. After more than a decade of implementing marine information systems for global maritime clients, in 1989 Roger became an external ICT expert to the European Commission, where since 1992 he focused on GIS technology and markets in the evolving Information Society. His special area of interest is GIS applied to the coastal zone. Currently a Ph.D. candidate in Information Policy at City University, London, his research focuses on regional spatial data infrastructures.

Simon Gomm
Ordnance Survey, Romsey Road, Southampton. SO16 4GU. UK. Phone: (+44)023 80305149

Simon has worked for Ordnance Survey in a variety of roles including geodetic surveying and data quality assurance and is now a Senior Research Leader where he is responsible for coordinating research on topics related to the capture, maintenance and use of spatial data.

Rongxing (Ron) Li
Department of Civil & Environmental Engineering and Geodetic Science, The Ohio State University, 470 Hitchcock Hall, 2070 Neil Avenue, Columbus, OH 43210-1275, Tel. (614) 292-6946, Fax. (614) 292-2957; e-mail: li.282@osu.edu, http://shoreline.eng.ohio-state.edu

Dr. Ron Li is a professor at the Department of Civil & Environmental Engineering and Geodetic Science of The Ohio State University. His research interests include digital mapping, coastal and marine GIS, spatial data structure, Mars Rover localization and landing site mapping.

Kaichang Di
Department of Civil & Environmental Engineering and Geodetic Science, The Ohio State University, 470 Hitchcock Hall, 2070 Neil Avenue, Columbus, OH 43210-1275, Tel. (614) 292-4303, Fax. (614) 292-2957; e-mail: di.2@osu.edu

Dr. Kaichang Di is a research associate at the Department of Civil & Environmental Engineering and Geodetic Science of The Ohio State University. His current research interests are coastal mapping using high-resolution satellite imagery, Mars Rover localization and landing site mapping.

Ruijin Ma
Department of Civil & Environmental Engineering and Geodetic Science, The Ohio State University, 470 Hitchcock Hall, 2070 Neil Avenue, Columbus, OH 43210-1275, Tel. (614) 292-4950, Fax. (614) 292-2957; e-mail: ma.106@osu.edu

Mr. Ruijin Ma is a Ph.D. candidate at the Department of Civil & Environmental Engineering and Geodetic Science of The Ohio State University. His current research interests are coastal mapping and GIS, 3D model reconstruction from LiDAR and photographs, and remote sensing applications.

Paul Pan
62 Llanishen Street, Cardiff, CF 14 3QD, United Kingdom; e-mail: pan@cardiff.ac.uk

Paul Pan was the Principal Investigator for a number of innovative coastal monitoring projects in South Wales. He lectured and researched on GIS with the University of Wales, Swansea and Cardiff University for over 10 years. Paul now works as an independent consultant

Eleanor Bruce
School of Geosciences, University of Sydney, Sydney, NSW, 2006, Australia. Phone: +61 2 9351 6443; Fax: +61 2 9351 3644; e-mail: ebruce@geosci.usyd.edu.au

Eleanor Bruce is a senior lecturer in the School of Geosciences at the University of Sydney. She teaches GIS, coastal management and advanced spatial data analysis. Her research interests include the use of GIS for marine park zoning, nearshore habitat mapping and coastal system modelling. Currently, she is Assistant Director of the Spatial Science Innovation Unit at the University of Sydney.

Sam Macharia Ng'ang'a
Department of Geodesy and Geomatics Engineering, University of New Brunswick, P.O. Box 4400, Fredericton, New Brunswick, Canada, E3B 5A3. Phone: (506) 447-3259 or (506) 455-7073; e-mail: sam.nganga@unb.ca

Sam Macharia Ng'ang'a obtained a Bachelor's degree in surveying from the University of Nairobi, Kenya and a Master's degree (Land Information Systems) from the Department of Geodesy and Geomatics Engineering, University of New Brunswick (Canada). He is a part time lecturer at UNB and is currently completing his Doctorate degree on marine protected area information systems. He holds memberships in (among other institutions) the Canadian Institute of Geomatics (CIG) and the Canadian Hydrographic Association (CHA).

Chul-sue Hwang
Department of Geography, Kyung Hee University, Seoul 131-701, Republic of Korea. Phone: +82-2-961-9313; e-mail: hcs@khu.ac.kr

Chul-sue Hwang is assistant professor of geography at Kyung Hee University, Korea, and a member of the editorial board of the *Journal of the Geographical Information System Association of Korea*. His recent research focuses on uncertainty of remote sensing data, spatial data mining, and exploratory spatial data analysis.

Cha Yong Ku
Department of Geography, Sangmyung University, Jongro-gu, Seoul 110-743, Republic of Korea. Phone: +82-2-2287-5043; e-mail: koostar@smu.ac.kr

Cha Yong Ku is assistant professor of geography at Sangmyung University. His research interests include the integration of GIS and remote sensing, classification accuracy assessment and scale effects in remote sensing, and land use/land cover information extraction and modelling for coastal wetlands. He received his Ph.D. in Geography from Seoul National University.

Simon Jude
School of Environmental Sciences, University of East Anglia, Norwich, Norfolk, United Kingdom, NR4 7TJ. Phone: +00 44 1603 591360; e-mail: s.jude@uea.ac.uk.

Dr. Simon Jude is a research associate in the School of Environmental Sciences at the University of East Anglia UK. His research involves developing the use of GIS, virtual reality and visualisation techniques for coastal decision-making.

Andrew Jones
School of Environmental Sciences, University of East Anglia, Norwich, Norfolk, United Kingdom, NR4 7TJ. Phone: +00 44 1603 593127; e-mail: a.p.jones@uea.ac.uk

Dr. Andrew P. Jones is a lecturer in the School of Environmental Sciences at the University of East Anglia UK.

Julian Andrews
School of Environmental Sciences, University of East Anglia, Norwich, Norfolk, United Kingdom, NR3 7TJ. Phone: +00 44 1603 592536.

Dr. Julian E. Andrews is a sedimentologist at the School of Environmental Sciences (University of East Anglia, Norwich UK) with special interest in modern and Holocene coastal sediments.

Roberto Mayerle
Coastal Research Laboratory (Corelab), Christian Albrechts University, Otto Hahn Platz 3, 24118 Kiel, Germany; e-mail: rmayerle@corelab.uni-kiel.de

Professor Mayerle is a specialist in numerical modelling of waves, currents, sediment transport and morphological changes in rivers, coastal areas and near hydraulic structures, with extensive experience in physical modelling of hydroelectric power schemes. He graduated as a civil engineer at the Federal University of Paraná in Brazil in 1979 where he worked for an energy concern involved in the construction and operation of several major hydropower schemes such as Itaipu. In 1988 he got his Ph.D. degree at the University of Newcastle-upon-Tyne in England. From 1989 till 1992 he was in-charge of a team working on the development of numerical models at the National Centre for Computational Hydroscience and Engineering in Oxford, USA. From 1992 till 1996 he worked at the Institute of Fluid Mechanics of the University of Hanover in Germany, being in charge of several research projects dealing with the investigation of the impact of climate changes on the morphological development both on the German North and Baltic Seas. Since 1996 he heads the Coastal Research Laboratory (Corelab) of the University of Kiel. Corelab is a research and teaching unit established to foster research in coastal environments. The Laboratory is engaged in applied research using a combination of in situ measurements and investigations as well as databases and numerical models embedded into decision support systems to help in the management of coastal areas.

Fernando Toro
Wilrijkstraat 37, 2140 Antwerpen, Belgium; e-mail: toro.gunst@skynet.be

Fernando Toro was born in Medellin, Colombia. He received his degree in civil engineering in 1993. He worked in Colombia in the construction of the Metro in the city of Medellin and in an engineering consultant company for three years. He pursued a Master of Science in computational hydrosciences, in the National Center for Computational Hydroscience and Engineering, at The University of Mississippi, USA, from 1996 to 1998. In 1998, he moved to Germany and did his Doctorate studies in the Coastal Research Laboratory, at the Christian Albrechts University in Kiel, until Summer 2003. He is presently working in an engineering consultant company in Antwerp, Belgium. His interests are numerical models and GIS applied to engineering problems.

Jacques Populus
Service des Applications Opérationnelles DEL/AO, IFREMER, BP 70, 29280 Plouzané, France
Phone: 0298224310; Fax : 0298224555; e-mail: jpopulus@ifremer.fr

Jacques Populus is a civil engineer who originally specialised in applications of high resolution remote sensing to coastal studies. His current activities concern the handling of geo-information for coastal applications, with a view to making it available to practitioners, in both developed and developing countries. This concerns GI as output of data analysis, remote sensing and hydrodynamic

modelling. Current applications deal with water and its use for aquaculture sustainability. More recently, he has focused on acquisition and processing of physical data (topography and bathymetry) in the coastal zone by way of innovative techniques such as the LiDAR.

Lionel Loubersac
Head of the Coastal Environment and Living Resources Laboratory of Ifremer in Sète (France). He is in charge of the organisation, coordination and planning of scientific and technical programs dealing with a) the monitoring of coastal environment and living resources quality along the Mediterranean shores, b) the development, interfacing and transfer of tools in the field of coastal oceanography; i.e. environmental monitoring networks and databases, hydrodynamic modelling, geographical data bases and their integration within standardized coastal GIS, new technologies of information and communication for transferring to the public scientific results on coastal environment quality. He is involved in training courses, scientific committees of symposiums as well as numerous projects at national, European and international levels in the field of the applications of Remote Sensing and Information Systems to coastal management. He has been selected as European evaluator and expert in the framework of the DG INFSO Programme Information Society Technology, Key Action "Systems and Services for the Citizen; Applications related to environmental protection."

Jean-François Le Roux
Jean-François is a computer engineer with a Master's Degree in computer science. He has been a software engineer at Simulog, a high-technology service company specializing in technical software engineering, between 1997 and 2000, detached at Thomson CSF Optronics, involved in several projects of technical and operational simulation (real-time 3D simulation). Now he is a system and software engineer at Ifremer for the operational applications service of the Environment and Coastal Planning Division (DEL/AO). He works on interfacing GIS, web and hydrodynamic models.

Franck Dumas
A coastal ocean circulation modeler, Franck graduated from Ecole Nationale Supérieure des Techniques Avancées. For the past seven years, he has been using the MARS-2D-3D modelling system intensively in various frameworks: in the context of pure physical oceanography and circulation along the French coast, but also in pluridisciplinary contexts for the understanding of complex coastal ecosystems such as that of the Baie du Mont Saint-Michel. He is now in charge of developing Ifremer's coastal ocean modelling system, and integrating all coastal ecosystem components developed over the past years within the Institute.

Valerie Cummins
Coastal and Marine Resources Centre, Environmental Research Institute, University College Cork, Naval Base, Haulbowline Island, Cork Harbour, Ireland. Phone: +353 (21) 4703100; Fax: +353 (21) 4703132; e-mail: v.cummins@ucc.ie

Valerie Cummins (B.Sc., M.Sc.) received her B.Sc. in marine geography from University of Wales, College of Cardiff, and her M.Sc. through the Department of Zoology and Aninmal Ecology in University College Cork. After several years working in the field of spatial data analysis/GIS in the UK at the British Oceanographic Data Centre, and subsequently at Landmark Information Group, Valerie returned to Ireland in 1999 to join the Coastal & Marine Resources Centre. She is currently manager of the CMRC with responsibility for the co-ordination of nineteen national and European funded research programs, with a current staff of 17.

Gerry Sutton
Coastal and Marine Resources Centre, Environmental Research Institute, University College Cork, Naval Base, Haulbowline Island, Cork Harbour, Ireland. Phone: +353 (21) 4703100; Fax: +353 (21) 4703132; e-mail: gerry.sutton@ucc.ie

Gerry Sutton graduated from University of Wales, Bangor, with Joint Honours degree in marine biology and zoology in 1984, following which he worked for two years as a fisheries officer with the Department of Fisheries in Sabah, East Malaysia. Here he focussed on research, development and subsequent local adoption of macro-algal cultivation techniques (*Eucheuma* spp.). Following his return to Ireland Gerry joined Hydrographic Surveys Ltd where, as senior hydrographic surveyor between 1991 and 1998, he was responsible for planning, conducting, processing and charting high precision coastal surveys associated with national and international civil engineering, dredging, and oceanographic projects. Since joining the CMRC in 1998 Gerry has been actively conducting research within the CMRC team, contributing to a number of EU and nationally funded projects, and consultative reports. Gerry recently received his M.Sc through the Department of Geography at University College Cork, in the field of marine resources and GIS. His primary research interests are currently in the fields of seabed mapping (specialising in multibeam sonar acquisition and processing); geophysics; oceanography; marine resources and technology; and marine geographic information systems. Gerry has been a professional member of the Irish Institution of Surveyors (IIS) since 1997.

Françoise Gourmelon
Laboratoire Géomer, LETG UMR6554 CNRS, European Institute for Marine Studies (IUEM), Technopôle Brest-Iroise, 29280 Plouzané, France. Phone: + 00 33 2 98 49 86 83; Fax: + 00 33 2 98 49 86 86; e-mail: francoise.gourmelon@univ-brest.fr

Françoise Gourmelon is a senior research worker at the CNRS (French National Center for Scientific Research). She is a member of the Géomer laboratory (LETG UMR 6554 CNRS), part of the European Institute of Marine Studies. She has been using GIS in ICZM studies since 1989, when she met François Cuq (Director of the CNRS Géosystèmes laboratory). She has been working with coastal and marine applications such as landuse and landcover changes in protected islets, habitat of marine fauna, in temperate and tropical coastal zones. Her current focuses are on the coupling of models with GIS for better knowledge of social/natural dynamics; on the use of remote sensing data for the long term monitoring of protected areas; and on the design of geomatic infrastructures dedicated to long term environmental observation.

Iwan Le Berre
Laboratoire Géomer, LETG UMR6554 CNRS, European Institute for Marine Studies (IUEM), Technopôle Brest-Iroise, 29280 Plouzané, France. Phone: 00 33 2 98 49 86 80 ; Fax: 00 33 2 98 49 86 86; e-mail: iwan.leberre@univ-brest.fr

Iwan Le Berre acquired his first experience with GIS when he joined the Géosystèmes laboratory as a Master of Science student in 1990 (and has stayed ever since!). His research interests deal with the implementation of GIS for synthetic mapping of coastal and marine environment. In 1992, he got a grant from the MaB committee of UNESCO for the achievement of a synthetic map of the Iroise Sea Biosphere Reserve. He defended his Ph.D., focused on the implementation of a coastal and marine GIS for the Iroise Sea, in 1999 and has been awarded by the Regional Council of Brittany in 2001. After several studies with different organisations in France (National Park Service, National coastal zone heritage agency, Ministry of Equipment) he got his position at the Western Brittany University in 2001 and he now teaches cartography, GIS and remote sensing for graduate, master and Ph. D. students.

R. Sudarshana
RI227, National Remote Sensing Agency, Dept. of Space, Govt. of India, Balanagar, Hyderabad 500 037, India; e-mail: sudarshana_r@nrsa.gov.in

R. Sudarshana conducted his doctoral research on seabed ecology in the Arabian sea and taught in Karnatak University, India for a while. He then joined the Department of Space, Government of India, wherein he developed an academic niche in marine science, developing and propagating remote sensing application skills. After several years of work in the field of marine applications of remote sensing, he now heads the programme planning affairs of the national remote sensing activities. He has been a consultant to

UNESCO in Africa, Arabia and Iran, besides being a visiting professor in institutions in Europe and Japan.

John Lindsay
John A. Lindsay, NOAA Pribilof Project Office, 7600- Sand Point Way NE, Building 3, Seattle, WA 98115. Phone: (206) 526-4560; e-mail: john.lindsay@noaa.gov

John A. Lindsay is the director of the Pribilof Islands Environmental Restoration Project. He began work with NOAA more than fifteen years ago following a long career as a marine invertebrate taxonomist and ecologist. At NOAA, Mr. Lindsay implemented the agency's natural resource trustee responsibility nationwide at hazardous waste sites, and chemical and oil spills. He also represented the U.S. Department of Commerce on the Joint U.S./Canada Atlantic Regional Environmental Emergencies Team.

Thomas J. Simon
NOAA Environmental Compliance, Health & Safety, and Security Office, 7600-Sand Point Way NE, Building 1, Seattle, WA 98115. Phone: (206) 526-6295; e-mail: Tom.Simon@NOAA.gov

Tom Simon is a geographer and GIS specialist who helped develop the NOAA Pribilof Project Office GIS project. His interests include the use of GIS to integrate varying technologies and develop interactive presentation tools.

Aquilina D. Lestenkof
Aleut Community of St. Paul Island, Tribal Government, P.O. Box 86, St. Paul Island, AK 99660. Phone: 907-546-2641; Fax: 907-546-2655; E-mail: aquilina@tdxak.com

Aquilina D. Lestenkof of St. Paul Island continually seeks ways to balance and blend the cultural knowledge of her people – Unangan (Aleut) – with present day life. Aquilina currently co-directs the Ecosystem Conservation Office of the Aleut Community of St. Paul Island's Tribal Government.

Phillip A. Zavadil
Aleut Community of St. Paul Island, Tribal Government, P.O. Box 86, St. Paul Island, AK 99660,
Phone: 907-546-2641; Fax: 907-546-2655; e-mail: pazavadil@tdxak.com

Phillip A. Zavadil of St. Paul Island co-directs the Ecosystem Conservation Office of the Aleut Community of St. Paul Island's Tribal Government. Mr. Zavadil enthusiastically seeks means to understand and improve the quality of life on St. Paul Island.

Peter Nwilo
Department of Surveying and Geoinformatics, University of Lagos, Lagos, Nigeria.

Dr. Nwilo is an associate professor of surveying and geoinformatics at the University of Lagos, Lagos, Nigeria, and is currently the sub-dean of the Postgraduate School of the University. Dr. Nwilo has a B.Sc. and M.Sc. in Surveying from the University of Lagos and a Ph.D. in environmental resources from the University of Salford, United Kingdom. His special research interests cover sea level variations and the impacts along the coast of Nigeria; GIS and its applications in coastal management; subsidence phenomenon along the coast of Nigeria; management of the navigable rivers of Nigeria; and management of Nigerian coastal areas. He has published extensively on these topics.

Tim Webster
Email: Timothy.Webster@nscc.ca

Tim Webster is a research scientist with the Applied Geomatics Research Group (AGRG) at the Centre of Geographic Sciences (COGS), a component of the Nova Scotia Community College. He currently is also pursuing his Ph.D. in earth sciences from Dalhousie University where he is applying DEM technologies including LIDAR to mapping geological landforms.

Charles Sangster
Email: sangstcw@gov.ns.ca

Charles Sangster is a graduate from the Applied Geomatics Research Program at COGS, and works in the field of conservation GIS. Currently, he is the GIS specialist for the Protected Areas Branch of the Nova Scotia Department of Environment and Labour.

Montfield Christian
Email: c_montfield@hotmail.com

Montfield Christian is a graduate from the Applied Geomatics Research Program at COGS, and works in Toronto, Ontario as an independent GIS analyst. His company is Green Eminent Consulting and they specialise in customised GIS projects.

Dennis Kingston
Email: Dennis.Kingston@nscc.ca

Dennis Kingston is the department head of the Information Technology Department, Annapolis Valley Campus, NSCC. Formerly, he taught GPS technology at COGS in the Survey Program.

Courtney Schupp
Department of Physical Sciences, Virginia Institute of Marine Science, Rt. 1208 Greate Road, Gloucester Point, VA 23062

Courtney Schupp focuses her research on shoreline behavior and its relationship to nearshore processes and underlying geology. After earning her B.S. in geology from Duke University, she worked as a GIS analyst at the U.S. Geological Survey and as a consultant to the Maryland Geological Survey. She is currently working towards an M.S. in marine science at the Virginia Institute of Marine Science at the College of William and Mary.

Rob Thieler
U.S. Geological Survey, Coastal and Marine Geology Program, 384 Woods Hole Road, Woods Hole, MA, 02543-1598, USA. Phone: (508) 457-2350; Fax: (508) 457-2310; e-mail: rthieler@usgs.gov; http://marine.usgs.gov

Rob Thieler is a research geologist with the U.S. Geological Survey in Woods Hole, MA. His research includes continental margin sedimentation, late Quaternary sea-level change, coastal hazards, and development of software to quantify rates of shoreline change.

James F. O'Connell
Woods Hole Oceanographic Institution Sea Grant Program, 193 Oyster Pond Road, MS#2, Woods Hole, MA, 02543-1525, USA. Phone: (508) 289-2993; e-mail: joconnell@whoi.edu

Jim is presently the coastal processes specialist with the Woods Hole Oceanographic Institution Sea Grant Program and Cape Cod Cooperative Extension (past 5 years). Prior to joining WHOI, Jim was the coastal geologist and coastal hazards specialist with the Massachusetts Office of Coastal Zone Management for 13 years, followed by a year with the Cape Cod Commission as a marine resources specialist. Jim's speciality is shoreline change analysis, analyzing human effects on coastal processes and coastal landforms, coastal floodplains, erosion control alternatives, and coastal hazard mitigation issues.

Jorge I. Euán-Avila,
Department of Marine Resources, CINVESTAV, Mérida, México; e-mail: euan@mda.cinvestav.mx.

Jorge I. Euán-Avila, Ph. D., is an engineer and researcher in the Department of Marine Resources, CINVESTAV, Mérida, México.

María de los Angeles Liceaga-Correa
Department of Marine Resources, CINVESTAV, Mérida, México; e-mail: liceaga@mda.cinvestav.mx.

María de los Angeles Liceaga-Correa,Ph.D, is a mathematician and researcher in the Department of Marine Resources, CINVESTAV, Mérida, México.

Héctor Rodríguez-Sánchez
Department of Marine Resources, CINVESTAV, Mérida, México; e-mail: hrs@mda.cinvestav.mx.

Héctor Rodríguez-Sánchez, M.Sc., is a biologist and research assistant in the Department of Marine Resources, CINVESTAV, Mérida, México.

David R. Green
Centre for Marine and Coastal Zone Management (CMCZM) / Aberdeen Institute of Coastal Sciences and Management (AICSM), Department of Geography and Environment, School of Geosciences, College of Physical Sciences, University of Aberdeen, Elphinstone Road, Aberdeen, AB24 3UF, Scotland, UK. / Tel. +44 (0)1224 272324 /Fax. +44 (0)1224 272331; e-mail: d.r.green@abdn.ac.uk Internet. www.abdn.ac.uk.cmczm or www.abdn.ac.uk/aicsm

David R. Green was educated in geography at the Universities of Edinburgh, Pennsylvania and Toronto. He is currently director of the Centre for Marine and Coastal Zone Management (CMCZM), and assistant director of the Aberdeen Institute for Coastal Sciences and Management (AICSM) at the University of Aberdeen in Scotland. He lectures in the environmental applications of the geospatial technologies (including remote sensing and GIS) with special research interests in online Internet-based GIS, mobile mapping, and user interfaces for use in integrated coastal zone management. David is currently president of the EUCC-The Coastal Union, and GIS Editor of the *Journal of Coastal Conservation* (JCC). He is also chief assessor and examiner for the ASET GIS Programme, chairman of the AGI Marine and Coastal Zone Management GIS Special Interest Group, and deputy chair of the ICA Commission on Marine Cartography (International Cartographic Association). David has presented papers and workshops at a number of national and international conferences, and has published a number of books on the use of GIS in landscape ecology, school education, marine and coastal applications, and use of remote sensing for coastal applications. He is currently involved in organising the Littoral 2004 and CoastGIS 2005 conferences.

Stephen D. King
Centre for Marine and Coastal Zone Management, Department of Geography and Environment, University of Aberdeen, Elphinstone Road, Aberdeen, AB24 3UF, UK.; Tel. +44 (0)1224 272324, Fax +44 (0)1224 272331; e-mail: s.d.king@abdn.ac.uk

Stephen is currently a research assistant in the Department of Geography and Environment at the University of Aberdeen. He has a B.A. in geography

(University of Liverpool) and an M.Sc. in environmental remote sensing (University of Aberdeen). His main interests are the application of remote sensing and GIS to coastal zone management and, in particular, the development of Internet-based coastal information systems and the use of mobile communications technology and GIS for field data collection.

Jean-Côme Bourcier
8 Rue Georges Laroque, Appartement 1021, 76300 Sotteville-Les-Rouen FRANCE. Phone: +33 02 63 87 30 or +33 06 88 43 54 95; e-mail: jean-come.bourcier@wanadoo.fr or geoinformatique@wanadoo.fr

J.-C. Bourcier obtained his Ph.D. at University of Le Havre, France, and works as a GIS specialist, environmental engineer and territorial planning engineer. His research concerns the use of GIS as a tool designed to create a better understanding of coastal processes, functioning and change and, more specifically, better management and development of coastal spaces such as estuaries. He is currently the president of GeoInformatique, an association which helps people to better use geographical information.

Anders Mosbech
National Environmental Research Institute, Department of Arctic Environment, Frederiksborgvej 399, P.O. Box 358, DK-4000 Roskilde, Denmark. Phone: +45 4630 1934; Fax: +45 4630 1914; e-mail: amo@dmu.dk

Anders Mosbech, Ph.D., is a senior scientist who performs ecological research in Greenland on marine birds, geese, muskoxen, marine mammals and vegetation. He is an advisor to the regulatory agencies in the Greenlandic and Danish governments concerning environmental impacts of oil exploration and development in Greenland.

David Boertmann
National Environmental Research Institute, Department of Arctic Environment, Frederiksborgvej 399, P.O. Box 358, DK-4000 Roskilde, Denmark. Phone: +45 4630 1934; Fax: +45 4630 1914; e-mail: dmb@dmu.dk

David Boertman is a senior research biologist with long experience in arctic ornithology and Arctic natural history, and has worked with environmental issues related to oil exploration in the arctic. He is currently associated with the National Environmental Research Institute, Denmark.

Louise Grøndahl
National Environmental Research Institute, Department of Arctic Environment, Frederiksborgvej 399, P.O. Box 358, DK-4000 Roskilde, Denmark. Phone: +45 4630 1934; Fax: +45 4630 1914; e-mail: lgr@dmu.dk

Louise Grøndahl holds an M.Sc. in physical geography. She has worked as research assistant at NERI with GIS and is now doing a Ph.D. on carbon flux in Northeast Greenland at the National Environmental Research Institute, Denmark.

Frants von Platen
Geological Survey of Denmark and Greenland (GEUS). E-mail: fph@geus.dk

Frants von Platen is a geographer and GIS-specialist who has been employed since 1983 at GEUS, where he works with geological databases and GIS development.

Niels Nielsen
Institute of Geography, University of Copenhagen, Denmark. Phone: +45 35322508; Fax: +45 35322501; e-mail: nn@geogr.ku.dk; www.geogr.ku.dk

Niels Nielsen is an associate professor in physical geography (coastal geomorphology) at the Institute of Geography of the University of Copenhagen.

Søren Stach Nielsen
Greenland Institute of Natural Resources, P.O. Box 570, DK-3900 Nuuk, Grønland. Phone: +299 328095 /ext. 243; Fax: +299 325957; email: SorenSN@natur.gl

Søren Stach Nielsen holds a Master of Technological and Sociological Planning degree from Roskilde University and is at present a project-researcher at the Greenland Institute of Natural Resources, investigating socioeconomic relations between hunting and hunting-gear and hunting and household economy, and incorporation of local knowledge into scientific research.

Morten Rasch
Danish Polar Center, Strandgade 100H, DK-1401 Copenhagen K, Denmark. Direct phone: +45 32880110 Mobile phone: +45 23490645; Secretary: +45 32880100; Fax: +45 32880101; e-mail: mr@dpc.dk; homepage, Zackenberg: www.zackenberg.dk, homepage, Danish Polar Center: www.dpc.dk

Morten Rasch, Ph.D, is a coastal geomorphologist educated at the Institute of Geography of the University of Copenhagen. He is a specialist in arctic coastal geomorphology and Holocene relative sea-level changes in Greenland. He has been working as station manager of Zackenberg Station, North East Greenland and is also head of logistics at Danish Polar Center.

Hans Kapel
SILA, The Greenland Research Center at The National Museum of Denmark, Frederiksholms Kanal 12, DK 1220 Copenhagen K. Phone: +45 33473256; e-mail. hans.kapel@museum.dk

Hans Kapel is a curator and archaeologist who has conducted archaeological research in Greenland since 1969. His field of responsibility includes The Central Register of Protected Monuments in Greenland.

André Laflamme
Environment Canada - Environmental Emergencies Section, Dartmouth, Nova Scotia, CANADA. Phone: 902-426-5324; Fax: 902-426-9709; e-mail: Andre.laflamme@ec.gc.ca

André Laflamme graduated from University of Sherbrooke, Quebec, in physical geography in 1994. He has worked since with Environment Canada Atlantic Region with the environmental emergencies section as an environmental emergencies officer. André is also the regional sensitivity mapping coordinator for Environment Canada. He was a co-author on scientific papers produced during several conferences such as the International Oil Spill Conference (IOSC), and the Arctic and Marine Oil Spill conference (AMOP). André was also part of a team tasked to develop a national oil spill contingency plan for the Republic of Chad (Africa) where he spent some time.

CHAPTER ONE

Coastal Spatial Data Infrastructure

Roger A. Longhorn

1.1 INTRODUCTION

The term Spatial Data Infrastructure (SDI) is now in common use in countries around the world, although definitions for the term differ quite considerably. The stated objectives of SDI initiatives vary as much as do the definitions, legal mandates, types of organisation responsible for specifying and implementing SDI and actual progress achieved in creating national and regional SDIs.

One complication in specifying any SDI is the nature of spatial information, i.e. information with an important location attribute, often said to represent 80% of all information held, especially at government level. The visionaries and designers of SDI must accommodate the widely varying information needs of highly diverse disciplines and sectors of society, business and government. Health epidemiologists are seldom interested in the same spatial data as geological surveyors, air traffic controllers or coastal zone managers. Yet an important overlap in jurisdiction and information needs may arise, e.g. when a potential health epidemic is generated by toxic chemical concentrations in marine fauna later consumed by area residents. Then knowledge of the coastal zone flora and fauna, hydrography, tidal states, nearby land use practices of industry and agriculture and transport routes, fishing practices and zones all become intertwined. The complex relationships between different types of spatial information are one reason that countries take different routes to specify their SDI, ranging from visions to strategies to goals to detailed content (data and standards) and implementation plans (rules and regulations).

We all recognize that the coastal zone is a difficult geographical area to manage due to temporal issues (tides and seasons) and the overlapping of physical geography and hydrography (offshore, near shore, shoreline, inshore), of jurisdictions, legal mandates and remits of government agencies and the often competing needs of stakeholders. Typically, many different local, national and regional government agencies are responsible for different aspects of the same physical areas and uses of the coastal zone, e.g. fisheries, environment, agriculture, transport (inland and marine), urban planning and cadastre, national mapping agency and the hydrographic service.

Conflict resolution in this complex piece of real estate called the “coast” is sometimes used as justification for special attention for the coast within NSDI initiatives. As Bartlett (2000) expresses it: “Given the diversity of interest groups, stakeholders, managerial authorities and administrative structures that converge at

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

the shore, conflicts are almost inevitable between and among coastal users, managers, developers and the wider public, as well as between human society and the natural environment."

Because of such complex physical and institutional relationships, it is not possible to develop a coastal SDI (CSDI) in isolation from the broader National SDI (NSDI) for a nation or Regional SDI (RSDI). CSDI will necessarily be a subset of a more comprehensive NSDI because the coastal zone covers multiple physical and institutional spaces included in the generic NSDI. For that reason, it is important that people and agencies with specific knowledge and experience of the coastal zone and marine offshore areas and information requirements be an integral part of the NSDI and RSDI planning process.

1.2 CSDI WITHIN NATIONAL, REGIONAL AND GLOBAL SDI

Few nations have specified separate SDI components for individual sectors such as the coastal zone. In the USA, a Coastal NSDI vision exists based on four goals that relate to the USA NSDI (NOAA, 2001). Practical implementation work is undertaken by the National Oceanic and Atmospheric Administration (NOAA) and the Federal Geographic Data Committee (FGDC).

Canada has proposed a Marine Geospatial Data Infrastructure initiative (MGDI) within the national Canadian Geospatial Data Infrastructure (CGDI) (Chopin and Costain, 2001). MGDI is seen as an extension to the CGDI in response to "the need for a comprehensive, integrated and common infrastructure of marine data and information … accessible to all stakeholders."

1.2.1 Regional SDI Initiatives

At regional level, the INSPIRE project (Infrastructure for Spatial Information in Europe) recognizes hydrographic data as one of its "selected topographic themes" for data content for a Regional SDI for Europe (INSPIRE, 2002). More detailed data requirements are presented in the European Commission's Water Framework Directive (European Commission, 2000), which underpins the need for INPSIRE. These two European regional projects are discussed more fully in a later section as they have legal mandates from a recognized regional government body—the European Commission—and have developed detailed descriptions of spatial data requirements, including marine and coastal zone data.

Work on specification for an Asia-Pacific SDI (APSDI) began in 1994 with formation of the Permanent Committee on GIS Infrastructure for Asia and the Pacific (PCGIAP) under the auspices of the UN Regional Cartographic Conferences (UNRCC). The APSDI model stresses institutional frameworks, technical standards, fundamental datasets and an access network (PCGIAP, 1998).

A new initiative started in 2000 for a Regional SDI for the Americas (PC-IDEA), but it is too new to have achieved anything more than creating a basic project organisational framework at this stage.

1.2.2 Global SDI Initiatives

Global level SDI initiatives include the Global Map Project (ISCGM, 2001), which began in 1996, the Global Spatial Data Infrastructure (GSDI) Association, which began as a series of international conferences in 1996, and the Digital Earth initiative sponsored by the US government (Evans, 2001). These initiatives intend to build on existing national and/or regional SDI work and existing data resources (primarily remote sensing imagery). They typically mention shoreline data, boundary data (including marine, ocean, inland waters) and references to cadastre that may or may not include marine cadastral data. GSDI and the Global Map project are discussed more fully later.

Of more immediate interest—and importance—to coastal and marine managers and researchers is the work of the Intergovernmental Oceanographic Commission (IOC) International Oceanographic Data and Information Exchange (IODE) working group mentioned later and described in some detail by Longhorn (2002).

1.3 CSDI IN THE US

The US NSDI initiative began formally in April 1994 with a presidential Executive Order (Clinton, 1994) in response to a national performance review of federal government. One of the main elements of the US NSDI is the creation, harmonisation and promulgation of technical standards by which all federal spatial information can be recorded, metadata being of highest importance so that existing spatial data resources can be identified, accessed and used. This major task fell to the Federal Geographic Data Committee (FGDC), which was created in 1990. Responsibilities with regard to NSDI implementation for all federal agencies in the US was set out in the revised OMB Circular A-16 in 2002 (OMB, 2002).

In the US, the Coastal SDI vision is based on four goals relating to the NSDI (NOAA, 2001). The US CSDI initiative is led by the Coastal Services Centre of NOAA (National Oceanic and Atmospheric Administration). The main goals of the US CSDI are:

- that the coastal management community should understand and embrace the vision, concepts and benefits of the NSDI,
- spatial coastal and marine framework data should be readily available to the coastal management community,
- technologies to facilitate discovery, collection, description, access and preservation of spatial data should be widely available to the coastal management community, and
- NOAA should help develop and implement spatial data applications to meet the needs of the coastal and marine communities.

Note the emphasis on support for coastal resources management, a role assumed by NOAA under the 1972 Coastal Zone Management Act, as opposed to

NOAA's historical focus and initial primary mission of ensuring safety of navigation.

The main elements of CSDI that NOAA promote are bathymetry, shoreline identification and marine cadastre, although other types of data are under review for attention as a formal part of CSDI, e.g. coastal imagery, marine navigation, tidal benchmarks and benthic habitats (Lockwood and Fowler, 2001). Development of technical standards to support the CSDI is undertaken by the FGDC's Marine and Coastal Spatial Data Subcommittee, under chairmanship of NOAA/CSC (FGDC, 2002). The committee's primary mission is to develop and promote the Marine and Coastal NSDI so that "current and accurate geospatial coastal and ocean data will be readily available to contribute locally, nationally, and globally to economic growth, environmental quality and stability, and social progress" (NOAA, 2003). In 2000, this committee assumed the remit of the FGDC Bathymetric and Nautical Charting Data Subcommittee, formed in 1993.

Bathymetric data is treated as a sub-layer of the Elevation layer data in the NSDI Framework. Marine cadastre is being examined within both the FGDC Marine Boundary Working Group (MBWG) which includes members of the FGDC Cadastral Subcommittee. The MBWG was formed in 2001 to address issues relating to the legal and technical aspects of marine boundaries, with the goal to alleviate cross-agency problems concerning marine boundaries, plus provide outreach, standards development, partnerships and other data development critical to the NSDI. A major product of the MBWG work to date is the FGDC's Shoreline Metadata Profile (FGDC, 1998).

Two further standards nearing completion for the CSDI are the National Hydrography Data Content Standard for Inland and Coastal Waterways (FGDC, 2000a) and Accuracy Standards for Nautical Charting Hydrographic Surveys (FGDC, 2000b).

The US CSDI initiative should help identify the basic reference data required to achieve goals for national programs such as those stated in the Clean Water Action Plan - Coastal Research and Monitoring Strategy, which represents "the first effort to integrate coastal monitoring and research activities on a national scale to provide thorough, cross-cutting assessments of the health of the nation's coastal resources" (CRMSW, 2000). These goals include:

- Improving monitoring programs for integration at national level
- Integrating interagency research efforts
- Conducting national and regional coastal assessments, and
- Improving data management.

Interestingly, a report from the US Commission on Ocean Policy found a tight connection between inland systems for development and agriculture to areas traditionally designated as coastal. "The coastal zone is not a narrow band. It's the whole country" (US CoOP, 2002). Regarding data collection and sharing, the US Ocean Policy report further found that "there is no marine equivalent to the networks of meteorological observation stations distributed on land on all continents. Ocean observation efforts are limited temporally and spatially." This

leads to the conclusion that "there is a need for a better and more comprehensive way to link the work of different disciplines in a manner that offers a more integrated understanding of the marine environment and the processes that control it… there is a need for standardized practices and procedures" (US CoOP, 2002). These findings reinforce the premise that CSDI cannot and should not be developed in isolation from the broader NSDI of a nation or region. Actions like the Clean Water Action Plan mentioned earlier provide important input into the political process for securing added support for creating a CSDI.

1.4 CSDI IN CANADA

In Canada, the NSDI is called the Canadian Geospatial Data Infrastructure (CGDI) with the snappier, market-oriented title GeoConnections. From its beginning, the CGDI recognized that "governments have a responsibility to make geospatial information available … for developing a knowledge economy in response to the needs of citizens, industry and communities in support of economic, social and environmental well-being" (Labonte, Corey and Evangelatos, 1998). Marine navigation and charting for pollution control, coastal zone management and environmental monitoring were considered important applications to be fostered under CGDI. The CGDI has five technical and policy thrusts: access, data framework, standards, partnerships and creating a supportive policy environment. The CGDI vision is "to enable timely access to geo-info data holdings and services in support of policy, decision-making and economic development through a co-operative interconnected infrastructure of government, private sector and academia participants. From the outset, CGDI planners realized that "institutional issues will likely eclipse technology as an impediment to CGDI development and implementation" (Labonte *et al.*, 1998).

Within the framework of the CGDI, the Marine Geospatial Data Infrastructure (MGDI) is being developed in Canada, "to enable simple, third party access to data and information that will facilitate more effective decision-making" (Gillespie *et al*., 2000) for anyone involved in coastal zone management. MGDI is described as comprising data and information products, enabling technologies as well as network linkages, standards and institutional policies. The concept for an MGDI-like information network was first proposed in 1988 as the "Inland waters, Coastal and Ocean Information Network (ICOIN)" (after Butler *et al.*, 1998 in Gillespie *et al.*, 2000).

In support of the five main elements of GeoConnections (the CGDI), a Marine Advisory Committee was created in 1999 at the time of publication of a draft concept report for the MGDI (CCMC, 1999). The committee's remit is to ensure the full functionality of the CGDI in providing service to all marine stakeholders. To aid in this, a Marine Advisory Network has been set up to act as the physical focal point for stakeholder outreach and consultation (GeoConnections, 2003).

The MGDI recognizes the need for common standards permitting data to be used seamlessly across disciplines and systems. Because of the principally land-based focus of most NSDI developments, MGDI also recognizes that standards that apply perfectly well to land-based applications and data are sometimes

incompatible with the marine world. It is also understood that simply making spatial data available across the Internet does not always provide solutions to specific problems. Data is not information and information is not knowledge. MGDI also recognizes that data pricing and related policy issues dealing with intellectual copyright will be crucial to the success of both CGDI and MDGI and that, while these potential barriers may not fall easily, they are not insurmountable. The needs of users and potential stakeholders were identified more completely in an extensive requirements analysis study in 2001 (DFO, 2001).

The MGDI architecture includes:

- A common spatial data model
- An integrated process and data modelling environment
- A common spatial language and data exchange format
- Methods for managing, querying and delivering data with integrity, and
- Open source productivity tools ensuring access for all.

Progress in implementing the MGDI as a coherent system has been slower than anticipated, due mainly to two things that affect nearly all such initiatives known to this author, i.e. lack of resources (especially any new or extra resources) and institutional barriers inherent in government whether local or national. Note that even the Presidential Executive Order creating the USA NSDI did not offer any new money, rather all work to achieve the NSDI had to be conducted from within existing budgets.

1.5 CSDI ELEMENTS IN REGIONAL SDI

Regional SDI (RSDI) initiatives have started in Europe (INSPIRE), Asia-Pacific (PCGIAP) and the Americas (PC-IDEA). These projects all intend to build on National SDIs located within their geographic regions. Unfortunately, since few NSDIs have reached an advanced degree of completion—and many have not yet even been specified or received legal mandates—it is still early to see how coastal and marine SDI requirements will be accommodated within the RSDI envelopes.

The Permanent Committee for SDI for the Americas (CP-IDEA/PC-IDEA) was only formed early in 2000 under the auspices of the UN Regional Cartographic Conference. This new initiative has yet to produce any substantial documents relating to how SDI will be coordinated across the nations of Central and South America. Initially it is focusing on institutional strengthening, metadata, access policies, outreach and similar issues to those being pursued by PCGIAP and within the global GSDI Association.

1.5.1 INSPIRE—Infrastructure for Spatial Information in Europe

INSPIRE recognizes hydrographic data as one of its selected topographic themes for data content for the proposed Regional SDI for Europe (INSPIRE, 2002). Hydrography is defined as "surface water features such as lakes and ponds, streams and rivers, canals, oceans and shorelines." During the many years that European SDI consultations progressed from the GI2000 initiative (1995–1999) through ETeMII (European Territorial Management Information Infrastructure 1999–2001) to INSPIRE (2001–present), reference to specific themes for spatial data content in the proposed SDI specification was initially resisted. After much debate, the hydrographic component (including coastal zones) was included, along with only two other "topographic themes" - transport and height. Hydrography is defined in INSPIRE as "surface water features such as lakes and ponds, streams and rivers, canals, oceans and shorelines." The "height" topographic theme includes "contour data showing heights by isolines, and including with the same data set spot heights, high and low water lines, breaklines and bathymetry" (INSPIRE, 2002). At the end of the consultation period, INSPIRE was extended to cover a wide range of coastal and marine data components, including "bathymetry, coastline, hydrography, surface water bodies, water catchments, oceans and seas, oceanographic spatial features, sea regions, aquaculture facilities, polluted areas and more (INSPIRE, 2003).

1.5.2 European Water Framework Directive

The EU Water Framework Directive (European Commission, 2000) represents the culmination of five years of consultation and negotiations for implementing a harmonized and integrated water policy for all European Union Member States (now 15, soon to be 25). The WFD places quite detailed—and some say onerous—monitoring and reporting requirements for the status of surface water in four regimes: rivers, lakes, coastal waters and transitional waters (estuaries and similar bodies of water which are partly saline but strongly influenced by freshwater flows).

The data relating to coastal and transitional waters required in order for EU Member States to report to the European Commission on water condition include: detailed location (boundary) information, various biological data for aquatic flora and benthic fauna, hydromorphological data including depth variations, tidal regimes, transparency, thermal conditions, oxygenation conditions, salinity, nutrient conditions and pollution.

In order to do this reporting, a very detailed GIS specification has been produced (European Communities, 2002). For coastal waters, the data to be captured include shape, name, various identifying codes, type of water body, status of the water body (artificial, heavily modified), salinity typology, depth typology, tidal typology, and more. The specification document is nearly 170 pages long—a far cry from the "hydrography" or "marine boundary" terms found in isolation, without further explanation, in other regional and all global SDI specifications. In

fact, one worries if the European government authorities and their national oceanographic and coastal research institutions will be able to provide data at the level of detail required within the timeframe set by the Directive, which comes into force in December 2003.

The WFD Directive has been used by various Directorates General at the European Commission to justify the INSPIRE European Regional SDI initiative, on the basis that much harmonised, integrated and interoperable basic reference data will be required if WFD reporting requirements are to be met at least cost. It remains to be seen if the level of detail already specified in the INSPIRE working documents will in fact be sufficient to help fulfil that requirement.

1.5.3 Asia-Pacific Regional SDI (APSDI)

In the Asia-Pacific SDI (APSDI), what are termed "fundamental datasets" are only presented in the most general terms and with no detail. The discussion on what data should be included in the APSDI began in 1998 and has yet to reach a conclusion. Due to the large number of participants—55 nations across Asia and the Pacific are members—and very limited development resources, we should not expect the situation to change any time soon in regard to formal data specification. At the most recent meeting of the Working Group on Fundamental Data held in April 2002, the working group recommendations included (PCGIAP, 2002):

- The contents of the Asia-Pacific Regional Fundamental Dataset shall be defined, and further, the technical specifications of the Asia-Pacific Regional Fundamental Dataset shall be developed, with the Global Mapping Specifications and Administrative Boundary Pilot Project Specifications, as reference.

- For the first version of the Asia-Pacific Regional Fundamental Dataset, the vector data shall be no less accurate than 1:1 million in map scale, and the raster data shall be no less than 1KM in ground resolution.

At a 2001 meeting of the PCGIAP Working Group on Cadastre, an item was recommended for the work plan covering "identification of broad types of marine cadastres in use throughout the world as they become established" (PCGIAP, 2001). Unfortunately, the meeting also noted "concern about the apparent direction of the Cadastre WG in majoring in activities on marine cadastre, boundaries being a very sensitive issue in PCGIAP."

One surmises that little practical progress has been achieved in more detailed data specification in nearly six years of work and that the small scale of the data will be of minimal use to local coastal managers or researchers. Also, political issues may limit the degree of actual detail that will be agreed within the very broadly based group.

1.6 CSDI AT GLOBAL LEVEL

At the global level, the not-for-profit Global Spatial Data Infrastructure (GSDI) Association primarily offers a forum for discussion and exchange of experiences, especially in relation to creating SDI at national level. The GSDI's 'SDI Cookbook' (GSDI, 2001) does not specify what types of data nations should have in their SDI, but rather it concentrates on general, though still important, matters such as metadata creation, access policy and other administrative and institutional issues. In a general listing of the types of data that should be considered for including in a National SDI, the cookbook does mention cadastre and hydrography. No further details are given and there is no working group specifically targeting marine or coastal data requirements. A more thorough review of how coastal zone information is related to the GSDI can be found in Longhorn (2003b).

The Global Map specification (ISCGM, 2000) makes reference only to "coastline/shoreline" and "ocean/sea" boundary data, "ferry routes" under a "transportation" heading and edges of "islands" and "inland water" under "drainage (hydrography)." The remainder of the specification is devoted to identifying existing public domain data sources (all at scales of 1:1 million or smaller), data models for vector and raster data, precision and accuracy and metadata issues. The primary data sources listed are VMAP Level 0 from the US National Imagery and Mapping Agency (NIMA), the Global 30 Arc Second Elevation Data Set (GTOPO30) and Global Land Cover Characteristics Database, both available from the US Geological Survey and other sources. These resources have been available in the public domain for some years now, and include only small scale data, some of which are rather old compared to the time frames of interest for much coastal management and research work. For these reasons, there is little new in the Global Map project that would excite coastal managers and researchers.

What approximates a useful global marine SDI does exist for oceanographic data due to long established information management and data exchange programmes of the Intergovernmental Oceanographic Commission (IOC) (Longhorn, 2002). At its most recent meeting in June 2002, the IODE working group considered including coastal data in its remit, only to have the possibility removed from its future agenda by refusal or reluctance of the governments of some important developing country members to permit ready access to coastal zone data for national security and economic reasons.

1.7 PRINCIPAL COMPONENTS FOR CSDI

Having reviewed the few formal coastal SDI initiatives that exist, all at national level, it appears that a CSDI mainly comprises: data sources, standards, enabling technologies and institutional policies. Work in relation to the first two components needs to be carried out with a specific marine or coastal focus, which is sometimes missing from generic SDI initiatives. The latter two aspects apply to

the wider requirements of any information infrastructure, not just that of coastal SDI or even for spatial data alone.

1.7.1 Basic Reference Data for the CSDI

The presence or absence of basic reference spatial data (also sometimes called 'framework' data) in National, Regional and Global SDI implementations that relate to the needs of a viable coastal SDI are shown in table 1.1. As one might suspect, the most common are bathymetry, shoreline and boundary data. For most Regional and Global SDI initiatives, there is not sufficient detail in specification of data elements to determine whether or not the needs of coastal and marine resource managers and researchers will be met (with the exception of INSPIRE/WFD). Since the basic data will be collected at national level, this might not appear to be a serious problem at the moment. Yet when data exchange is required for research purposes, resolving boundary disputes or to satisfy a nation's responsibilities regarding various international data exchange conventions, then the absence of regional and global agreement on SDI contents and access issues will become noticed.

Table 1.1 Coastal SDI components in national, regional and global SDIs

SDI Component	USA	Canada	INSPIRE-WFD	APSDI	GlobalMap
bathymetry	yes	yes	yes	maybe	maybe
shoreline	yes	yes	yes	yes	yes
marine cadastre	yes	yes	no	yes	maybe
coastal imagery	maybe	maybe	yes	no	no
marine navigation	maybe	yes	maybe	no	maybe
tidal benchmarks	maybe	maybe	yes	no	no
benthic habitats	maybe	maybe	yes-WFD	no	no

A 'yes' indicates that the component in the left-hand column is formally listed as an important data component in the definition of spatial data infrastructure at national, regional or global level. The number of 'no' and 'maybe' entries is disquieting. Fortunately, the 'nos' appear mainly in regional or global initiatives while 'maybes' indicate that detailed user requirements or specifications have been identified and published, along with existing data sources that might provide this data. However, no firm decisions have been made as to how or if this data will be included within the higher-level NSDI or not.

1.7.2 CSDI Is More Than Data

Other components of an SDI mentioned in most SDI descriptions cover: metadata creation and standards, technical guidance (including standards) on spatial precision, accuracy and data formats (both raster and vector), data access policies (some of which are more liberal than others) and intellectual property guidance.

Standards issues in the spatial data world are now much better addressed than a mere five years ago due to the extensive work of the International Standards Organization's Technical Committee 211 (TC/211) on Geographic Information/Geomatics which is creating "a structured set of standards for information concerning objects or phenomena that are directly or indirectly associated with a location relative to the Earth" comprising some 40 new GI-related standards (ISO, 2002). In parallel with ISO, the global reach and uptake of the GIS interoperability work of the Open GIS Consortium, Inc., and OGC Europe, Ltd., is providing a clear way forward in regard to integrating GI applications and data sources, especially using the Web as the service delivery machinery (OGC, 2002).

Other important standards developments relating to coastal and marine data include the S-57 (Special Publication No. 57) cartographic standard developed for and maintained by the International Hydrographic Organisation (IHO) and International Hydrographic Bureau (IHB) in Monaco (IHO, 1996). This standard is used for collection and exchange of hydrographic data among national Hydrographic offices globally. It is also very important for marine navigation as applied to the new Electronic Chart Display and Information Systems (ECDIS) now being introduced throughout the maritime industry. S-57 comprises a hydrographic data model, an object catalogue and an electronic nautical chart (ENC) product specification that are standard for ECDIS data.

Various shoreline and boundary data metadata standards have been developed at national level, as mentioned previously for the USA within the FGDC shoreline metadata working group. Looking to the future, two projects are underway that aim to specify a globally agreed standard for marineXML, a marine-specific implementation of the eXtensible Markup Language (XML) now used widely on the Internet for conveying semantic content of information as opposed to only the display specifications provided by HTML (Hypertext Markup Language). MarineXML is described as "an interoperability framework for global ocean observation systems" (ICES, 2003) which will encompass coastal zone elements as well. The development work on marineXML is undertaken by the European Union, via a part-funded project in the EU's Framework RTD programme (IOC, 2003a) in conjunction with the Intergovernmental Oceanographic Commission's Committee on International Oceanographic Data and Information Exchange (IODE) based at UNESCO headquarters in Paris (IOC, 2003b). National initiatives on creating marineXML specifications are also underway, for example in Australia and the USA (Sligoeris, 2002; Davis *et al.*, 2002).

More serious barriers remain in regard to harmonised data access policies and exploitation rights for spatial information, particularly that collected by public sector agencies. The European Union is trying to address this problem at a regional level via a new Directive setting out an agreed EU-wide framework for access to

and exploitation of public sector information (European Commission, 2002). Similar initiatives are under discussion, in consultation or being implemented in both developed and developing nations across the globe. The impact that these initiatives will have on the coastal zone (and larger research) community cannot be underestimated. Even in countries with strong "freedom of information" cultures, such as the USA, some public sector marine information is not disclosed due to fear of liability actions against the data providers (Lockwood and Fowler, 2001). With intellectual property (IP) legislation in a state of flux across the globe while attempts are made to accommodate the prior IP regime and existing international IP conventions to the digital world, resolving many of the non-technical data-related problems is far easier than the institutional ones.

1.8 CONCLUSIONS

The CZM community should be aware that their input, based on knowledge and experience of the coastal zone, is imperative during specification of SDI initiatives, whether at national, regional or global level. What we can conclude from the above examination of various types of spatial data infrastructures that are under development—national, regional and global—is that, at regional and global level, the emphasis is virtually all on process, standards, metadata and institutional issues, and rarely on data specifications for the content of an SDI. Thus, for the most part, these initiatives will almost certainly never have a separate strong coastal or marine focus. The only exception at Regional SDI level is that of INSPIRE, justified partly by the legal data reporting requirements of the European Water Framework Directive, the latter of which focuses very heavily and in great detail on coastal and near-shore waters. As more such regional (non-European) environmentally focused initiatives evolve, we can expect a similar emphasis on the need to arise for wider access to and use of coastal and marine spatial data in regard to environmental monitoring.

At the global level, some of the most important work in regard to major elements of what comprise an SDI has been implemented within major international environmental monitoring and research programmes, such as those of IOC, the World Meteorological Organization (WMO), International Geosphere-Biosphere Program (IGBP) and others (Longhorn, 2003a).

At national level, where one tends to find more detail in specification of the SDI and a more advanced state of actual implementation of elements of SDI, there is evidence that only the more obvious data needs are being considered, e.g. shoreline, hydrography/bathymetry and (sometimes) cadastre/boundaries. Yet other important elements such as habitat and navigation do not fit well within the primarily land-focused sections of NSDI specifications. This may be due partly to the absence of coastal zone/marine professionals on the SDI development teams or for other reasons, e.g. a national decision that the SDI should focus on only the most basic 'reference data' that is considered commonly needed to underpin broadly based economic activities and governance.

Finally, one should not forget that spatial data is only one facet of an SDI implementation. Important institutional, jurisdictional, data policy and standards/interoperability issues also Figure high on the agenda. These appear to

be the principal focal points for most regional and global SDI initiatives, rather than detailed basic reference data specifications.

CHAPTER TWO

Bridging the Land-Sea Divide Through Digital Technologies

Simon Gomm

2.1 INTRODUCTION

There are many different types of users of coastal zone information, from the casual user who may only want to browse, to the sophisticated user who makes frequent use of mapping and demands continuous improvement. These user communities are diverse in the topics they address, covering such areas as Local and Central Government, environmental and economic analysis, and also increasingly leisure use.

A common mapping framework that bridges the land-sea divide allows users to build applications and decision-making tools necessary to promote the shared use of such data throughout all levels of Government, the private and non-profit sectors and academia. A consistent framework also serves to stimulate growth, potentially resulting in significant savings in data collection, enhanced use of data and assist better decision-making.

As well as a physical division, the land-sea divide has also, for many spatial data suppliers, acted as a limit to their area of responsibility, or formed a data product boundary. As a result users wanting to model the diverse aspect of the coastal zone across this divide have had to identify, obtain and combine separate datasets to provide the data coverage they require. The combination process must resolve integration problems resulting from the differing projections, scale of capture and other specification issues of the source datasets. This process can be time consuming, result in inconsistent data and can cause a hindrance to the management of a particularly sensitive environmental zone.

This chapter will look at the technical issues involved with the integration of data across the land-sea divide and identify means for resolving these. Examples within this chapter have been drawn from the work done by Ordnance Survey of Great Britain, United Kingdom Hydrographic Office and the British Geological Survey on integrated coastal zone mapping project (ICZMap) (Gomm, 2001).

2.2 DATA SPECIFICATIONS

At the commencement of a project the user will need to have assessed the project's spatial and non-spatial requirements, and these will provide the key criteria for defining and selecting suitable data. Typically such criteria will include: physical extent of the project area, data content, attribution, positional accuracy, spatial resolution, currency, projection, datum and transfer format. These criteria are all discussed in more detail below.

2.2.1 Spatial Extent

The extent of the area for which data are required needs to be defined clearly in the coordinate system to be used in the project. At a minimum the extent should be defined by a bounding rectangle using the x and y coordinates of 2 diagonal corners. Ideally the extent should be delineated by a bounding polygon at an appropriate spatial resolution. A bounding polygon will allow for better selection of relevant information and itself provide a tool for analysis within the project. In defining the extent a sufficient margin should be included to allow for inclusion of features which may have an influence on the application.

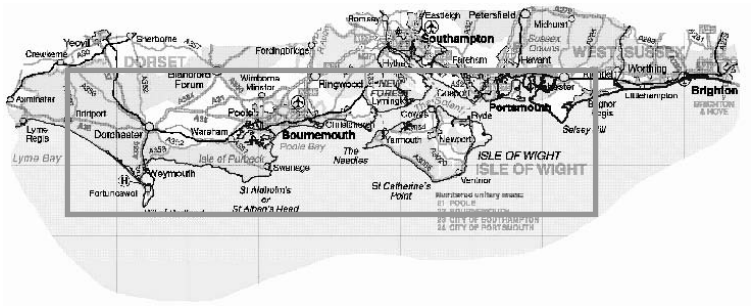

Figure 2.1 Bounding Rectangle. © Crown Copyright 2004. All rights reserved.

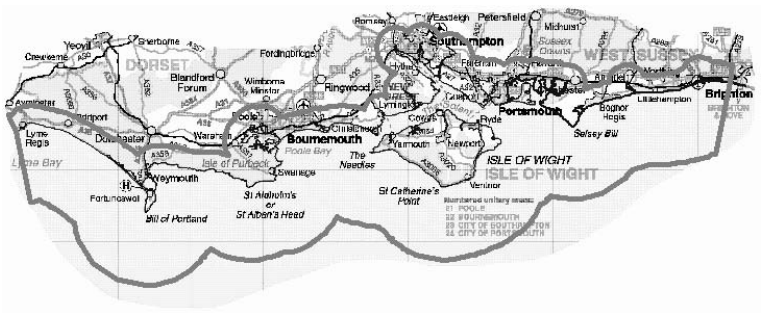

Figure 2.2 Bounding Polygon. © Crown Copyright 2004. All rights reserved.

In Figure 2.1 the extent of the ICZMap coastal zone project is defined as a simple bounding rectangle and in Figure 2.2 as a polygon defined by buffering the coastline 20km offshore and 5km inland. In practice, the latter was more appropriate for the application and datasets of the ICZMap project, with its emphasis on the processes and dynamics of the land-sea interface.

Whilst it is normal to consider defining extent only in two dimensions, it is worth noting that there will be applications where height/depth extents, along with the temporal aspect may need to be specified.

2.2.2 Data Content

The use to which data are to be put will define the features that are required. At the simplest level this may merely be raster imagery for use as backdrop mapping within an application. At a more complex level, where the data are required to form part of the analysis, the user will need to consider what features and object classes are required. In defining these requirements there will be some features that fall uniquely on the land or in the sea, but there will also be others that by their nature bridge this land-sea divide.

2.2.3 Attribution

Attribution of features within a dataset can be at a number of different levels. As a minimum this could take the form of feature coding, allowing selection of required features for analysis and symbolisation. Beyond this, additional attribution concerning the real-world properties of the feature and how it was captured will increase the versatility of the data. These attributes will vary for different features within a dataset depending on the real-world object they represent, and the uses for which the dataset was intended.

2.2.4 Positional Accuracy and Spatial Resolution

An appreciation of the positional accuracy requirements of a dataset is important to ensure that the data are used in an appropriate way with other datasets, and to put results of any analysis in to the correct context. The positional accuracy of spatial data can be expressed both in terms of its absolute accuracy and its relative accuracy.

Absolute accuracy is a measure to which a coordinated position in the dataset corresponds to the true position of the real world feature it represents. Relative accuracy expresses the positional accuracy between points in a dataset, and is a comparison of the distance between features in a dataset with the real world distance. Datasets with a high relative accuracy but low positional accuracy may indicate a systematic shift in the data with respect to the coordinate system.

The spatial resolution represents the coordinate precision to which data are stored in the dataset, and affects the maximum achievable accuracy for a dataset,

e.g. if the spatial resolution is only 10m then this could affect the absolute accuracy of a point by up to 7m.

2.2.5 Currency

Currency is sometimes overlooked as an aspect of a dataset's specification. Attribution should ideally allow for the recording of temporal information at feature level. This can include creation date, capture date and modification date (with nature of modification). Occasionally, temporal information will be limited to the date of the dataset's last update. The temporal information is important both from an analysis point of view, but also for the initial selection of data for the project. For example, the ability to select the position of the top and bottom of coastal slopes for a given year can allow predictive analysis of coastal erosion processes to be studied.

2.2.6 Projections and Datum

Coordinates within a dataset will be relative to a given projection and datum. Map projections attempt to represent the curved surface of the Earth on a flat plane. All projections are approximations and some will better represent large areas of the world, albeit with large distortions, while others are more suitable for small specific areas with much smaller distortions.

A geodetic datum or spheroid is a mathematical approximation of the surface of the Earth, which itself is an imperfect sphere. Numerous geodetic datums have been calculated over the years, some suitable for global applications and others calculated to minimise errors on a country-by-country basis.

Height datum represents a base level from which elevations are measured and each information source may have its own. Datasets on land will often share a common height datum (e.g. use of Ordnance Survey Newlyn Datum in Great Britain); however different datums will usually be used for marine datasets. Frequently, with marine datasets having their origin from navigation charts, depth values will be typically based on local lowest astronomic tide values.

For a project it is important to determine what projection and datum are most suitable for the application, and to ensure that you are aware of what the projections and datum of the source datasets are.

2.2.7 Data Transfer Format

Datasets are transferred between media using a chosen transfer format. Whilst there is no single common transfer format there are a number of commercial ones, such as Autodesk-AutoCAD DXF, ESRI Shapefile and MapInfo TAB and MIF/MID formats, which are becoming more widely adopted as *de facto* standards. Such formats can be limited as they are primarily intended for transfer between users of the same software. When read by other software, information may be lost due to data model differences.

Ideally a neutral, non-software-specific, transfer format is needed. Many attempts have been made to try to implement these, one of the most recent examples being GML (Geography Markup Language) promoted by the OpenGIS consortium as a development of the more widely used XML Web document markup language. However, in practice, the software being used for a project may act as a limiting factor in what formats it can and cannot read.

2.2.8 Metadata

Much of the information describing a dataset should be included in its metadata if present. As well as accompanying a dataset, metadata are now frequently being held on readily accessible databases, allowing users to identify datasets suitable to their requirements. The international standard for digital geospatial metadata (ISO 19115) is now being adopted by many national bodies, such as US Federal Geographic Data Committee (FGDC) for its Content Standard for Digital Geospatial Metadata (CSDGM) (http://www.fgdc.gov/metadata/metadata.html/), and the UK's Association for Geographic Information (AGI) with its GIGateway project (http://www.gigateway.org.uk/default.asp/).

2.3 DATA SELECTION

The properties of datasets that have been outlined above cover some of the points that need to be considered in establishing a project and specifying data requirements. Metadata services provide a tool for locating data, but they will not tell you if they are best suited for your purposes. It is unlikely that any dataset will fully match your requirements, but what should be considered is the ability to integrate and modify them to satisfy your needs. Typically, more flexible datasets will have a richness of feature classes and attribution, and good positional accuracy, but these will come at an increase in cost and data volumes.

2.4 DATA INTEGRATION

It is unlikely that a single dataset will satisfy the full needs of a project. This is particularly true when modelling the coastal zone, where there is likely to be one source for the land, another for the sea and potentially other subsidiary datasets straddling both. In these cases there will inevitably be some data integration issues. Typical problems and potential solutions are discussed here.

2.4.1 Differences in scale

Datasets which have been captured from graphic products can be said to have a nominal scale at which they were intended to be used. In these datasets, differences in scale will show themselves in the positional accuracy and spatial resolution, as well as in the features and attributes that are present e.g. field

boundaries may be shown at a scale of 1:25,000 but not at 1:50,000. At smaller scales data will also normally have been generalised, simplifying the geometry of the features. These factors are not a problem in themselves, as long as the data meet application requirements, but problems do nonetheless occur when trying to join together data captured at different scales.

The following example illustrates the relevance of this to the coast, using datasets from the Ordnance Survey of Great Britain and from the UK Hydrographic Office respectively.

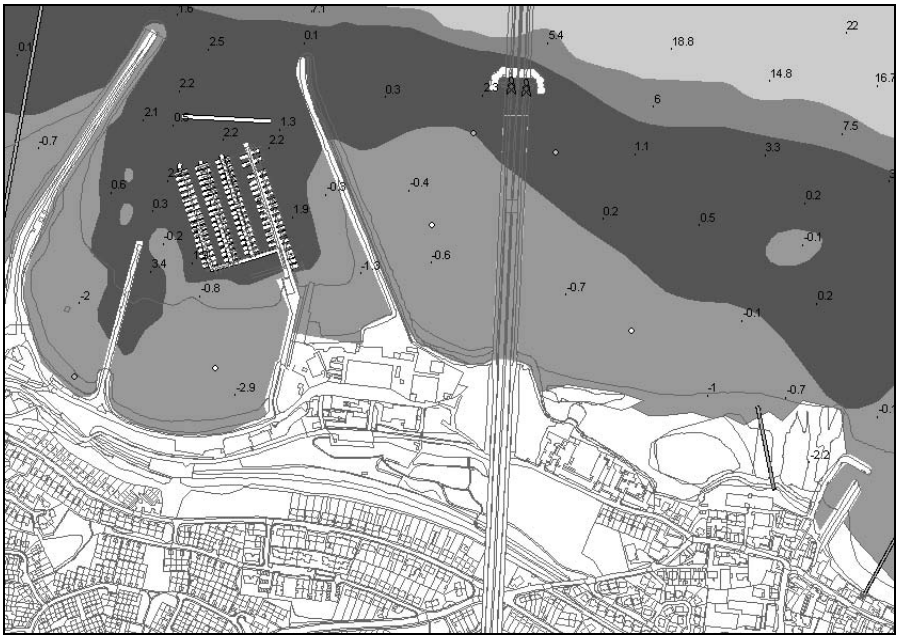

Figure 2.3 Overlay of hydrographic and terrestrial datasets. © Crown Copyright 2004. All rights reserved.

In Figure 2.3 the landward data have been captured at a scale of 1:2,500 and on the seaward side at a scale of 1:25,000 (this being the highest resolution data available for the area). The result of this is a disparity in the features common to both zones, and a greater density of detail on the land compared with the sea. In such situations a choice can sometimes be made as to which feature is most useful to the application, and the software system functionality used to remove or suppress the other. In a similar way features that are superfluous to the application can also be removed or suppressed by the software, provided that features can be distinguished from each other by their attributes.

If the geometry of the large-scale data is too complex, then filtering this using line-simplification or other generalisation algorithms can be considered. Within a project for a user this is probably only appropriate to features where line vertices can be removed whilst keeping the basic shape of the feature.

2.4.2 Projection

Where the datasets to be used are in different projections a choice will have to be made as to which to use, based on the application and the type of output required. Transformation facilities, with parameters to convert between most common map projections, are supplied with mainstream GIS packages. For projections not included these can also be transformed, provided the parameters defining the projection are known.

How the transformation is applied depends on the functionality of the software being used. Frequently this will allow transformation of data coordinates to be done either as a permanent process, storing new coordinates for the features in the new projection, or as a real-time transformation when the dataset is required for display or analysis.

2.4.3 Currency

Where different datasets abut each other or overlap, the same real-world features may be represented in both datasets. In such cases a decision will normally need to be made as to which features to retain. Such selection may be done on the currency of the data i.e. the date of capture of the feature. However, this may not give the best quality in terms of fidelity or resolution. In these situations the final decision as to whether the feature gets included will be based on the specific needs of the application.

2.4.4 Accuracy

As with currency, an appreciation of the relative positional accuracies of datasets that are to be integrated will ensure that data are combined in an appropriate manner. Where features representing the same real-world objects exist in two or more datasets, the positional accuracy will offer one means of selecting which to keep. In some instances it will not be appropriate just to take the data with the highest positional accuracy. For some applications the more accurate data may take up more space, be slower to manipulate, and not enhance the analysis, so ultimately it is up to the user to decide what best fits their needs.

2.4.5 Data Overlap

Many of the issues discussed above cover situations where data in different datasets overlap spatially and represent the same real world objects. It is assumed that in such situations a decision will need to be made as to which features to keep, and that this selection will be driven by the requirements of the application. In the case of a marine and a terrestrial dataset bounded by a coastline, due to the different representations of the coastline in the two datasets, features may overlap (as shown in Figure 2.4).

These overlaps can be treated in a number of ways:

1) Ignore them, accepting that both overlapping features are valid in the context of the source datasets and their specifications. This may not be a real solution when the application requires a single seamless layer of information with no duplication of common features.

2) Spatially intersect overlapping features and retain all the features that result.

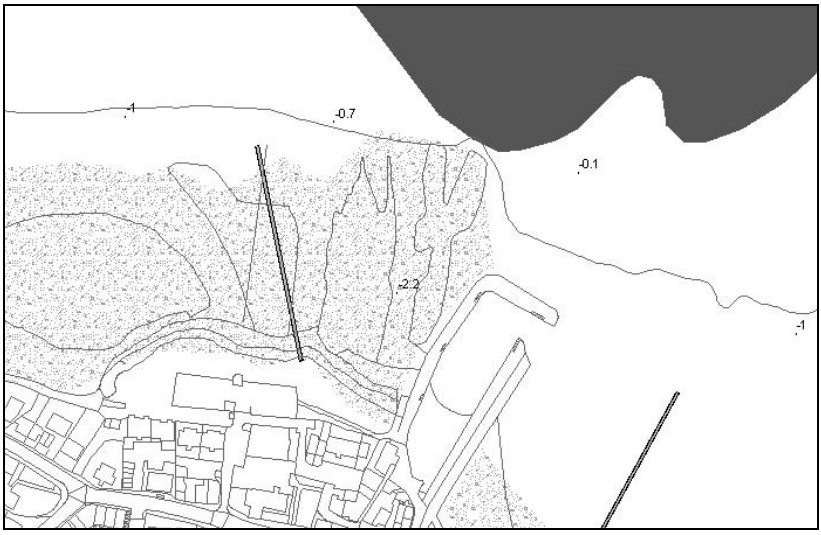

Figure 2.4 Data overlap example. © Crown Copyright 2004. All rights reserved.

Features will be split by others that overlap them and the resulting features will need to retain the attributes of both source datasets to be flexible. This is the most flexible solution but has a potential storage overhead of having to store the two sets of attributes.

3) Spatially intersect overlapping features and retain only one set of features. This will ensure no overlap, but some features will be truncated or split and as a result may present problems when used for analysis.

4) Edit datasets together using a single boundary between them. This can be labour-intensive, but will give the best solution. However, if datasets are updated independently then this work will need to be repeated to maintain currency of the combined dataset.

2.4.6 Height Datum Correction

2D plan data need not necessarily be physically combined into a common dataset to be of use. This is not true in the case of 3-dimensional data. Terrestrial and marine elevation data can be displayed graphically in 2D, but where any use of terrain modelling is required, such as for an analysis of the inter-tidal zone, a combined height model needs to be created. As mentioned previously, the terrestrial and marine elevation data will frequently be relative to different datums. As a result, prior to combining them into a single height model, one or more of the datasets need to be corrected to the other's datum as well as any re-projection of the data onto the other's coordinate system (Milbert and Hess, 2001).

In the simpler cases, correction of a datum can be achieved by a single difference applied to all elevation values in a dataset, but more frequently the difference will vary across an area. In the case of UK Hydrographic Office (UKHO) data, bathymetric values are based on lowest astronomic tides for navigation purposes, as computed for specific locations on each chart. The relationships between these different datums are shown in Figure 2.5.

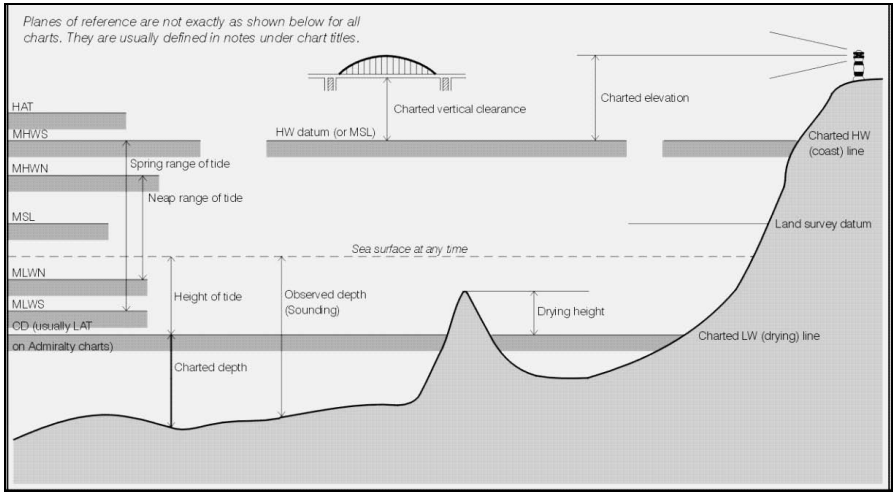

Figure 2.5 Datum Relationships. © Crown Copyright 2004. All rights reserved.

There is a complex and varying relationship between Ordnance Survey of Great Britain's single, standard Newlyn height datum (which applies to all terrestrial mapping by the OS) and the values used in Hydrographic charting, with the latter differing widely along the coast, due to the varying tidal conditions that occur. To convert the UKHO bathymetry values to Newlyn datum, a surface of differences has to be created so that correction value can be calculated for all points (Capstick & Whitfield, 2003). Once a surface of differences has been created this can be used to interpolate values for all bathymetry points. The corrected points can then be used with the terrestrial elevation data to generate an integrated land-sea model for display and analysis.

Figure 2.6 shows a representation of integrated elevation data for the Isle of Wight, UK, with the bathymetry information coming from UKHO sounding values and the terrestrial elevation from Ordnance Survey Land-Form PROFILE contours and spot heights.

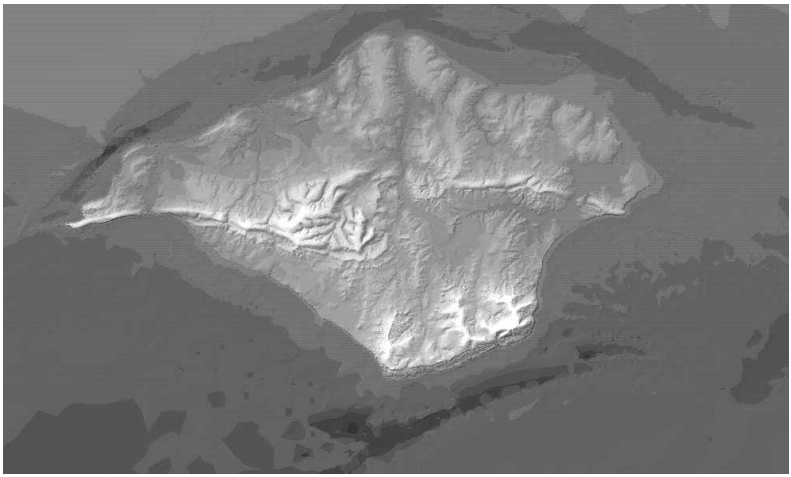

Figure 2.6 Integrated Height Model. © Crown Copyright 2004. All rights reserved.

2.5 CONCLUSIONS

Whilst there may be limited availability of single datasets covering the land-sea divide, digital technologies offer the capabilities to combine and resolve available adjacent datasets to satisfy diverse applications for the coastal zone. In satisfying an application, the user must have a clear specification for their data requirements so as to be able to assess the suitability of candidate datasets, and the issues that are likely to be encountered in their integration. Although not exhaustive, this chapter has attempted to highlight the main areas to be addressed in the selection and integration of spatial datasets for the coastal zone.

CHAPTER THREE

A Comparative Study of Shoreline Mapping Techniques

Ron Li, Kaichang Di, and Ruijin Ma

3.1 INTRODUCTION

The shoreline is a unique and complex feature and has been recognized as such by the International Geographic Data Committee (IGDC), which designates it as one of 27 key distinct features on the earth's surface. A shoreline is defined as the line of contact between land and a body of water. Although it is easy to define, the shoreline is difficult to capture because of the natural variability of water levels. An accepted method of capturing this line of interface is to determine the *tide-coordinated shoreline*, which is the shoreline extracted from a specific tide water level. NOAA uses Mean Lower Low Water (MLLW) and Mean High Water (MHW) in this way to map shorelines that can be georeferenced. Both the MLLW and MHW are calculated from averages over a period of 18.6 lunar years.

Like the shoreline, shoreline mapping techniques are changing and being improved upon. At present, photogrammetric techniques are employed to map the tide-coordinated shoreline from aerial photographs that are taken when the water level reaches the desired level. Aerial photographs taken at these water levels are more expensive to obtain than remote sensing (RS) imagery. With the development of remote sensing technology, satellites can capture high-resolution imagery with the capability of producing stereo imagery: one such source is the IKONOS satellite images. The question is: is it possible to use RS imagery to map the shoreline so that we can reduce the costs and improve mapping efficiency and accuracy?

During our study we extracted shorelines from aerial photos, simulated and actual IKONOS imagery, and the intersection between a Coastal Terrain Model (CTM) and the water level. We estimated the accuracies of these shorelines and analyzed the potential of these techniques for practical shoreline mapping by comparing the extracted dataset with the shorelines from the United States Geological Survey (USGS) topological maps and National Oceanic and Atmospheric Administration (NOAA) nautical charts.

3.2 SHORELINE EXTRACTION

To evaluate the new shoreline mapping techniques it is necessary to compare the results with a current shoreline product. In our study, the shoreline extracted from the tide-coordinated aerial photos was used as the reference shoreline and the other shorelines were compared with it to assess their relative accuracies. Shorelines from USGS Digital Line Graphs (DLG) and a NOAA Nautical Chart were digitized to facilitate the evaluation of the new results. The extraction methods used are discussed in the following sections.

3.2.1 Shoreline from aerial photos

A shoreline was digitized from tide-coordinated aerial orthophotos. This product was chosen as the baseline in our analysis due to its high accuracy. The aerial photos were commissioned by NOAA in 1997 when the water surface reached the specified level (MLLW). The photo scale is about 1:20,000 and the pixel size is about 0.6 meters on the ground. This shoreline is tide-coordinated to the mean lower low water level. A Global Positioning System (GPS) survey was carried out in 2000 to obtain control points for the bundle adjustment. Eight control points were used in the adjustment. The Root Mean Square (RMS) numbers indicate a good precision in this adjustment: 0.106, 0.107 and 0.073 meters in the X, Y and Z directions, respectively. Based on the bundle adjustment results, Digital Terrain Models (DTMs) and orthophotos were generated in sequence. Then, the orthophoto mosaic was created with a resolution of 1 meter. The shoreline was digitized manually from this orthophoto mosaic. The task was accomplished using ERDAS software.

3.2.2 Shorelines from simulated and actual IKONOS images

IKONOS imagery has two resolutions, 1-meter panchromatic and 4-meter multispectral. We first obtained 4-meter multispectral geo-referenced imagery for our project. The stereo 1-meter images were still pending when we produced the shorelines in this paper. To study the potential of 1-meter stereo imagery in shoreline mapping, we simulated the imaging procedure and obtained the simulated IKONOS 1-meter stereo imagery using rational functions (RFs). The shoreline extracted from aerial orthophotos was used for back-projecting to the simulated IKONOS raw backward- and forward-looking images. The resulting shorelines on IKONOS raw images show that RFs work very well. This indicates that we can use RFs to extract high accuracy 3-D shorelines from real IKONOS 1-meter imagery provided that we can find well-matched conjugate points on raw IKONOS images along the shorelines. To improve the accuracy of 4-meter IKONOS real data, 8 control points were used to perform planar polynomial geo-correction. The RMS in the X and Y directions are 1.048 meters and 1.1028 meters respectively. A shoreline was extracted from the refined IKONOS image.

3.2.3 Shoreline from the intersection between a CTM and the water level

This idea comes from the definition of a shoreline as the contact or intersection line between the water level and the land. We tried to obtain the land model and water surface model (WSM) and then compute the intersection line of these two models. This method is intuitive to people's perception of shoreline (See the profile in Figure 3.1 and the colour insert following page 164). The CTM depicts the elevation and bathymetry in the coastal area. The water surface model is obtained from the Great Lakes Forecasting System at The Ohio State University (OSU). To extract the shoreline, these two models were overlaid and the WSM was subtracted from the CTM to get an output layer. Theoretically, the shoreline should be the line with the zero value in the output layer. In practice, the zero pixels do not form a line due to random errors in these two data models introduced from data acquisition and sampling. We chose a small value range for the study and obtained a shoreline strip. We then took one side edge of the strip as the shoreline for our study. We employed this method because the strip is very thin and it is very small compared to the error of the CTM.

3.2.4 Shorelines from other sources

Besides the above shorelines, four other shorelines were used for the analysis in our study. Among them, two digital shorelines were provided by the Ohio Department of Natural Resources (ODNR), the third one was extracted from a USGS DLG and the fourth one was digitized from a NOAA Nautical Chart.

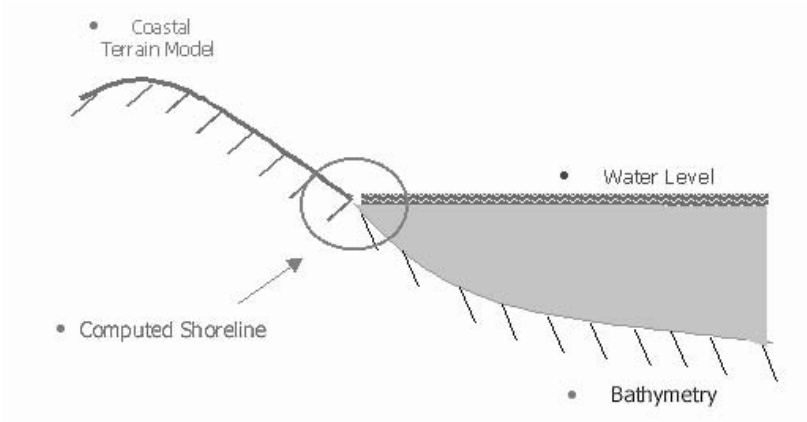

Figure 3.1 Generation of Digital Shorelines

3.3 ESTIMATION OF THE ACCURACY OF THE SHORELINES

The accuracy of these shorelines was analyzed in our study by considering the data sources and the extraction methods. More extensive work will be done in the future to further investigate this important issue.

From the bundle adjustment and conjugate point matching, the DTM standard deviation derived from the aerial photographs is estimated to be 2.1m in X and Y coordinates. Considering the error introduced by resampling from the aerial photos of a 0.6m resolution, the 1-meter orthophoto has an estimated standard deviation of about 2.1m. The identification error of the shoreline from the orthophoto may introduce 1.5 pixels, that is 1.5m, considering those situations where the water and land separation is very hard to define. Therefore, the shoreline from the aerial orthophoto has an estimated standard deviation of about 2.6m if we apply a simple model of error propagation.

The accuracy of the shoreline derived from 1-meter simulated IKONOS imagery should be about 2-4m (Zhou and Li, 2000), considering the fact that the accuracy of 3D ground points reaches 2-3m with GCPs and the accuracy of identifying and locating conjugate shoreline points is about 1.5 pixels (1-2m). The 4-meter IKONOS images have an accuracy of 23.6m (http://www.computamaps.com/ikonos_tech.html). After polynomial georectification using 8 GPS control points, the difference between the GPS and computed coordinates at the control points is about 6m. An optimistic estimation of the shoreline accuracy derived from the 4-meter IKONOS images in this specific case is about 8.5m.

The accuracy of the shoreline derived from a CTM and the water level is affected by the accuracy of the CTM and the accuracy of the water level. The CTM comes from the DTM generated in turn from the aerial photos and the bathymetry. The DTM has an accuracy of 2.1m and the bathymetry has an estimated accuracy of 40m. When we merged these two data sets, we select the DTM grid points in the overlapping area. If there is gap between the two data sets, we interpolate the elevations using weights of 2/3 from DTM and 1/3 from bathymetry where the standard deviation of the CTM is about 13.4m. Overall the accuracy of the CTM is from 2.1m to 13.4m for the area where the water surface model intersects with the CTM. The water level data is accurate to several centimeters. Taking 5 degrees to be the coastal slope in worse cases and 5cm the water level error, we can estimate the horizontal accuracy of the intersected shoreline caused by the water level error to be about 0.6m. Therefore, the final accuracy of the digital shoreline is about 13.4m with the CTM contributing the greatest source of error.

The NOAA T-sheets have large and medium scales: from 1:5,000 to 1:40,000. Taking 0.5 mm on the map as error source, the accuracy of the digitized shoreline from the T-sheet is about 2.5m to 20m. The shoreline digitized from the USGS DLG (1:24,000) should have an accuracy of within 12m. The ODNR map scale is 1:12,000. Again, using 0.5mm as the shoreline digitizing error, the estimated error of the shoreline is about 6m.

Table 3.1 Estimated accuracy of the shorelines derived from various sources

Shoreline	Estimated standard deviation
T-sheet	2.5m to 20m depending on scale
USGS DLG	12m (1:24,000)
ODNR map	6m (1:12,000)
Orthophoto	2.6 meters
CTM and water level	2m-13m dep. on CTM quality
IKONOS 1-meter simulated image	2-4 meters
IKONOS 4-meter image	8.5 meters

3.4 DIFFERENCE AND SHORELINE CHANGE ANALYSIS

The shorelines were acquired at different times and differences can be seen in the results (Plate 3.1). There are two possible interpretations of the shoreline differences. One is that the shoreline indeed changed in the real world. The other possibility is that the differences were introduced as shoreline mapping errors.

From our analysis of the accuracies above, the shoreline from the aerial orthophotos has the highest accuracy, and so we used it as the baseline for the difference analysis. The analysis was performed in raster format because of the efficiency of this method. The first task was to convert the vector shorelines into raster shorelines. The resulting pixel size was 2.5 meters. The procedure is outlined in Figure 3.2.

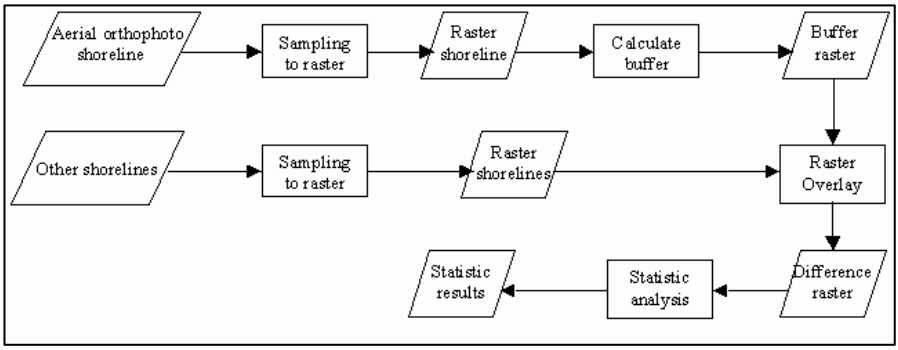

Figure 3.2 Difference Analysis Procedure

This analysis involved comparing every point on the test shorelines with the reference shoreline, which was derived from the aerial orthophoto, in a perpendicular direction toward the reference shoreline. In the buffer zone of the reference shoreline we created pixels whose value represented the distance of each

pixel to the reference shoreline. By overlaying other raster shorelines with the buffer image we were able to discern and quantify differences between the shorelines and the reference shoreline. For example, for the shoreline from the simulated IKONOS images, each point on the shoreline has a value of the shortest distance to the reference shoreline. Finally, we calculated some statistic indicators including RMS of the differences for the shorelines derived from the 4-m IKONOS images and the digital models (table 3.2).

Table 3.2 Statistics of the differences between derived shorelines and the reference shoreline

	Points used	**Avg. Dif. (pixel)**	**Avg. Dif. (m)**	**Max. Dif. (pixel)**	**Max. Dif. (m)**	**RMS (pixel)**	**RMS (m)**
Shoreline from 4-m IKONOS images	6652	4.02	10.04	16	40.0	4.91	12.27
Digital shoreline	4590	2.34	5.84	9	22.5	2.74	6.84

The accuracies of the shorelines derived from the 4-meter IKONOS images and the aerial orthophoto are 8.5m and 2.6m respectively; as a result, the estimated accuracy of the difference between them should be 8.9m, which is smaller than the RMS value 12.27m in table 3.2. This may indicate the actual shoreline change during the period from July 1997 when the aerial photos for the reference shoreline were taken to October 2000 when the 4-meter IKONOS images were taken. In addition, the IKONOS shoreline is an instantaneous shoreline, instead of a tide-coordinated shoreline. The water level in October was 0.2-0.3 meters lower than in July creating artificial shoreline accretion. We are developing methods that correct instantaneous shorelines to tide-coordinated shorelines and then compare them. For the digital shoreline from the CTM and WSM intersection, the RMS value 6.842m in table 3.2 is smaller than the worse case shoreline error of 13m in table 3.1. The difference can be introduced by two different factors. One is the seasonal water level difference, which can introduce a large difference in a flat area like Sheldon Marsh. Another factor is the difference between the accuracies of DTM and bathymetry in CTM. If the DTM covers the coastal surface up to the MLLW or better (this is the case in our research), the water surface model intersects with the DTM portion of the CTM and results in smaller errors; otherwise, the shoreline would be intersected by the water surface model, and the bathymetric part or the interpolated part of the CTM produces large errors.

Observing the differences between the reference shoreline and earlier shorelines from the maps, they may represent the shoreline changes (erosion) that occurred in long time periods. The earliest shoreline in our study is the shoreline from 1973 ODNR map, 24 years before the aerial photos for the reference shoreline were taken in 1997.

3.5 CONCLUSIONS

From the analysis above, we can draw several conclusions. First, we determined that the method for generation of digital shorelines from CTM and WSM can be used in mapping instantaneous shorelines. The generated shorelines can meet the accuracy requirement for certain user communities. Additionally, this work shows that high-resolution satellite imagery, such as IKONOS imagery, has the potential to become a tool in shoreline mapping and coastal change detection, and that it may reduce mapping costs. Finally, our study confirms that to detect coastal changes, tide-coordinated shorelines must be derived from the instantaneous shorelines so that the amount of shoreline change can be estimated objectively.

3.6 ACKNOWLEDGEMENTS

The research was supported by a Sea Grant – NOAA Partnership program with the collaboration of CSC, NGS and OCS of NOAA. Special thanks go to Dr. Keith Bedford and Dr. Philips Chu for providing the water level data. We appreciate the assistance and co-operation of Dr. David Schwab of the GLERL of NOAA during Ruijing Ma's PEGS Professional Development Project in Ann Arbor, MI. We also appreciate the continuous support and help from Dr. Scudder Mackey of the Lake Erie Geology Group of the ODNR in Sandusky, OH.

CHAPTER FOUR

Monitoring Coastal Environments Using Remote Sensing and GIS

Paul S.Y. Pan

4.1 INTRODUCTION

This paper concerns the monitoring of the marine and coastal environment in South Wales using state-of-the-art survey techniques and a geographic information system (GIS). One of the most important natural resources in South Wales is its marine aggregate. This resource is vital to the regional economy in that it provides the building industry with that most essential of raw materials, sand and gravel. However there are growing concerns as to the possible effects of the commercial extraction of aggregate on the coastal and marine environment, and a number of environmental monitoring procedures are in place to detect changes. These range from traditional beach profile surveys to state-of-the-art airborne remote sensing techniques. The National Assembly for Wales has pioneered the use of airborne LiDAR (Light Detection and Ranging) for the acquisition of highly detailed topographical data on beaches, and CASI (Compact Airborne Spectrographic Imager), for the determination of the state of the vegetation along part of the coastline. LiDAR is capable of accurately detecting changes in beach levels. The procedure began in 1998 and will continue until at least 2003, giving an unprecedented insight into coastal changes over time.

Another remote sensing technique has also been deployed. Close-range photogrammetry has been used to determine the degree of retreat of unstable sea-cliffs. All the data collected is used to populate a GIS. Data acquired in this way is compared with that from various monitoring procedures carried out previously (aerial photography and beach profiles). A number of advanced techniques have been developed in parallel to the GIS for the interpretation, analysis and visualization of the data. A number of invaluable lessons have been learned.

Apart from the site-specific monitoring procedures, other strategic data sets such as the macro-fauna community distribution, modelled parameters, etc., have also been acquired from a number of sources. Amongst these parameters, the most important of all is the sediment environment. It defines the fuzzy geographical boundaries in which distinctive hydrodynamic regimes operate. A summary on the resources and constraints is generated for each of the sediment environments. These resources and constraints summaries together with the GIS form the basis of a decision-support system for assisting the formation of policy for the management

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

of the marine resource. The findings will shape future decisions about the sustainable use of the marine resource in South Wales.

4.2 BACKGROUND

The marine and coastal environment is important to Wales. About 75% of the length of the country is coastal, allowing the waters of the Irish Sea and the Bristol Channel to lap its shores (Figure 4.1 and the colour insert following page 164). South Wales lies adjacent to the Bristol Channel, a body of water largely unaltered in its current dimensions since its beginnings as a marine transgression in the early Holocene. (The Holocene, or post-glacial epoch, covers the period for the end of the Pleistocene about 10,000 years ago to the present day). Here the coastal areas are not only characterized by a number of urban and industrial centres, such as Newport, the capital city Cardiff, Bridgend, Port Talbot and Swansea, but also by many cherished areas of special landscape and nature conservation interest, such as: the Gwent Levels; the Kenfig National Nature Reserve and candidate Special Area of Conservation (cSAC) designated under the European Habitats Directive; the Gower Area of Outstanding Natural Beauty (AONB) – the first to be designated in the United Kingdom; and the Glamorgan Heritage Coast (Figure 4.2 and colour insert). Together, and for different reasons, these coastal areas attract thousands of visitors every year, providing employment opportunities for some of the local population. One of the unseen resources of the Bristol Channel, however, contributes to the local economy in a different way – by yielding high quality building sand for local industry, an essential prerequisite for many forms of economic activity.

Whilst this economic activity brings undoubted prosperity to South Wales and neighbouring regions in mid Wales and South-West England, many people perceive changes to their familiar coastlines, and in particular, to the sandy beaches. There are growing concerns as to the possible effects of the extraction of marine sand from the Bristol Channel, and not everyone thinks the removal of this resource is acceptable or sustainable.

Generally, in Welsh waters, the extraction of sand from the marine environment by dredging is licensed by the Crown Estate. (The Crown Estate Commission is the representative of the Crown, which, in the UK, constitutes the owner of the seabed out to a 12-mile territorial limit). However, the decision on whether a production license should be granted essentially rests with the Environment Minister at the National Assembly for Wales – a devolved and autonomous arm of central Government that came into being in 1999. With its inception has come a desire to increase outside involvement in policy-making and administration, and to increase transparency and accountability in deciding major issues. The challenge for the Assembly's civil servants is to continue to provide objective advice to Ministers in an ever-evolving social, economic, environmental, cultural and political context. This advice must be based on facts and scientific evidence, together with the specialist and professional judgement of the officers involved. All of the dredging licenses granted in recent years have stringent environmental monitoring conditions attached. It is the scientific data from these monitoring procedures that form the basis of sound advice.

This paper discusses the introduction of a Geographic Information System (GIS) into part of the National Assembly for Wales for the analyses of the monitoring data. It highlights the technique's influence on the monitoring procedures and the way it has helped reshape the environmental monitoring requirements in relation to dredging licenses. By way of illustration, a number of the state-of-the-art procedures currently deployed are examined.

Figure 4.1 Wales and its surrounding areas.

4.3 DATA ANALYSES USING GEOGRAPHIC INFORMATION SYSTEMS

The benefits of modern computerized GIS have been well documented by others, for example, Clark *et al.*, 1991 and Maguire, 1991. GIS was first introduced to the former Welsh Office (now the National Assembly for Wales) in early 1997 for analysis of the monitoring data acquired in respect of the dredging license at Nash Bank. A prototype was developed using ESRI's (Environmental Systems Research Institute Inc.) ArcView GIS. The benefits of the technique over the traditional paper-based reporting were immediately apparent. It:

- provided a stable platform for the integration of disparate data from different sources;
- allowed a large quantity of data to be stored and processed;
- provided a seamless geographical database overcoming the restrictions of traditional map/chart boundaries;

- provided facilities for sophisticated analysis and cross-examination of data; and
- provided advanced facilities for the display and visualization of data to a wider audience.

After a period of evaluation, the technology was adopted for operational use. It would play a key role in re-shaping the environmental monitoring procedures. GIS highlighted the weaknesses of some of the established procedures in terms of both the quality and coverage of the data. The capability of GIS in handling spatial data, in particular, has also presented new opportunities for the introduction and subsequent adaptation of more efficient and cost-effective procedures. The following sections discuss some of these new and innovative environmental monitoring techniques. They are: the assessment of cliff instability using close-range photogrammetry; repeated topographical surveys using Light Detection and Ranging (LiDAR); and habitat mapping of sensitive sites of nature conservation interest using Compact Airborne Spectrographic Imager (CASI).

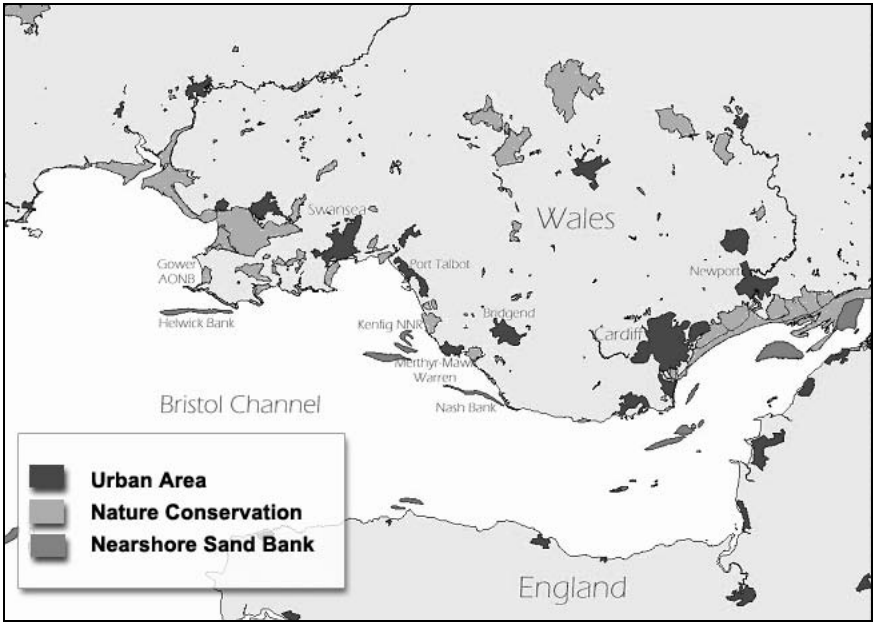

Figure 4.2 South Wales and the Bristol Channel

4.3.1 Assessment of Cliff Instability Using Close-Range Photogrammetry

The Nash Bank lies in the Bristol Channel very close to part of the Glamorgan Heritage Coast. The sandbank contains about 200 million tonnes of material and is a relic feature of the last (or "Devensian") glaciation. The bank is formed ostensibly from pre-existing glacial and glacio-fluvial deposits subsequently

moulded by advancing seas. At low water its eastern end is often exposed above the surface of the sea, and it resides, at its nearest point, only 300 metres from the shore. Its physical orientation and proximity to this area of sensitive coastline means that it acts as a "barrier" to incoming waves, and is therefore an important structure in terms of coast protection. Physical processes such as the movement of sediment in, on and around the feature, as well as human activities, are altering the shape of this sandbank. One way of measuring the "vulnerability" of the nearby coastline to such changes is by careful scientific examination of instability in the highly unstable Blue Lias cliffs that predominate. Extremely accurate measurements of the geometry of a representative 800-metre section of this geologically special part of the Glamorgan Heritage Coast, and including part of the Southerndown Coast Site of Special Scientific Interest (SSSI), have been undertaken since 1997 using close-range photogrammetry. Its application in this context is unique in the United Kingdom.

Annual surveys have been undertaken in August of each year between 1997 and 2000. A further one took place in February 2001.

4.3.1.1 Close-Range Photogrammetry: The Technique

Close-range photogrammetry operates on the same principle as aerial photography. It produces highly detailed geometric data of three-dimensional structures. Data capture involves the use of a specialist metric camera oriented horizontally on a tripod, and usually mounted on top of a theodolite. The lenses are calibrated and their distortion characteristics considered for subsequent data processing. The technique is also known as terrestrial photogrammetry. Both aerial and close-range photogrammetry have been described in detail in Wolf (1985).

Close-range photogrammetry involves photographing the features or structures being surveyed using the metric camera in a known orientation from two positions. The camera positions and their orientation can be established by "traditional" surveying methods, such as using visual intersection combined with theodolite measured distances from known control points. Alternatively, a number of control points can be set up in the area being surveyed and subsequently included in the photogrammetric survey. These control points are used to compute the position and orientation of the two camera positions.

Data is derived from the photographic images by simulating the relative orientation of the two camera positions, and processing involves the generation of a three-dimensional stereo model representing the geometry of the structure. It is relatively labour-intensive because the orientation of the two camera positions is not always parallel, and this means additional computational requirements. However, the generation of the 3D geometric model has been helped by advances in automatic image matching techniques in the past decade.

Close-range photogrammetry has been used widely for surveying architectural structures worldwide. Its main advantage is that it can survey the physical dimension of any structure that does not lend itself readily to traditional surveying techniques. It has also been used extensively by traffic accident investigators for collecting data from the scenes of accidents where a very limited period is available for data capture. It is therefore a technique which is characterized by a short set up time, data capture by relatively straightforward

photographic means and an ability to survey structures and features which are difficult to examine by any other means.

The intention was twofold: to (a), "test" the technique in the "real-world" of unpredictable environmental change, and (b), establish accurate rates of retreat which could be looked at against historical records. The technique is well suited to the task for several reasons. First, it allows data capture by photographic means without the need to get too close to the area being surveyed – an important consideration given the inherent instability of the Blue Lias cliffs! Also, because the Bristol Channel has the second highest tidal range in the world, only limited periods of time are available for data capture. The technique allows surveyors to record data very quickly around mean low water. Finally, the photographic images captured can be manipulated and rectified to provide a geometrically-correct picture called an orthoimage. An orthoimage is a distortion-free map-like image of an original photographic record. It is produced by rectifying the original photographic image using geometric data derived subsequently. It provides a definitive visual record of the conditions of the cliff at the time of the survey. Figure 4.3 (see colour insert following page 164) is illustrative.

Figure 4.3 The rectified image of the study area for the year 2000.

In addition, the distortion-free orthoimages of the study area can be displayed in the GIS environment where they can be used to help make accurate quantitative measurements, while the map-like orthoimages can be used in conjunction with the 3D geometry derived earlier in the process to produce a realistic representation of the cliffs using advanced computer visualisation techniques such as Virtual Reality.

The combined use of orthoimages and 3D geometric models in a GIS environment has provided a robust platform for analysis of changes to the cliffs. Quantitative contours are interpolated at 0.5 metre and 1-metre intervals using information derived from the geometric data sets. These contours, representing the degrees of change, are displayed on the rectified orthoimage. This innovative visualisation technique allows quantitative measurements of yearly change to be related directly to the cliff face and its geology. This may be vital in guiding interpretative analysis of why change occurs and in attempting to understand whether or not rates of recession are increasing.

An example will help illustrate the techniques. A large rock fall occurred in the winter of 2000-01. Figure 4.4 illustrates the extent and magnitude of the event (in the middle right of the picture) from an oblique angle.

A geometric representation of this event can be displayed and visualised in a couple of interesting ways. Firstly, the interpolated surface can be colour-coded in relation to distance between the viewer and the cliffs. Figure 4.5 shows the data for a 200-metre wide area centred on the fall. Darker shades represent features further away from the observer.

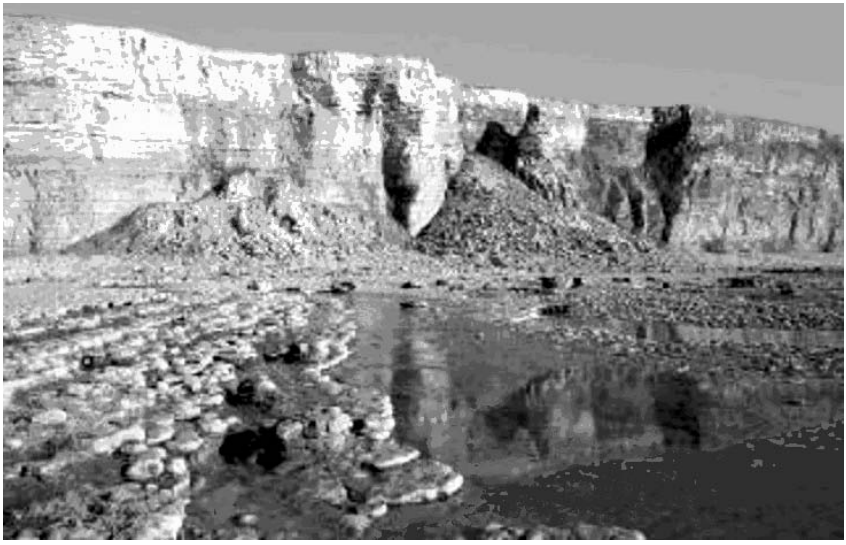

Figure 4.4 The Large rock-fall of winter 2000-01. The cliffs are comprised of Blue Lias rocks and are about 65 metres high. In the foreground is part of a wave-cut platform in the same formation that has been developing for about 7,000 years.

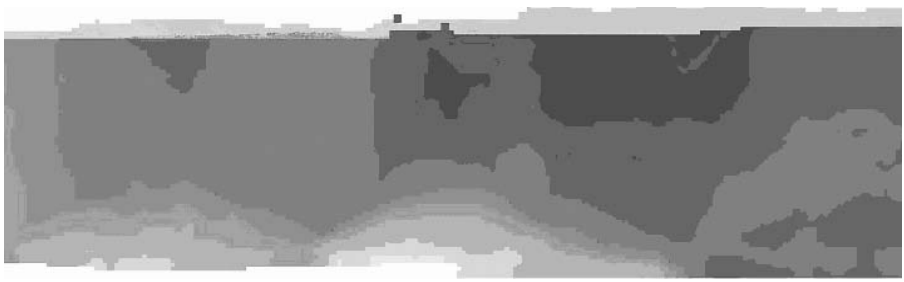

Figure 4.5 Data for a 200-metre stretch of coastline north-west of Cwm Bach

Secondly, the changes brought about by the fall between surveys can be colour-coded to illustrate the changes to the cliffs, and interpolated surfaces may produced using the GIS. Changes at the sampling positions are shaded in reds and blues, depending on the nature of the change recorded. Data collected in February 2001 was compared with that for the summer of 2000. Colour Plate 4.1 (following page 164) shows the results.

The fairly large area of the cliffs represented by deeper reds "failed," causing materials to be deposited as a "classic" debris fan at the base (in deeper blues). The thin area in blue towards the right of the failure represents an "advance." This is, in reality, a rock column which has become detached from the main body of the cliff, and which has been left as a freestanding pillar with a considerable void behind (see Figure 4.4). Future movements will be interesting to monitor!

4.3.2 Topographical Survey Using Light Detection and Ranging

Light Detection and Ranging (LiDAR) is a modern airborne remote sensing technique for surveying topography. It operates on the same basic principle as traditional Radio Detection and Ranging (RADAR), but uses laser as the detection medium. It accurately measures the distance between the instrument and its surrounding environment, and consists of three components: a laser-scanning device, an on-board Differential Global Positioning System (DGPS), and an Inertial Reference System (IRS).

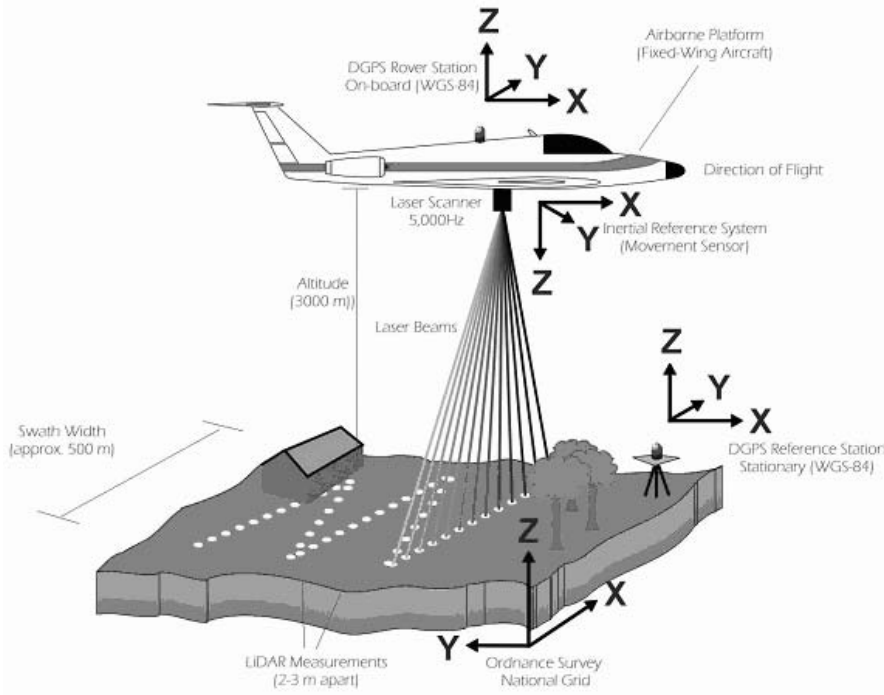

Figure 4.6 A systematic diagram of the three components of airborne LiDAR.

The laser-scanning device is used for the measurement of the distance between the instrument and the topography being surveyed. It emits laser pulses in perpendicular directions to the flight path. By measuring the time required for the laser pulse to return, the distance between the instrument and the topography can be accurately determined. At the same time, an on-board DGPS communicates

with navigation satellites and a stationary ground reference station. It gives the positions of the airborne platform, usually a fixed-wing aircraft, in relation to the earth's surface. The last component of the system is the IRS. This is essentially a motion sensor, and detects minute movements of the aircraft in terms of its yaw, pitch and roll (i.e. movements about its three axes). It corrects the orientation of the laser pulses that can become distorted because of aircraft movement. When the three components work in unison, the surveyed topography is recorded very accurately. Routine field validations of the technique by the Environment Agency have indicated an accuracy of better than 15 cm generally. Ground resolution of data is directly dependent on flying height and speed of the surveying aircraft, as well as the scanning rate of the laser pulses. For example, when flying at 70 knots at an altitude of 3,000 feet LiDAR, with a 5,000 Hz scanning rate, can acquire topographical data with a ground resolution of about 2.5 to 3.5 metres. At the time of writing, the Environment Agency has plans to operate a newer version of LiDAR with a scanning rate of 33,000 Hz. The new instrument should produce topographical data with a 0.5 metre ground resolution! Figure 4.6 shows the three main components of airborne LiDAR.

In South Wales, the coastline is diverse, characterized as it is by bays, inlets, estuaries, beaches, rocky-shores, high cliffs, sand dunes, near-shore sand banks and mud flats. Traditional monitoring on some of the beaches using linear profiles has provided some limited data. In addition, accurate identification of ground features from aerial photographs has been difficult and is relatively expensive. LiDAR, however, has provided a high-value and cost-effective solution. Its capability in capturing very detailed topographical data, without the need to physically visit most of the locations being surveyed, makes it well suited for environmental monitoring purposes, especially for inter-tidal zones where it can survey a large area within a short space of time. One of the few restrictions for the deployment of LiDAR is the tidal window.

LiDAR was first available in the UK in early 1998. The National Assembly for Wales has long realized the potential of the technique and has pioneered its use in Wales. As early as March 1998, in relation to dredging at Helwick Bank, the National Assembly for Wales decided to include the technique as one of the environmental monitoring requirements to measure change along the coastline. As such, the procedure would be deployed annually to monitor levels of key beaches in South Gower. This will continue until at least June 2003. This requirement is believed to be the first of its kind in the UK, and highlights the fact that the analyses of the highly accurate topographical data over time is innovative and pioneering.

To complement these activities, in early 1999, a collaborative project called the "Glamorgan Coastal Monitoring Initiative" was launched by the Welsh Office. This was designed to further embrace the potential of this airborne remote sensing technique, and to marry the data to high-resolution habitat information derived from the Compact Airborne Spectrographic Imager (CASI). This is discussed in the following section.

LiDAR produces extensive data sets. In Kenfig National Nature Reserve (NNR), for example, over 30 million data points have been collected under the Glamorgan Coastal Monitoring Initiative. A number of custom-built computer programs have been written to reduce the data files to more manageable sizes. The data sets have been transferred to an ArcView GIS for interpolation and further

analysis. Some important derivatives, such as slope and aspect, have also been computed. Plates 4.2 to 4.4 show examples of the interpolated elevation surface, and subsequent derivations of slope and aspect from LiDAR data of the same area in the Kenfig NNR.

4.3.3 Habitat Mapping Using Compact Airborne Spectrographic Imager (CASI)

Compact Airborne Spectrographic Imager (CASI) is a state-of-the-art remote sensing instrument for measuring radiation reflectances in the electro-magnetic spectrum. The classification of CASI data can produce a "map" by positively identifying the radiation reflectances of different "objects." In the case of habitat mapping, CASI can "see" a clear boundary between different types of vegetation as long as they emit different levels of radiation – the so-called spectral signature. Habitat mapping using CASI involves three components: an airborne survey using CASI; a simultaneous ground-truthing exercise; and image classification to produce the habitat map (Plate 4.5).

Table 4.1 The classified values, the classifications and their corresponding display colours in plate 4.6, the classified habitat map of Kenfig NNR.

Category	Classification	Colour
1	water	dirty green
2	bare sand	yellow
3	scrub	dark green
4	*Phragmites*	red
5	*Calluna*	light green
6	*Pteridium*	pale blue
7	successionally-young grassland	blue
8	orchid-rich slack	purple
9	successionally-young slack	light brown
10	tall rank grassland	light blue
11	embryo dune slack	pale blue

The data acquisition stage is characterized by an airborne survey using CASI. The ideal timing for the airborne survey is around midday. This is the time when the sun's angle is at its highest, casting minimum shadow and giving the most accurate representation of radiation reflectance. While the CASI survey is being carried out, a team of specialists undertakes a ground-truthing exercise to determine the ecology of selected locations within the study area. The ecological parameters are measured using traditional methods such as 1m x 1m quadrats with the aid of modern DGPS for accurate determination of position. The exercise provides important information to allow the airborne CASI data to be cross-referenced with known vegetation types. The last stage is the classification of CASI data in conjunction with the ground-truthing information to generate a map of the vegetation types. This classified map is subsequently interpreted to form the basis for a habitat map.

CASI has been used as an integral part of the "Glamorgan Coastal Monitoring Initiative." The main objective has been to provide a benchmark survey for Kenfig NNR which together with Merthyr Mawr Warren makes up the European Union's candidate Special Area of Conservation (cSAC). Both sites are of national and international importance. For example, Kenfig NNR holds over 40% of UK's population of the rare fen orchid (*Liparis loeselii*), whilst Merthyr-Mawr Warren is the second highest mobile sand dune system in Europe.

Kenfig has many other features of conservation interest. The successionally-young stages of dune development, in particular, are species-rich, with more than 40 plant species usually found in a 1m x 1m quadrat. These habitats have been prioritised for management and monitoring purposes under the current European Habitat Directive. However, there are growing concerns that the over-stabilization of the mobile sand dunes at Kenfig NNR is threatening the biodiversity of the cSAC.

For discussion purpose, Kenfig NNR has been divided into two broad areas: a southern and northern section (Figure 4.7). The southern section is mostly dominated by mature dune vegetation, whereas successionally-young seral stages are more prominent in the north of the site. The boundary is situated where one starts to grade into the other.

Figure 4.7 Kenfig NNR divided. The section in darker grey represents the ecologically older and more mature southern region of the Reserve. The northern area is depicted in pale grey.

The area Figure for the successionally-young grassland has been calculated by carrying out a pixel count for the habitat type based on a pixel size of 2 x 2m (Table 4.2). The area measurement for the whole site has been calculated in the same way.

Table 4.2 Area measurements for successionally-young grassland at Kenfig NNR, taken from the classified CASI images.

Section	Area of Section ($m^{2)}$	Area of successionally-young grassland (m^2)	%
Southern	1,771,276	201,248	11.3
Northern	2,706,684	782,120	28.8
Whole site	4,477,960	983,368	21.9

Preliminary results show that successionally-young grassland not only covers a much greater area in the Northern Section (which might have been expected because it is considerably larger than the Southern Section), but also occupies a much larger percentage of the area than in the South. This evidence confirms observations that the dunes in the southern part of Kenfig are generally in an advanced state of stabilisation, while this is less so in the northern part of the site where successionally-young grassland is relatively well distributed.

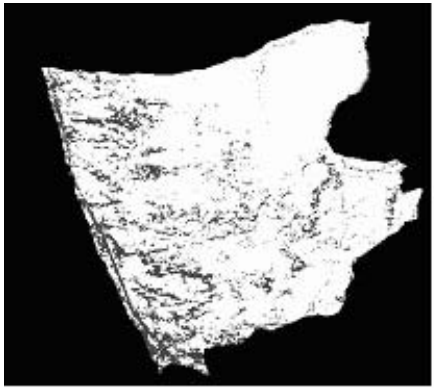

Figure 4.8a Areas classified as successionally-young grassland in the southern section

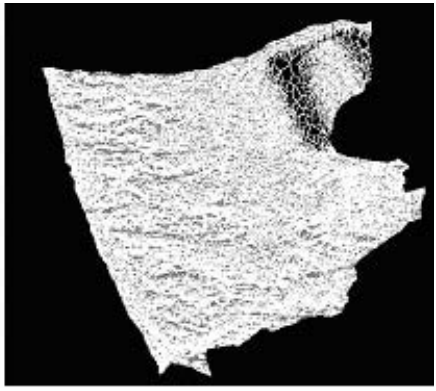

Figure 4.8b Areas with a south-facing aspect

Figure 4.8c Areas classified as successionally-young grassland in the south-western part of the southern section

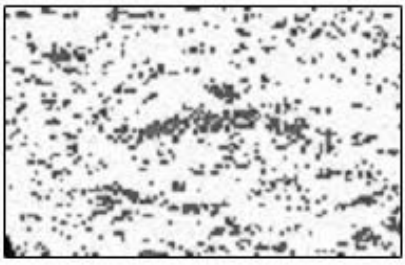

Figure 4.8d Areas with a south-facing aspect

Evidence from the joint analysis of topography and habitat classification in the southern section provides interesting comparison. A high proportion of the areas classified as successionally-young grassland occur close to the top of south-facing slopes. Figures 4.8a and b show the areas classified as successionally-young grassland in the Southern Section, juxtaposed with those showing a south-facing slope. There is also some correlation between the successionally-young grassland and aspect, and this is particularly evident in the south-western part of the section. Figures 4.8c and d are illustrative.

4.4 THE NEXT FRONTIER – MARINE AGGREGATE RESOURCE MANAGEMENT AND PLANNING SYSTEM (MARMPS)

Data collected from these innovative monitoring procedures helps to shed light on some of the plethora of natural processes causing change to the coastal environment. It also helps to expose the implications of some human activities. The data sets are used to populate a GIS. This provides a technical tool to underpin an embryonic decision-support system which will be used for the management and planning of the marine aggregate resource in South Wales to ensure it is only extracted in a sustainable way.

This system, entitled the "Marine Aggregate Resource Management and Planning System (MARMPS)," will operate using data and information on three layers: the site-specific monitoring data sets acquired in relation to the dredging licences, including those relating to bathymetry, 3D cliff analysis and topographical beach data; the regional data from the Glamorgan Coastal Monitoring Initiative, including data from both the LiDAR topographical survey and CASI habitat mapping survey; and the broad-scale and comprehensive strategic data sets derived from the "Bristol Channel Marine Aggregates: Resources and Constraints" project. This research, completed in August 2000, examined the available marine aggregate resources, and the technical, economic, environmental and cultural constraints operating to deter extraction. Two of the many significant outcomes of this work were, firstly, the delivery of an abstractive GIS database with about 100 data themes for the Bristol Channel and, secondly, the derivation of sediment environments representing sub-areas of the physical system that are considered to exhibit similarities across various components of the sediment regime. Together, these will help form the basis for future strategic policy and decision-making.

MARMPS will adopt a multi-criteria approach to aid decision-making at a more local level. In the Bristol Channel, a complicated number of conflicting objectives co-exist, for example, the economic demand for marine aggregate and possible environment impact. MARMPS will define the relationship between these by quantifying them in commensurate terms. In doing so, the conflicting objectives will be summarized and "optimised." The decision-makers will also take part by defining, in their own way, the relative importance of these conflicting objectives, and a weighting mechanism will be applied to take account of these views. Clearly, the weighting may change over time. MARMPS, when completed, will be the first system of its kind in the United Kingdom. It will be operational, designed to tackle real world issues. It will assist decision-makers in reconciling the conflicting interests of different users in the coastal zone.

It is not within the scope of this paper to discuss MARMPS in extended detail. However, the availability of good quality data sets is essential to the success of the development of the system. The National Assembly for Wales will continue to strive to acquire data sets that are robust and meaningful. Continual monitoring of the coastal and marine environment is key to an understanding of the mechanisms of coastal change.

But MARMPS is not just about data collection. There are, for example, a number of identifiable interfaces: the relationship between the coastal and the marine environment; the interaction between various bodies and organizations who have a common interest in the coastal zone; and the need to find lines of communication between science and the general public. The most important interface is, however, the one that brings about an understanding of the strengths and limitations of the natural environment and the formulation of a complementary sustainable policy to ensure wise use of its resources. The outcomes from this interface will, of course, have socio-economic implications.

The development of MARMPS is the latest in an ever-increasing list of new ways of collecting, analysing and using data and information by the newly devolved National Assembly for Wales — the introduction of GIS; routine deployment of LiDAR to monitor coastal change; habitat mapping using CASI; and 3D geometric monitoring of cliff instability. MARMPS will no doubt assist decision-makers at the National Assembly for Wales in making better informed and evidence-based decisions on the future sustainable use of our coastal heritage for many generations to come.

4.5 EPILOGUE

A dissemination seminar for the “Glamorgan Coastal Monitoring Initiative” took place in Porthcawl, South Wales, United Kingdom, on 11 July 2001. (Further details are available at: http://www.swansea.ac.uk/geog/gcmi.) The main objective was to report the results of the Initiative to participating partners, as well as to communicate knowledge about these advanced scientific techniques to the general public.

4.6 ACKNOWLEDGEMENTS

The authors would like to thank the National Assembly for Wales and the University of Wales for their support in the production of this joint work. They would also like to thank Clive Hurford of the Countryside Council for Wales and Graham Thackrah of the University of Wales, Swansea (now at University College London) for their assistance in the habitat mapping of Kenfig cSAC.

The authors are responsible for the contents of this paper, and none are attributable to either the National Assembly for Wales or the University of Wales.

CHAPTER FIVE

Spatial Uncertainty in Marine and Coastal GIS

Eleanor Bruce

5.1 INTRODUCTION

The dynamic nature of coastal landscapes and the inherent complexity of the biophysical processes operating in these environments challenge the application of GIS methods. It is well recognised that spatial data models representing static objects are rife with uncertainty (Fisher, 1999; Foody, 2003). However, the mobility of many coastal and marine phenomena and the nebulous nature of boundaries in these environments provide an additional dimension to the problems associated with spatial data uncertainty. In abstracting the infinite complexity of reality into a finite computer based storage structure, multiple levels of uncertainty are introduced. The more encompassing or inclusive a data set, often the more complex the process of abstraction. Users of coastal and marine GIS are faced with both uncertainty in the information derived from spatial data, and uncertainty that inherently exists in the models. The ubiquitous nature of uncertainty in spatial analysis highlights the need to examine the implications for coastal and marine decision-making. This chapter examines the sources of uncertainty, methods for assessing reliability, model uncertainty and the cognitive and practical implications associated with the communication and incorporation of uncertainty in coastal and marine GIS.

5.2 SOURCES OF UNCERTAINTY IN COASTAL AND MARINE GIS

Uncertainties arise in the conceptualisation, measurement and analysis of geographic phenomena (Longley *et al.*, 2001). Distinctions have been made between different types of spatial uncertainty, to assist in identifying the problems and consequences that may emerge. There are a range of terms used to describe uncertainty including accuracy, error, reliability, precision and indeterminacy. Fisher (1999) identified three major types of uncertainty: these include error, vagueness and ambiguity.

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

Uncertainty is associated with error when both the class of object and the individual represented in the GIS data model are clearly defined (Fisher, 1999). This form of uncertainty is probabilistic in nature. However, some uncertainties are inherent in the geographic phenomena, such as the transition zone between two coastal vegetation communities, and cannot be attributed to randomness (Cheng, 1999; Fisher, 1999; Longley *et al.*, 2001).

Vagueness relates to the difficulty in assigning classes or crisp boundaries to poorly defined objects. For example, the question of whether an area can be described as a saltmarsh requires a threshold value of a measurable parameter, such as the relative or absolute occurrence of saltmarsh species, or recourse to expert opinion (Fisher, 1999; Longley *et al.*, 2001).

Ambiguity occurs when there are differing perceptions of a phenomenon and how it should be classified (Fisher, 1999; Foody, 2003). For example, different standards may be used to define shoreline position, such as Mean High Water (MHW) or Mean Low Water (MLW). These differences in definition will lead to ambiguities in shoreline change analysis (Anders and Byrnes, 1991). Sources of uncertainty frequently encountered in coastal and marine GIS include indeterminate environmental boundaries, the fragmentation of jurisdictional responsibilities over data capture and the scientific uncertainty associated with models.

Despite the prominence and in some cases the requirement for sharply defined boundaries in GIS databases, most objects in geographic space have unclear, fuzzy or non-existent boundaries (Couclelis, 2003; Frank, 1996). This is particularly evident in coastal and marine environments, in which the transition or transient state of many phenomena exacerbates the boundary delineation problem. For example, in defining the extent of a coastal wetland, which is subject to seasonal inundation, there will be temporal variation in boundary location. A range of local interacting environmental factors, including surface hydrology, soil property and groundwater recharge, will influence rate of inundation and consequently the position of the wetland boundary. Potentially compounding this problem, there may be uncertainty in the appropriateness of the definition adopted as the basis for determining the inclusion of an area in the description of wetland. If a wetland has been artificially modified to restrict tidal influences can it still be classified as a coastal wetland? This is described as uncertainty due to indefinite correspondence between concepts and the represented world, where the information may be precise but the classification unclear (Freksa and Barkowsky, 1996). Maps delineating coastal habitats such as wetlands or mangrove communities often form the spatial framework for establishing reserve areas, applying environmental protection legislation or restricting development. Users may assume data certainty based on the neatness of the precise line used to represent an area of habitat on a map while the zone of uncertainty surrounding each boundary remains ignored in the decision process. Management protocols and legislative frameworks often require crisp boundaries for coastal and marine phenomena that are continuous in nature.

Although the legacy of disparate government and private-sector responsibility in coastal and marine management is being addressed in many countries, through the adoption of integrated resource management (Harvey and Caton, 2003), such fragmentation is often still reflected in the capture and custodianship arrangements of spatial data. Bathymetric data is primarily

compiled by hydrographic agencies for marine navigation, transport planning and maritime safety (Ward *et al.*, 2000). Terrestrial elevation data is collated by state or federal land mapping agencies operating under different spatial data capture programs. However, the mapping and spatial modeling of coastal phenomena that traverse the water line, such as historical shoreline change, nearshore dynamics or intertidal sediment accretion, requires these datasets to be merged. The merging of these data involves careful consideration of the reference ellipsoid and water level datum (Li, 2000). Paradoxically, data discrepancy, and consequently uncertainty, is often greatest in the zone of highest research significance, the inter-tidal region. GIS based models designed to examine the coastal impacts of sea-level rise scenarios are particularly sensitive to inconsistencies between merged elevation surfaces (Bruce *et al.*, 2003). Recent developments in coastal applications of Airborne Laser Hydrography are providing detailed 'seamless' Coastal Terrain Models (CTMs) (Sinclair *et al.*, 2003). However, if these data are to become available to broader GIS research applications, there will be a need to reconsider the appropriateness of the shoreline as the delineation for the division of spatial data capture responsibilities.

A second consequence of multiple jurisdictional responsibilities is the incompatibility of classification systems used to describe coastal and marine biophysical environments that extend administrative boundaries. This may generate greater uncertainty at state or national boundaries. For example, in Australia the system of Marine Protected Areas (MPAs) is required to meet principles of comprehensiveness, adequacy and representativeness through strategic inclusion of diverse examples of marine life. In achieving this, the mapping of nearshore waters has involved the use of benthic habitats as a surrogate for biodiversity by most jurisdictions (state and territory governments). However, jurisdictional differences in the spatial scale of responsibility, the nature of marine environments (water clarity and depth), and conceptual divergence in definitions of mapping elements have resulted in considerable variation in mapping standards in Australian nearshore waters (ANZECC TFMPA, 2000). An attempt has been made to organise different jurisdictional mapping approaches and construct a single hierarchical ecosystem-based classification (ANZECC TFMPA, 2000). These issues are particularly evident in coastal and marine environments in which biophysical processes transcend jurisdictional boundaries.

It is clear that uncertainty in the conception and measurement of geographic phenomena will lead to uncertainty in analysis results (Longley *et al.*, 2001). However, in many coastal and marine GIS applications uncertainty in the model must also be considered. The exact values of model parameters are rarely known; therefore it is often necessary to estimate values, but there is always an associated error in that estimation (Heuvelink *et al.*, 1989). Increasing concern by researchers and environmental managers for the potential impacts of projected climate change to coastal environments has highlighted the importance of comprehensive model-based approaches for predicting and assessing longer-term change (Capobianco *et al.*, 1999). However, in developing appropriate spatial models there is a need to account for the scientific uncertainty that surrounds predicted sea-level conditions on which these models are based (Cowell and Zeng, 2003). The sensitivity of model results to variation in sea-level predictions can be demonstrated through alternative impact scenarios or coastal risk maps derived by modifying sea-level

curves. However, coastal managers are then faced with the challenge of transferring these alternative predictions into response policies.

5.3 METHODS FOR EXAMINING LEVELS OF DATA UNCERTAINTY

The reliability of spatial data sets can be assessed using techniques that extend beyond simple field sampling and verification to provide useful indicators of data uncertainty. Assessment methods provide indicators of data uncertainty that can be used by decision makers to determine a data set's fitness of use for the intended application. These techniques deal with measurement and processing uncertainty in the capture of spatial data. There is a broad range of techniques for assessing the reliability of spatial data that will reflect the nature of the data (categorical or continuous) and the form of uncertainty being examined (position and/or attribute). Two of these include the error matrix and the epsilon boundary model.

An accepted method for reporting accuracies in categorical data derived from remotely sensed classifications is the error matrix (Congalton and Green, 1993; Congalton and Mead, 1983; Veregin, 1999). Error matrixes cross tabulate the classified or mapped data with the referenced or field sampled data (Janssen and van der Wel, 1994). The technique has been applied to provide accuracy measures in the mapping of shallow temperate water habitats including seagrass communities and coral reefs (Bruce *et al.*, 1997; Mumby and Edwards, 2002). This approach allows the appropriateness of the assigned map classification to be assessed. For example, when mapping nearshore coastal habitats using remotely sensed data, light attenuation may distort reflectance signals resulting in confusion in the interpretation of classes such as dense seagrass and reef or low biomass seagrass species and sandy substrate. Direct comparison of field and mapped data in the error matrix provides reliability measures that allow end users to assess the level of misclassification associated with each class providing insight on the appropriateness of the data for its intended use. However, this approach assumes a formal conception or definition of the phenomena being mapped and that there is consistency in the descriptions assigned by the map producers and the field samplers. For example, the rule sets used in the interpretation of satellite imagery to define areas of dense seagrass based on reflectance signatures may not translate in the field for divers measuring the biomass density of sampling quadrats.

A useful technique for the assessment and representation of uncertainty associated with the cartographic representation of mapped boundaries is the epsilon error model (Blakemore, 1984; Chrisman, 1982; Chrisman, 1989). The epsilon error is based on the principle that the true position of a boundary line will occur at a displaced distance from the represented or mapped line (Chrisman, 1989). The epsilon area can be described geometrically as the zone extending either side of the mapped line delineating a probability density function of the boundary's real world location (Chrisman, 1989). True boundary position can be measured in the field through transect surveys to record changes in cover type. Using the line intercept method transect results are then overlaid with the mapped data to determine boundary offset (Skidmore and Turner, 1992). In the marine environment this can be conducted using an underwater video camera towed behind a vessel or detailed dive transects. The width of epsilon bands can be set uniformly according to the standard deviation of the uncertainty of the mapped

boundary; in this way the epsilon zone represents a form of mean error (Chrisman, 1989). However, these boundary; error concepts originated in forestry science (de Vries, 1986) and are not easily transferred to the marine and coastal environment. The distribution of error and the corresponding shape of the error band may not be uniform in width (Caspary and Scheuring, 1993; Veregin, 1999). In the nearshore environment factors such as water depth and turbidity may influence the distribution of error around the mapped line. Research conducted in temperate shallow-water environments in southeastern Australia has demonstrated that the depth at which seagrass boundaries can be detected is not an absolute measure but rather a relative measure influenced by the same conditions that control seagrass growth (Mount, 2003).

Quantifying uncertainties in measurement and classification will guides users and decisions makers in assessing the limitations of the data and their decisions. Estimates of measurement error also provide valuable input in examining the implications of uncertainty in analysis results. If spatial data are to be incorporated into coastal and marine models it is important to examine how measurement and processing errors influence model output.

5.4 APPROACHES FOR EXAMINING AND REPRESENTING MODEL UNCERTAINTY

Uncertainty in coastal and marine data and models is inevitable and useful descriptions of the properties of error are provided in the literature (von Meyer *et al.*, 2000). An important consideration for coastal and marine GIS users is how this uncertainty can be managed. Innovative approaches designed to model and represent underlying data uncertainty have emerged from recent spatial uncertainty literature (Morris, 2003). This section briefly describes three of these approaches and presents examples in which they have been applied to modelling coastal and marine environments. These include error propagation, sensitivity analysis and fuzzy set theory. Error propagation and sensitivity analysis measures the impacts of uncertainty in the input data on the analysis or model results. Fuzzy set theory allows an object's inclusion in a class to be assigned along a continuum, offering a definable approach for dealing with inexact concepts (Cowell and Zeng, 2003; Zadeh, 1965).

Analysis of error propagation allows the way in which uncertainties accumulate and affect the end result of the model to be explored (Burrough and McDonnell, 1998). Errors may continue when the output of one spatial operation (such as map algebra or polygon overlay) is used as the input for a subsequent operation (Heuvelink, 1999). The exactness of quantitative results derived from multiple input data layers in spatial models often makes it difficult for the end user to recognise the effects of data and model error. Although uncertainty in both the input data and the model will influence the value of results, it is also critical to examine the way the data and the model interact (Burrough and McDonnell, 1998). For example, uncertainties in elevation will propagate when bathymetric surfaces compiled at different dates are used to compute estimates of sedimentation rates (Van der Wal and Pye, 2003). If sedimentation is measured as the change in elevation the standard error is the root of the squared error deviations of the two bathymetric surfaces (Van der Wal and Pye, 2003). This has significant

implications for the quantification of morphological change if standard errors exceed finer scale change estimates. In tracking error behaviour throughout the model comparisons can be made between the contribution of data input and model error (Heuvelink, 1999). This allows developers and those implementing the model to assess the appropriateness of the model in relation to the available spatial data. However, an error propagation analysis can only yield plausible results if the errors associated with each model input have realistic values (Heuvelink, 1999).

Sensitivity analysis is the controlled variation of parameter values in isolation and in combination, and the observed response of model output (Conroy *et al.*, 1995; Lodwick *et al.*, 1990). By imposing variations on the input data sets, measurement of effects on the model results can provide an indication of reliability. An example of this in spatial analysis is the alteration of input data resolution. Identification of the variables with the greatest influence on model results is not only critical to model calibration but also provides direction for future research (Hamby, 1994). The effects of an input parameter on model outcome can be divided into two types. Parameters whose uncertainty contributes to the results are referred to as 'important' parameters, and those that have a significant influence on the results are 'sensitive' parameters (Hamby, 1994). Sensitivity analysis has been used to examine levels of uncertainty in marine habitat modeling (Bruce, 1997). Bayesian probability theory was applied to predict dugong distributions in a semi-enclosed coastal embayment in Western Australia (Bruce, 1997). Sensitivity analysis was applied to examine the effect of species mobility on the model results as dugongs may range over an extensive area within a preferred habitat potentially contributing to uncertainty in sighting location. It was demonstrated that the model was sensitive to positional error in species sighting data at positional offsets of greater than 800 metres (Bruce, 1997). Sensitivity analysis examines uncertainty from output back to input, which is the reverse direction to the error propagation approach that provides a quality test for the input data and the model (Crosetto and Tarantola, 2001). However, these approaches assume certainty in the definition of an object or the conceptual model used to represent a phenomenon. Methods are needed to deal with the polythetic (defined by multiple attributes) and inexact nature of many natural geographic phenomena.

An approach that addresses problems associated with vagueness of definition is fuzzy set theory (Fisher, 1999). In classic set or Boolean theory an object is defined as belonging or not belonging to a class or set. This membership status is coded as values of 1 or 0 respectively (Fisher, 2000; Fisher, 1999; Robinson, 2003). In fuzzy set theory, membership is defined by a real number in a range from 0 (nonmember) to 1 (full member) (Bernhardsen, 2002; Cowell and Zeng, 2003; Fisher, 1999). Fuzzy set theory allows an object membership to a varying degree and to more than one set (Robinson, 2003). For example, in representing the presence of seagrass using classic set theory a seagrass patch may be assigned a value of 1 and an area of bare substrate a value of 0. The same patch represented using fuzzy set theory may have a value reflecting its high degree of membership in the class of seagrass (e.g. 0.85) and a low value indicating a small degree of membership in the class of sand (e.g. 0.1). The assignment of the membership function of a fuzzy set is subjective in nature but the process of assignment is not arbitrary (Robinson, 2003). A range of approaches for assigning grades of membership can be adopted when applying fuzzy sets in GIS (Robinson, 2003).

Fuzzy membership is further complicated when representing natural phenomena that change. Cheng (1999) presents a method to identify coastal features and their dynamics using fuzzy spatial extent (regions) extracted at different epochs. Application of fuzzy set theory for predicting coastal geomorphic hazard associated with sea-level induced recession and storm erosion has also been demonstrated for beach environments in SE Australia (Cowell and Zeng, 2003). Although not a complete solution to the problem of vagueness, an important strength of fuzzy set theory is that it allows partial implementation of the vagueness concept (Fisher, 1999; Robinson, 2003).

5.5 COGNITIVE DIMENSIONS OF UNCERTAINTY

Certainty in the spatial representation of reality has been contested in the broader spatial science community since the earlier stages of GIS (Burrough, 1986; Chrisman, 1982; Chrisman, 1984; Goodchild, 1989). Conceptualization of the nature of uncertainty in GIS has been documented (Fisher, 1999) and methods have been developed for the representation and handling of uncertainty (Agumya and Hunter, 2002; Veregin, 1999). In recent GIS literature there has been recognition of a shift in the perception of uncertainty. Rather than focusing on uncertainty as the consequence of empirical failings Couclelis (2003) argues for accepting uncertainty as an intrinsic property of knowledge. The challenge faced by users of coastal and marine GIS is how these insights on uncertainty translate to the decision-making process.

With the increasing flow of spatial data, facilitated through web-based data clearinghouses, Internet mapping and interoperability, there is potential for unchecked dissemination of associated data uncertainty. Attached metadata documents and national and international spatial data quality standards assist in addressing the unsuspected promulgation of errors and inherent bias. However, in order to accommodate uncertainty coastal and marine managers, planners and communities must convert these data qualifiers into guidelines that will form the basis of meaningful decisions. There is a cognitive dimension to the communication of uncertainty that must extend concepts accepted in the realm of GIS to ensure accessibility to the diverse community of end users. For example, inclusion of an uncertainty measure in the output of a coastal hazard risk model will result in risk being mapped along a continuum rather than an absolute (Zerger *et al.*, 2002). In contrast, emergency managers require clear guidelines for identifying and evacuating risk areas (Zerger *et al.*, 2002).

There is often a requirement from end-users of GIS derived coastal and marine information for unambiguous information that can be incorporated directly into decision structures. These user requirements need to be considered in any definition or representation of uncertainty if end-users are expected to recognise and adopt adequate precautionary approaches. Returning to the wetland boundary example presented earlier, depiction of the ‘zone of confusion’ surrounding each wetland boundary, although highlighting uncertainty, does not provide a clear basis for administrative decisions. Legislation relating to the environmental protection of a coastal wetland system may require precise definitions of spatial extent. For example, under the New South Wales Coastal Protection Act in Australia definition of the coastal zone includes all coastal rivers to the upstream

limit of mangrove plants. Although inclusive of a critical estuarine habitat, this definition does not include saltmarsh communities resulting in the occurrence of these habitats outside the jurisdiction of associated coastal management policies. Many approaches for the representation and handling of spatial uncertainty do not translate neatly into legislative frameworks designed to ensure the protection and ecological sustainability of coastal and marine environments.

Ensuring end-user awareness of spatial uncertainty is not restricted to coastal and marine managers, policy makers and other practitioners. There is a growing role for GIS in encouraging community involvement in environmental decision-making. Recent approaches for integrating local expertise and perceptions into a GIS framework have been described as GIS for participation (GIS-P)(Cinderby, 1999; Weiner *et al.*, 2002). An example includes the adoption of participatory GIS to capture local fisheries knowledge from a Newfoundland fishing community on the northeast coast of Canada (Macnab, 2002). These applications further highlight the cognitive aspect of spatial uncertainty. If results are presented without building the capacity of participating groups to understand limitations associated with the analysis and input data, conflict within communities may be exacerbated by the implementation of GIS-P (Cinderby, 1999). There is value in the use of fuzzy representations over distinct map boundaries in these circumstances. Exact boundaries may infer a level of positional precision that could potentially prompt dispute. Successful development of participatory GIS applications in the coastal and marine environment will require approaches that ensure concepts of uncertainty are communicated in an accessible way to the broader community.

Difficulties associated with incorporating uncertainty measures, fuzzy boundaries or relative values may depend on the temporal scale and the legislative framework of the decision-making process. There is greater capacity for longer-term coastal planning strategies to accommodate fuzzy results and translate these to precautionary decisions based on acceptable risk. However, faced with the immediate responsibility to approve or reject a development proposal under the threat of habitat loss a decision maker may require absolute values on which to base and defend, perhaps in court, their decision.

The exactness of legislative statements relating to the protection of coastal and marine environments is not suited to vague or ambiguous representations and often requires the conversion of fuzzy values into Boolean structures, forced classifications and precise boundaries. This need to simplify the world may reflect an underlying familiarity with the traditional cartographic paradigm of discrete entities. Perhaps there is a need to investigate approaches for accommodating flexible definitions in coastal and marine policies and associated legislative frameworks.

5.6 CONCLUSION

Uncertainty in GIS is inevitable; it is how this uncertainty is perceived and handled which is important. Fragmentation of the landscape into manageable spatial data models is required in many applications of coastal and marine GIS. During this process of abstracting reality the loss of detail potentially introduces levels of uncertainty that may have significant consequence in analysis and modeling

results. Compounded by this is the uncertainty that stems from the complexity of coastal and marine systems (Cowell and Zeng, 2003). Techniques exist that allow the quantification, assessment and communication of uncertainty in GIS applications as demonstrated by the range of coastal and marine case studies cited in this chapter. However, if widespread awareness of spatial uncertainty issues is to be achieved amongst the coastal and marine GIS community a greater understanding of users' cognition, perception and incorporation of uncertainty is needed.

CHAPTER SIX

New Directions for Coastal and Marine Monitoring: Web Mapping and Mobile Application Technologies

Sam Ng'ang'a Macharia

6.1 THE VALUE OF COASTAL AND MARINE RESOURCES

Coastal and marine areas are ever increasing in value to the welfare of nations. These areas provide natural, social and economic functions that contribute to increased quality of life. The oceans are instrumental in determining climate that beneficially affects all life on Earth (Payoyo, 1994). Other natural functions include habitat for endangered species, species breeding and resting areas, water treatment, groundwater recharge and flood attenuation. Some social and economic functions include tourism, commercial and recreational fishing, oil and gas development, and construction (Eckert, 1979; Prescott, 1985; Gomes, 1998).

It is clear that coastal and marine areas are of vital importance to human life. Yet human terrestrial and marine activities have proven to have destructive effects on these areas. According to Canada's National Program of Action (CNPA) (2000) the major threats to the health, productivity and bio-diversity of the marine environment result from human activity in the coastal areas and further inland. Approximately 80 percent of marine area contamination results from land-based activities such as municipal, industrial and agricultural waste and run-off, in addition to the deposition of atmospheric contaminants resulting from human industrial activities (CNPA, 2000; Sanger, 1987).

There is a need for a wider dissemination of knowledge relevant to the importance of coastal and marine areas to the world's well-being, and a re-evaluation of societies' attitudes towards these spaces. Good coastal and marine governance (e.g. information dissemination, management, monitoring, etc.) is therefore a key factor in the sustainable use of these environments and will require an integrated, coordinated and equitable approach (Crowe, 2000). If governance is about decision-making and steering, then up-to-date, accurate, complete, usable information (which feeds into the acquisition of knowledge) is indispensable to governance. This is especially critical in the information age of rapid changes, interconnectivity, and globalization that have brought more information to more people making them acutely aware of the unsustainable nature of current social,

economic and political use of marine and coastal spaces (Juillet and Roy, 1999; Rosell, 1999; Miles, 1998).

Where informed decisions have to be made using real-time information there is a need for architecture that quickly disseminates information affecting coastal and marine resources. Accurate, up-to-date, complete and useful spatial information (on many levels) regarding the resources that currently exist, the nature of the environment within which those resources exist, as well as on the users of those resources is always a requirement for effective monitoring of coastal and marine areas. Information on (but not limited to) living and non-living resources, bathymetry, spatial extents (boundaries), shoreline changes, marine contaminants, seabed characteristics, water quality, and property rights all contribute to the sustainable development and good governance of coastal and marine resources (Nichols, Monahan and Sutherland, 2000; Nichols and Monahan, 1999).

6.1.1 Web Mapping and CMM Networks

There are several Coastal and Marine Monitoring (CMM) networks in the world. Most of them are involved in obtaining real-time quantitative indicators that impact on coastal and marine health such as water temperature, water level and meteorological conditions (wind speed and direction, temperature, barometric pressure), together with qualitative indicators such as visual images of the beach and nearshore. Others are involved in collecting quantitative and qualitative indicators of coastal environmental quality. The networks involve government, academic and environmental NGO institutions. They consist of huge repositories containing databases of archival and current material. They vary in scope - from local to regional to national and international networks. Their results are provided in synchronous and asynchronous fashion but increasingly, electronic means of communication are being used to provide information needed by the various interest groups.

The World Wide Web has had a tremendous effect on the way businesses communicate. Large amounts of information can be made available quickly and conveniently to anyone with Internet access and a web browser. The ability to distribute and view spatial information has quickly shifted from a desktop application (fat client) to a browser-based architecture (thin client). This latter architecture is referred to as thin client since the user only needs a web browser to access services and information on the web (Fitzgerald, 2000). With particular reference to spatial information, there has traditionally been the question of accessing the volumes of information, especially if it resides in several different geographical locations. The web lets a data provider make spatial information available to a wider audience. The data provider can therefore provide a virtually centralised repository of resources without having to change the physical location of the data. This prevents any problems that might arise from maintaining or updating duplicate data sources, such as limited space or corrupt data. The web therefore makes it easy to provide the most up to date spatial data (Fitzgerald, 2000).

It is therefore common practice to go to one of several websites dedicated to CMM and download (or interact with) information about a specific geographical location that one is interested in. Whether it is the "Enviromapper for Watersheds" interactive mapping application that provides an index of watershed indicators for US aquatic resources, or the "Scorecard" mapping application, which maps toxic chemicals released from facilities, institutions like the Environmental Protection Agency in the USA are increasingly providing these CMM indicators through their websites (United States, 2003). The US Department of Commerce's National Oceans and Atmospheric Administration (NOAA) and the Canadian Department of Fisheries and Oceans (DFO) provide a variety of information on their websites on oil and chemical spills, tides, marine weather, and fisheries. This information is superimposed on maps to give a geographical context to the information. The superimposition of information on maps – and the provision of such information on the web, together with limited GIS functionality – is what is referred to as web mapping, webGIS or interactive mapping.

6.1.1.1 Web Mapping Technologies

The emergence of web-GIS technologies is providing the catalyst for easier collaboration, integration and cooperation among organizations with a stake in good governance and sustainable development. This is done by providing an environment for data sharing and integration over the Internet, sometimes without organizations having to make any major changes to the structure and formats of the data they maintain. The full range of analytical capabilities available in most contemporary desktop GIS however is not available on the web browser (or WebGIS client) since they are built on the thin-client concept. To include more functionalities at the client end would seem to defeat the concept of the low cost and convenience of utilizing only a web browser to access spatial data.

Traditional mapping issues still pose challenges to web mapping. Some of these new technologies support different data formats (e.g. ESRI shape files, CARIS, MapInfo files etc.), projections, scales, datums, etc., with conversions and visualization being done "on the fly." Certain web-GIS technologies now facilitate the transmission, integration, visualization and analysis of spatial information stored in geographically dispersed locations. A user with permission to access the geographically dispersed data sets need only have access to a web browser in order to view, query, and analyse the data sets. In some instances however, some webGIS can only deal with data residing on one server.

6.1.1.2 A Web Mapping Example - CARIS Spatial Fusion™

Let us briefly describe a web-mapping technology in order to explain the underlying architecture. CARIS Spatial Fusion™ is a "web-mapping" technology that lets users integrate distributed data sources using a web browser. It is an Internet-based technology whose primary function is accessing, visualizing, and analysing heterogeneous, distributed data sources (Fitzgerald, 2000, Webmapper.com, 2000). Spatial Fusion™ combines the speed, convenience and simplicity of the Internet with the ability to read multiple data sources in their native format. Earlier versions of Spatial Fusion™ consisted of a customized Java

client and a number of Fusion Data Services. On the server side, Spatial Fusion™ was made up of the following components (CARIS, 1999, Fitzgerald, 2000):

- A Web Server: One must already be running on the network.
- The Orbix™ Runtime needs to be installed on every machine that hosts a Fusion Data Service. The Orbix™ Runtime lets the Spatial Fusion™ applet and the Data Services communicate across the Internet.
- Catalog Service: This service lists all of the available Fusion Data Services.
- Fusion Data Services: These services must be registered with the OrbixWeb™ Implementation Repository. Each service has an accompanying configuration file that contains the name used to register the service with the daemon and the location of the data source.
- Configuration Utilities: CARIS MapSmith™ and CARIS dbMaps™ are provided to help customize the display of CARIS, Oracle 8i Spatial, or Shapefile data.

Recent changes in Spatial Fusion™ Version 3.0 have removed the Orbix runtime component and replaced it with TAO ORB - an open source implementation of an Object Resource Broker using Common Object Request Broker Architecture (CORBA). In Spatial Fusion™, the Object Request Broker (ORB) is the broker for information from the java servlets to various data services. The servlet container is Tomcat developed by the Apache Software foundation to manage and invoke servlets when requested. The normal setup is to have a web server such as Microsoft Internet Information Services (IIS) conFigured to connect to Tomcat. When an action is performed, the Spatial Fusion™ applet sends a request to a servlet, which is handled by the Jakarta Tomcat Servlet container. The request is then sent by the servlet to the data services through the ORB (CARIS, 2003).

As far as the user is concerned, they simply download the Spatial Fusion™ applet from a web server. At that point, a user can easily open data from any fusion service they have access to, providing them with a secure and fully scalable environment (CARIS, 1999, Webmapper.com, 2000). In addition, CARIS Spatial Fusion Developer™ lets users customize the client, so that specialized applets can be rapidly built in a drag and drop environment, giving the ability to tailor applets for specific users (Fitzgerald, 2000).

Thin client web mapping applications such as Spatial Fusion™ have traditionally depended on “wired” infrastructure because large amounts of spatial information have to be sent from the server to the client. The need to have information provided on mobile devices such as PDAs and cell phones is however driving information dissemination towards a wireless infrastructure. But would there be a need for wireless access to CMM networks? Is the general public ready to embrace this technology? In the following section we address these questions.

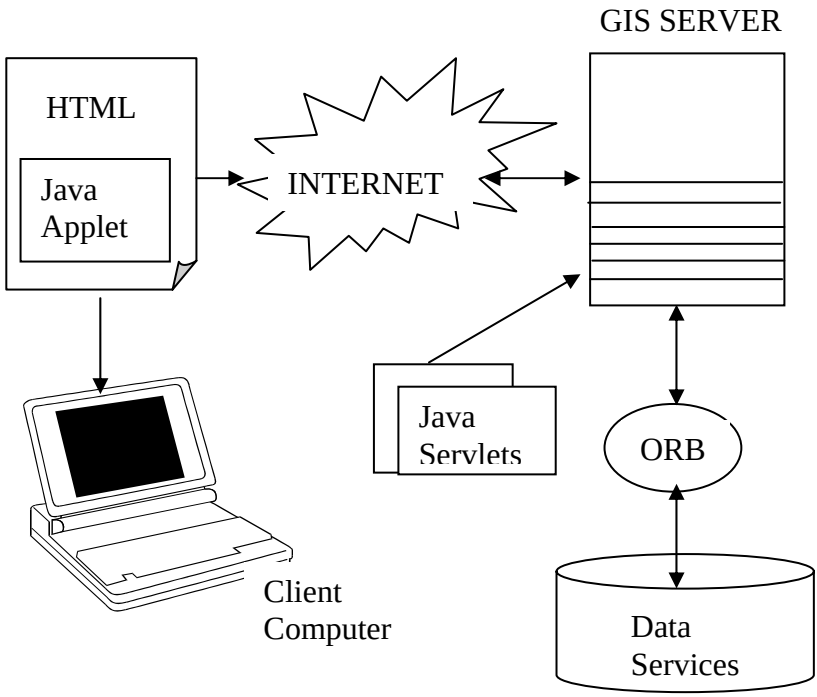

Figure 6.1 CARIS Spatial Fusion Architecture (from the CARIS Spatial Fusion Administrators Guide)

6.2 RE-ENGINEERING MARINE MONITORING NETWORKS

There exists in every jurisdiction a public policy issue associated with information collection (McLaughlin, 1991). This issue is related to the notion of providing ready and efficient access to information about resources, and rights associated with them, to all members of the community. The public is defining itself as an individual property owner – the property being the marine commons and its resources – and is realigning itself to be a primary decision maker. Most people are therefore interested in how resources are being utilized and whether resource use is being policed effectively.

Coastal and marine monitoring networks fulfill the role of providing information effectively. But they are also builders of communities of interest i.e. a forum where participants are able to interact on a specific topic. These online communities are valuable as they are increasingly providing forums for like minded individuals to participate in the decision-making process. With more citizens being involved in advocacy efforts and words like “stewardship of

resources" increasingly being used to rally the general public into participation in the decision-making process, provision of information about the space that citizens inhabit is becoming critical.

Sociologists have traditionally viewed this kind of participation as social capital – a relationship that can blur social inequality and enhance transactions that lead to capital accumulation and social growth. We are seeing the public being involved in a culture of participation, through these networks, although this is concentrated on citizen access to information. What is needed is the enhancement of citizen participation, to citizen-based leadership: where the citizens pro-actively seek information (and are able to receive it as it happens) rather than react to information that they come across. This is where wireless access to information becomes important.

6.2.1 Wireless Access to Information

Developments in Internet-enabled spatial data integration and analysis tools are now allowing decision-makers the opportunity to have access in real-time (or near real-time) to spatial information. The public is becoming more technologically "savvy" and is using newly available devices to access various kinds of information. What one finds online is also now available on mobile devices – and with evolving wireless technology we are seeing web-enabled mobile devices being used to integrate and retrieve geographic data as it is collected. Additionally, it makes sense for companies to focus on wireless Internet services given projections for future growth: the Yankee Group predicts that there will be more than one billion mobile devices worldwide by 2003. Some estimate that half of those will be web-enabled (Obeid, 2000).

This is not a new trend. Increasingly, we now have various types of information being sent to us via our mobile devices – allowing us to remain informed about various topics that we are interested in. Take the example of access to information about entertainment or restaurant locations, based on one's geographical location, delivered to a mobile phone. This represents a relatively new trend referred to as Location Based Services (LBS).

6.2.2 Location Based Services – The Driving Force

When this paper was written in 2001, the author had been following the evolution of killer applications in mobile mapping technologies – location based services (LBS). In addition to maps and directions, LBS allows customers to locate branches, service centres, stores or any points of interest near their home. A business can use LBS to locate its customers, manage its supply chain, and to implement its business rules. In fact, recently Microsoft has joined with AT&T Wireless to provide location-based services (Francica, 2002). LBS are now the driving force in wireless mapping applications.

In the coming years, Location Based Services (LBS) are expected to play a defining role in driving not only the mobile Internet but also mobile commerce as well. Location based services find the geographical location of a mobile device

and provide services based on that location. LBS applications automatically identify subscribers' locations from the wireless networks and combine this with other information to obtain maps and driving directions, perform proximity searches and find places and points of interest. Although there has been a slow rollout of LBS, Konish (2002) indicates that the slow economy is forcing wireless carriers to look for revenue-bearing services. Inevitably these are being found in making wireless devices location aware and providing location based services. Many LBS applications are already available especially in the field of asset tracking and fleet management (Sweeney, 2002). Other applications include automatic vehicle location and tracking, sale and marketing automation, consumer travel services, wireless call centre tracking, and location-based billing.

6.2.3 Providing Web Mapping to Mobile Devices

LBS can be provided in several different ways – from simple text messages providing a list of options e.g. restaurant names and locations – to a full webcentric interaction with the LBS service – involving GPS locations superimposed over interactive maps. This latter option is accomplished by using a dedicated protocol, the Wireless Application Protocol (WAP), which enables a mobile device to behave like a micro browser (Buckingham, 2000; Mobile Applications Initiative, 2001; Mobile Lifestreams Ltd, 2000). The Wireless Application Protocol (WAP) is an open, global specification that empowers users of wireless devices to easily access and interact with information and services themselves (Buckingham, 2000, Mobile Applications Initiative, 2001). This information is available through a data portal that allows the user to access services in a manner similar to that found on the Internet. The protocol however has certain limitations to it – for example, it only allows the use of sequential menus for users to browse for information. However, WAP is continually evolving to encompass greater functionality (Buckingham, 2000).

The Wireless Application Protocol incorporates a relatively simple micro-browser into the mobile phone. As such, WAP's requirement for only limited resources on the mobile phone makes it suitable for thin clients and early smart phones. WAP is designed to add value-added services by putting the intelligence in the WAP servers whilst adding just a micro-browser to the mobile phones themselves. Microbrowser-based services and applications reside temporarily on servers, not permanently in phones. The Wireless Application Protocol is designed for use with anyone's standard such as Code Division Multiple Access (CDMA), Global System for Mobiles (GSM), or Universal Mobile Telephone System (UMTS) and is aimed at turning a mass-market mobile phone into a "network-based smart phone" (Buckingham, 2000; Mobile Applications Initiative, 2001).

Wireless terminals incorporate a Handheld Device Markup Language (HDML) microbrowser that uses the Handheld Device Transport Protocol (HDTP). HDML is a version of the standard HyperText Markup Language (HTML) Internet protocol that is specifically designed for effective and cost-effective information transfer across mobile networks themselves. This protocol is used to link a mobile device terminal to a server that is connected to the Internet (or Intranet) where the information resides. The content at the site is tagged with

HDML tags that can be easily read and converted by the microbrowser in the handheld device themselves (Buckingham, 2000; Mobile Applications Initiative, 2001).

A user with a WAP-compliant phone uses the in-built micro-browser to make a request for information or service. This request is passed to a WAP Gateway that then retrieves the information from an Internet server either in standard HTML format or preferably directly prepared for wireless terminals using Wireless Markup Language (WML) themselves. In this paper, WML and HDML are used interchangeably. If the content being retrieved is in HTML format, a filter in the Wireless Application Protocol Server may try to translate it into WML. The requested information is then sent from the WAP Gateway to the WAP client, using whatever mobile network bearer service is available (Buckingham, 2000; Mobile Applications Initiative, 2001; Mobile Lifestreams Ltd, 2000).

6.2.4 Extending the Trend to CMM Networks

N'gang'a *et al*. (2001) provided a possible scenario that utilized the technological components mentioned in the preceding sections of this article. A summary of the scenario that had previously been proposed is as follows:

1. A marine event involving coastal or marine environments occurs. This event could be a oil-carrying tanker being involved in an accident, or as diverse as enforcement against banned activities or the enhancement of safety of navigation;
2. The event is detected by remote sensing means or by visual observation. These event sources are important as they establish how the event will enter into the marine event information circle. The marine event information circle is a term that has been coined by the author to represent the flow of information from the event source to the interested group;
3. If the event is detected by visual observation, the observer has the option of using a VHF radio to communicate with someone who has access to a web-mapping server (e.g. a Spatial Fusion™ data server). Alternatively, the user can use other means of event dissemination such as the mobile phone and Internet connectivity. The term "event content" refers to the information that is recorded regarding the event. In this work, this information is the location and the nature of the event;
4. The event is then registered with the event server, which in this case is analogous to a Spatial Fusion™ Data server. In particular, the data needs to be conFigured so that it can be accessed using the fusion services. An event coordinator (or moderator) must exist in the marine environment information circle to serve this purpose;
5. Transmission of information updated with the marine event is then accomplished using electronic means. An email list of a registered interest group can be used to contact the users of the marine environment information circle, or the information can be relayed to a website that the general user can access. Alternatively if there is a WAP server, the information can be relayed (with additional functionality) to members of

the registered interest group who are within geographic proximity of the event. These options allow the event server to provide alternative value-added services.

6. Information dissemination is accomplished using the wireless application protocol and existing GSM networks. In the near future GSM combined with GPRS or the third generation UMTS networks can be used for broadband access to marine events.

Once the information is served up to a user group, decisions can be made regarding implications of the marine event on existing policies, activities, or populations within (or adjacent to) the marine environment. Informed decisions are therefore made with available information about the nature and location of marine events.

6.2.5 What about Bandwidth Issues?

Spatial data involves the transmission of geometric as well as attribute information. It can therefore be argued that a substantial amount of data must be transmitted which implies that a large bandwidth must be available. There is a general consensus in the wireless industry (see Salvo, 2000; Mobile Lifestreams, 2000; Villalobos, 2000) that in the near future bandwidth will no longer be a problem especially when the third generation of mobile phone network becomes available.

We now are connected using the Global System for Mobiles (GSM) wireless network that provides data rates of 9.6 Kbytes/s. An ancillary service on the GSM network is the General Packet Radio Service (GPRS), which provides compression technology that improves data transmission rates to 100 Kbytes/s (Mobile Lifestreams, 2000; Villalobos, 2000). In the near future, the Universal Mobile Telephone System (UMTS) will provide 2 Mbytes/s (Villalobos, 2000). This will definitely change the way we use both wireless and Internet technologies.

Third-generation wireless communication (3G) such as UMTS will definitely play an important role in web based spatial visualisation in the near future. It is forecast that the mobile phone will become a portable terminal where the Internet, video and audio will be supported in a multimedia environment (Pinto, 2001). Therefore, it is expected that the WAP will adapt to the potential offered by this technology. There have been arguments that the WAP protocol is not a protocol for the future[1] due to its graphical limitations and access speed (see Salvo, 2000; Mobile Lifestreams, 2000; Villalobos, 2000); however, the protocol is still evolving and advances in technology and application are expected to eventually address these concerns.

The solution simply requires data connectivity from devices. The amount of data passed over the wireless network for the LBS applications is quite small and doesn't require the higher bandwidth allowed by 2.5G and 3G networks.

---

[1] Note that a competitor to WAP is the imode format, which uses compact HTML (cHTML) as opposed to WAP and is in use in Japan (Archey, 2002; Eurotechnology.com, 2003)

6.2.6 Some Examples

While there are several web mapping software that exist, only recently has the provision of web mapping services begun to move to mainstream mobile devices. Some of these products include (Geoplace.com, 2003;Webmapper.com, 2003)

- AutoDesk's MapGuide and Onsite – Onsite enables viewing of digital design data on Microsoft Windows CE-based handheld computing device.

- ESRI's ArcIMS and ArcPad – ArcPad provides database access, mapping, GIS, and global positioning system (GPS) integration to users out in the field via handheld and mobile devices.

- MapInfo's MapExtend and MapExtreme - *MapInfo*® *MapXtend*® is a developer tool for creating location-based applications running on wireless handheld devices.

- Microsoft Map Point Webservice – The MapPoint Web Service is the Microsoft® platform for location-based services (LBS) and can be used by mobile applications.

In Canada there are several researchers already working successfully on the kind of approach outlined in this paper. Canadian researchers Nickerson et al. (2003) have already provided a general-purpose architecture for real-time web access to mobile geospatial operations. The research demonstrated that their three-tier architecture, using Wireless Application protocol (WAP), along with eXtensible Markup Language (XML) tags embedded in a Uniform Resource Locator request, provided a sound basis for decision support of real time geospatial operations. Real time field activities were viewed by web users globally as well as stored in (and retrieved from) an online central server and database.

In Ng'ang'a et al., (2000) the authors had drawn attention to some advances in web mapping location-based services such as the automatic vehicle locator (AVL) application used at the city of Fredericton Police department[2]. This was part of the Wireless Public Safety Decision Support System (WPSDSS) for the city of Fredericton (Lunn, 2001). The application uses a cellular digital packet data wireless data network to transmit information about the location and status of police vehicles. The information is overlaid onto the City's GIS mapping layers and orthophoto imagery. While the application does not display information on mobile devices (like cell phones or PDAs), it is just a matter of time before it does.

On the CMM front in Canada, Fisheries and Oceans Canada, Environment Canada, the Defence Department, Transport Canada and the Canadian Space Agency are already collaborating on a program called Integrated Satellite Targeting of Polluters (I-STOP), to use a satellite operated by Radarsat International to identify ocean slicks (Calgary Herald, 2002; CCMC, 2002).

[2] Located in the province of New Brunswick, Canada

Canada's Radarsat satellite will be used to provide all weather, day/night images of the Earth's surface and give officials an indication of suspicious activity in a vast area that couldn't easily be covered by any other means, such as aircraft. The technology is only being used on the East Coast for now. If it proves successful, it could also be used on the Pacific coast. The Calgary Herald (2002) reported that the first hit came nine days into the project when the satellite spotted a spill off Newfoundland's south coast, near one of the province's most valued marine bird reserves. A plane was sent to the area off Cape St. Mary's and the ship was ordered back to port, where its operators now face charges under the Migratory Birds Act for allegedly creating a 116-kilometre-long, 200-metre-wide slick. While WAP technology is not being used in this program, one can see that soon enough there will be a situation where individuals interested in coastal and marine monitoring will have information delivered about this fragile ecosystems health to their mobile devices.

6.3 SUMMARY

This paper has begun by discussing the importance of information to coastal and marine governance and then expanded the discussion by outlining existing technologies that can be used to facilitate enhanced decision-making. In particular, the paper has followed developments in wireless application protocol (WAP), and associated technologies, and indicated how this trend can be adopted to disseminate marine information. This paper has then outlined an original scenario that the author had hypothesized, given the technology trend that was being observed in 2001 - and has concluded by giving real world examples of similar scenarios currently in effect.

This paper is not intended to provide an in-depth technological review of the wireless application protocol (WAP) or of advances in mobile applications. It is intended to provide an overview of trends in wireless technology and how they can be used to address the very real issue of disseminating information using commonly available devices to the interested public.

CHAPTER SEVEN

Exploring the Optimum Spatial Resolution for Satellite Imagery: A Coastal Area Case Study

Chul-sue Hwang and Cha Yong Ku

7.1 INTRODUCTION

Researchers in geography are much interested in issues of scale and resolution, and the strong influence these may have on the results of analyses of spatial patterns (Harvey, 1968; Stone, 1972; Goodchild and Quattrochi, 1997). Issues of scale usually arise from not knowing the optimal unit size for a study area; while MAUP (the Modifiable Area Unit Problem), one of the fundamental research problems in geographical information science, can also be considered to be related to the understanding of the scale for spatial data (Openshaw, 1984; Fotheringham and Wong, 1991).

GIS and remote sensing have shown active interests in both the operational scale and measurement scale of data. Technological developments in GIS and remote sensing have led to the gradual detailing and elaboration of the measurement scale. In the field of remote sensing, for example, the 78m resolution Multi-Spectral Scanner (MSS) data of the 1970s has given way to 30m Thematic Mapper (TM) data in the 1980s, SPOT in the 1990s, and 1m IKONOS imagery in the 21st century. Such improvements in the measurement scale will allow for the new understanding of geographical phenomena that could not be measured at the previous scales.

Changes of the ground resolution of satellite imagery have modified the inherent characteristics of imagery due to the "scale effect" (Goodchild and Quattrochi, 1997). Therefore, researchers have to select the image with the optimum resolution among the satellite imagery at diverse resolutions, at which a specific geographical phenomenon can be understood more effectively. In order to explore the optimum resolution, the objective procedures or indices must be designed for the image characteristics at different resolutions. They should be able to represent the changes in image characteristics that occur at different resolutions.

The aim of the present study is to propose a procedure for identifying the optimum resolution for the study of coastal wetlands. These wetlands, as the point where the ecosystem of the land meets the ecosystem of the ocean, have unique

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

and diverse topographical features, giving rise to the formation of vegetation colonies, and exhibits diverse spatial distribution due to diverse environmental factors. Due to the dense vegetation and unstable topography of the coastal wetland, it is more effective to use satellite imagery to understand its characteristics, rather than through field investigation (Lyon and McCarthy, 1995). However, it is not necessarily effective to use the satellite imagery of higher ground resolution in the coastal area. For example, in the case of the salt marsh where colonies appear as clusters, the use of low-resolution imagery of the approximate size of the clusters is more effective (McNairn *et al.*, 1993).

In this vein, this study will attempt to find procedures and techniques for the optimal spatial resolution of satellite imagery in the study of coastal wetlands. To achieve this goal, it firstly selected the indices considering the following conditions: (1) the sensitivity of the indices, which change in response to the different resolutions, should be high enough to respond accurately to the changes in image characteristics; (2) the indices should be the ones that can provide the approximate estimate of the final result only with the minimal procedure; (3) the indices should reflect the classification accuracy of the attribute information. We then coarsened the resolution of the satellite data, to produce images at various resolutions, and observed the changes in the textural and attribute information characteristics of these images at various resolutions. As a result, the study was able to decide the operational scale, an optimum resolution in the use of satellite imagery.

7.2 SATELLITE IMAGERY CHARACTERISTICS BY RESOLUTION

7.2.1 Textural Characteristics of Satellite Imagery

The local variance method is frequently used in the search for the optimum resolution. Proposed by Woodcock and Strahler (1987), the local variance method measures the variance by placing a 3 x 3 moving window over the image data, to capture the textural characteristics of the image. However, local variance is limited by the fact that it relies on the overall variance of the image. In other words, the local variance measurements of one image cannot be compared to the results for another image. In addition, using this index makes it impossible to understand the spatial distribution of the variance within the image.

Cao (1992), in an attempt to calculate the fractal dimension of satellite imagery, compared and analysed the Isarithm method (Goodchild, 1980), the Variogram method (Mark and Aronson, 1984) and the Triangular prism method (Clarke, 1986). From the analysis, he found the Isarithm method most useful. In general, the fractal dimension *D* of satellite imagery appears as a real number between the 2D and 3D. As the complexity of the image's spatial structure increases, the value of the fractal dimension also gets higher. Within this principle, obtaining the fractal dimension gives a numerical representation of the satellite imagery characteristics by resolution.

In order to understand how the distribution characteristics of images change during the coarsening of resolution, the images of variances as well as the images of averages are needed. It is similar logic that we use the variance to make up the weak points in using the arithmetic mean (or average) to represent a data set. The variance of an image set provides a measure of the average squared deviation of a set of values around the mean. While the images of averages represent the image as one pixel, taking the arithmetic mean of the original pixels, the images of variances represent the dispersion characteristics or the variability of the original image during the coarsening of the resolution (Figure 7.1). During the resolution coarsening, if the heterogeneity between the pixels is large, the variance of the generated image will be large. Conversely, if the pixels are of similar value, the variance of the generated image will be small. Low variances are recorded for smooth and wide regions during the resolution coarsening, and high variances are recorded for narrow and complex regions.

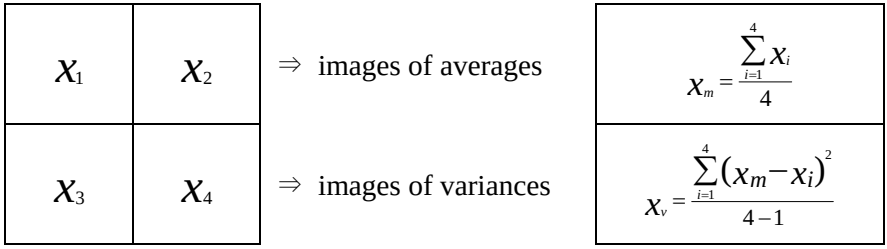

Figure 7.1. Calculating images of averages and images of variances.

Understanding the spatial distribution pattern of the images of variances derived from the process of the resolution transformation leads to the analysis of changes in image characteristics by resolutions. Therefore, the analysis of the spatial distribution of the images of variances can be used to understand the image transformation that follows the resolution coarsening. The spatial autocorrelation of the images of variances is selected to measure the spatial distribution in which the image characteristics transform. The spatial autocorrelation using Moran's *I* is generally appropriate to measure the distribution pattern for data with a continuous variable such as satellite imagery.

7.2.2 Measuring the Spectral Separability of the Training Set

Divergence is a common measurement to estimate the statistical separability of satellite imagery. Divergence is measured using the average of the statistics by class and the covariance matrix gathered through the supervised classification of the training set. However, since divergence has a tendency to increase abruptly as the distance between the classes increases, it is difficult to generalise divergence (Jensen, 1996).

The Jeffreys-Matusita distance (Matusita, 1966) is a value calculated by the exponential transformation of the Bhattacharyya distance that has been modified from divergence (Kailath, 1967; Wacker, 1971). This J-M distance is more widely

used than divergence for calculating the spectral separability of multi-variate classified classes because the J-M distance does not exhibit the abrupt increase in the spectral separability. However, complex calculations and a long processing time are some of the disadvantages of the J-M distance.

Mahalanobis distance (Mahalanobis, 1936) is a value that takes into account both the correlation and distribution features between the data in terms of Euclidean distances. Mahalanobis distance multiplies the Euclidean distance by the covariance matrix between classes. In contrast to the J-M distance, Mahalanobis distance requires simpler calculations and less processing time. In addition, it does not exhibit the abrupt increases in the spectral separability. For these reasons, Mahalanobis distance is the most widely used method for measuring the spectral separability.

7.3 PROCEDURE FOR EXPLORING THE OPTIMUM SPATIAL RESOLUTION

The optimum spatial resolution using satellite imagery is the one that provides good representation of the attribute information, and is referred to as the 'operational scale.' In order to select the image with the optimum resolution from satellite images at different resolutions, the objective procedures or indices must be designed for the image characteristics at different resolutions.

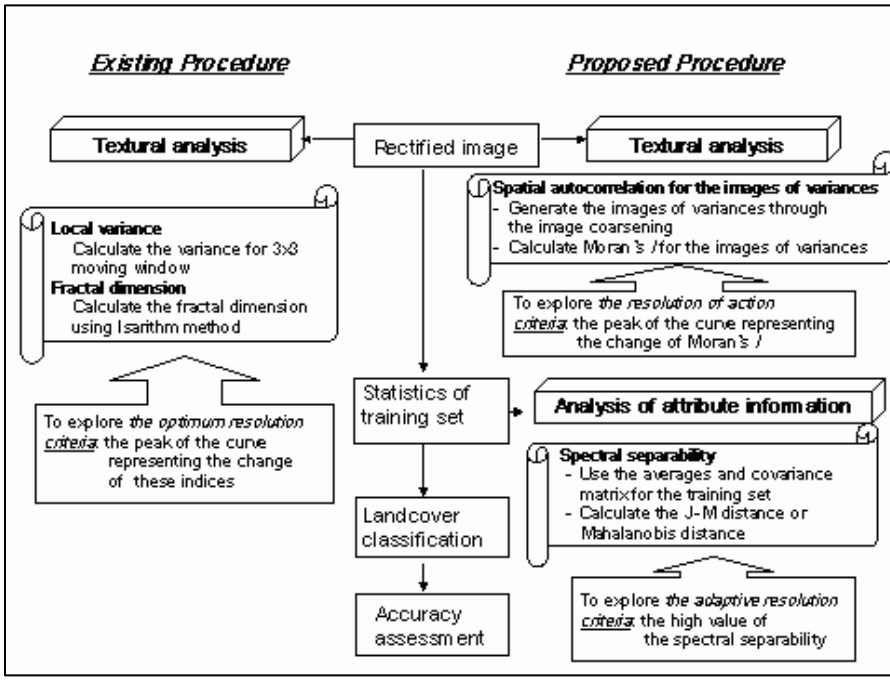

Figure 7.2 The proposed procedure to explore the optimum spatial resolution of satellite imagery.

However, it is unreasonable to rely on a single index to select the optimum spatial resolution. Indices have their own specific objectives to understand the characteristics of the imagery. Therefore, this study will attempt to combine the various indices and present a procedure for exploring the optimum spatial resolution (Figure 7.2).

Until now, existing studies on selecting the optimum resolution have focused only on the textural changes of the images at different resolutions. Local variance and fractal methods are particularly mentioned in such studies. However, because they only reflect the result without illustrating processing procedure of attribute information obtained from the images, they should not be used to understand the changes in attribute information.

This study will attempt to approach the exploration of the optimum resolution using satellite imagery using a two-step procedure. First, through the measurement of the image's textural characteristics, the resolution of action will be selected, and then, through the estimation of the spectral separability, the adaptive resolution for the attribute information will be chosen.

7.3.1 Textural Characteristics: Searching for the Resolution of Action

If the resolution of the original image is gradually scaled down to produce images at low resolutions, the image achieves a structure much like that of a pyramid. This method of the scale transformation is called the pyramid model (Figure 7.3). When producing an image at a low resolution, producing both images of averages and images of variances at the same time is more effective for the analysis of the satellite imagery. The images of variances are the ones that reflect the differences between the original images and the coarsened images during the resolution coarsening.

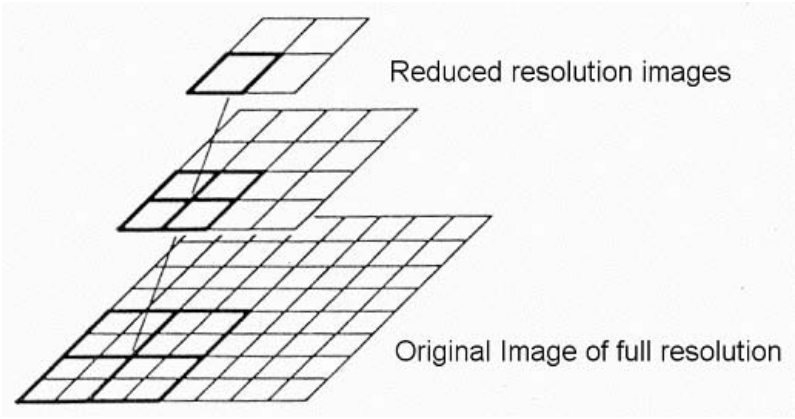

Figure 7.3 Construction of an image pyramid (source: Richards, 1993, p. 33).

- *Step 1*: Moran's *I* is calculated based on the images of variances. It can be said that the higher the Moran's *I* value, the higher the spatial autocorrelation will be and the spatial distribution pattern will then

concentrate. The concentrated spatial distribution pattern for the images of variances means that there is a large transformation in some regions following the resolution coarsening.

- *Step 2*: Graph the Moran's *I* values measured at each resolution.
- *Step 3*: Find out the changes in the Moran's *I* value to select the resolution of action. The resolution at the apex of the curve on the graph is the one at which the image information changes. In other words, the image information changes with respect to this resolution (i.e. the resolution at which the satellite image characteristics are changing) and lowers the classification accuracy.

7.3.2 Attribute Information: Searching for the Adaptive Resolution

In searching for the optimum spatial resolution to acquire the proper attribute information, it is effective to apply the measurement of the spectral separability of the training set (Markham and Townshend, 1981). The J-M distance and Mahalanobis distance are the indices that give precise representations of the spectral separability. The resolution where the J-M and Mahalanobis distances are high and the accuracy of the image classification is also high is the one that can best acquire the attribute information of the image. It can be called the *adaptive resolution*.

- *Step 1*: Select the training set in the satellite image.
- *Step 2*: Obtain the statistical calculations (average, standard deviation, minimum and maximum value, covariance between bands, etc.) for the image training set at each resolution and save them as a signature file.
- *Step 3*: Measure the spectral separability, J-M distance and Mahalanobis distance from the signature file.
- *Step 4*: Graph the J-M distance and Mahalanobis distance measured at each resolution.
- *Step 5*: Find out the changes in the J-M distance and Mahalanobis distance to select the resolution that best represents the image's attribute information. The point on the graph at which the indices abruptly increase is the resolution that best represents the image's attribute information. In particular, of the resolutions that are lower than the resolution of action, the resolution at which the spectral separability increases is determined to be the one where the classification accuracy increases. In other words, this resolution can be selected as the adaptive resolution (or the optimum resolution) that best represents the attribute information of the satellite image.

7.4 APPLICATION AND EVALUATION OF THE PROPOSED PROCEDURE

7.4.1 A Case Study Area and Data

The two-stage procedure to explore the optimum spatial resolution proposed in this study was tested by its application to Landsat TM imagery, that covers Suncheon Bay, a typical coastal area in a southern part of Korea (Figure 7.4). Suncheon Bay area has various land cover types such as coastal wetland (i.e., salt marshes, tidal flats, waterways, etc.), urban areas, agricultural areas, and forest.

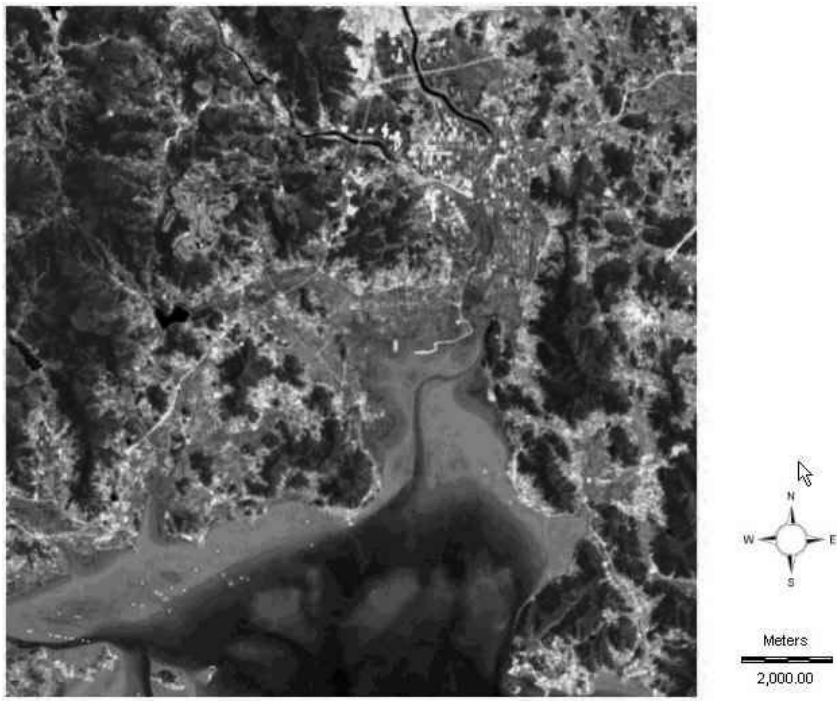

Figure 7.4 Landsat TM image of Suncheon Bay (original in colour).

7.4.2 Applying the Steps Proposed

7.4.2.1 Image Coarsening

To coarsen the resolution, the averages and variances of the adjacent pixels were calculated and then these values were used to produce the images of averages and variances. The images of variances were used to measure textural characteristics through the spatial autocorrelation analysis, and the images of averages were used to measure spectral separability. In this study, the 30m image was coarsened in 30m intervals up to a resolution of 480m, for the production of a total of 16 images (Figure 7.5).

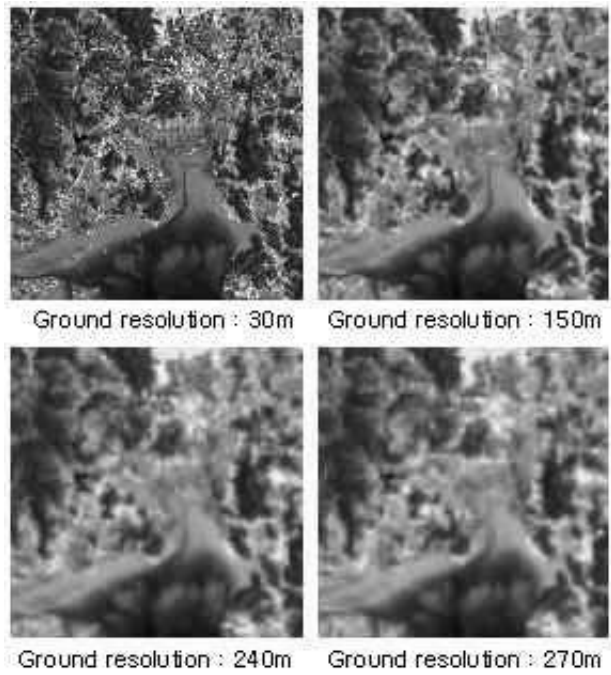

Figure 7.5 Images coarsened into various resolutions.

7.4.2.2 Step 1: Measuring the Textural Characteristics

By measuring the spatial autocorrelation of the images of variances, the following characteristics were discovered (Figure 7.6). In most bands, the Moran's *I* value gradually decreases to a resolution of 120m and then starts to increase at a resolution of 150m. However, this value then begins to decrease again at a resolution of 180m. In other words, the spatial autocorrelation rises abruptly at a resolution of 150m and then falls at later resolutions. Similar phenomena can be seen at resolutions of 300m and 390m. The increase in the Moran's *I* value means

that the spatial distribution of the variance is clustered at a certain region. It indicates that there is a large fluctuation in the specific region during the resolution transformation process. As follows, the point at which the Moran's *I* value increases and then decreases can be understood to be the resolution at which the variance drift is changing. In other words, the resolutions of 150m, 300m and 390m are the points at which a change is occurring in the spatial distribution pattern of the images of variances.

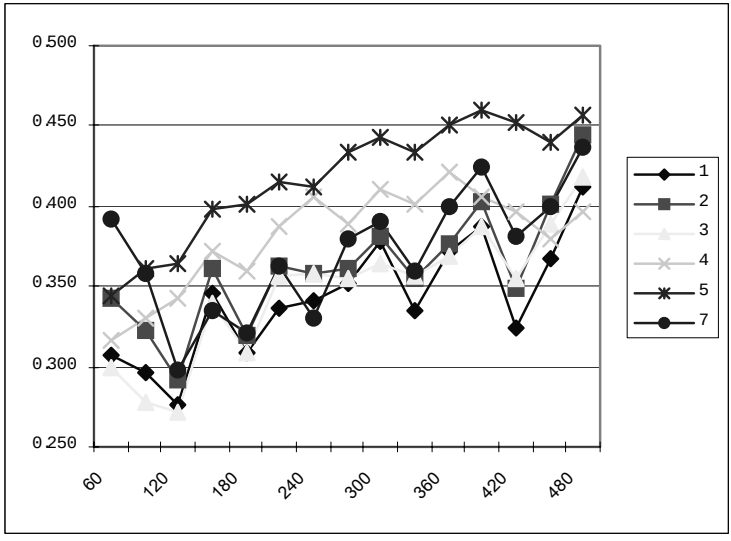

Figure 7.6 The changes of spatial autocorrelation by 7 bands.

In the case of the image of Suncheon Bay area, it can be said that a significant spatial change has occurred in the image as the resolutions changed from 120m to 150m and from 270m to 300m. Therefore, the resolutions of 150m and 300m are the points at which the image's textural characteristics change and can be interpreted as being the resolutions of action. Why does this happen? It is because there exists salt marsh in the study area that has a maximum breadth of 120m with its cluster having the maximum breadth of 280m. Although the image up to a resolution of 120m, which is the maximum size of the salt marsh, can reveal the features of the study area, it is difficult to portray the changes in image characteristics at lower resolutions. At a lower resolution, the salt marsh is portrayed as a cluster, but at a resolution of 300m, which is larger than the size of the cluster, the characteristics can no longer be displayed. It can be said that the characteristics of this study area are reflected in the spatial autocorrelation changes of the images of variances.

7.4.2.3 Step 2: Measuring the Spectral Separability

The land covering types of Suncheon Bay were classified into 6 groups. They were water body, tidal flat, forest, agricultural area, salt marsh and urban area. In addition, two training areas were selected from each land cover type. The information about training sets was saved into the vector formatted file allowing for the same application of the resolution image. The basic statistical information of the training set and the covariance between bands was calculated by every image at resolutions. Based on it, the J-M distance and Mahalanobis distance were measured.

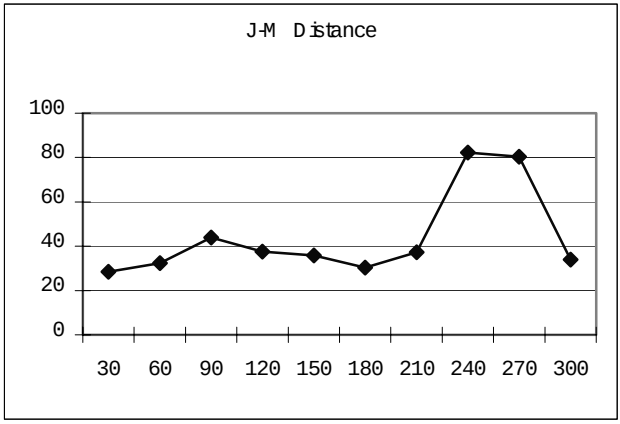

Figure 7.7 The changes of the J-M distance at various resolutions**.**

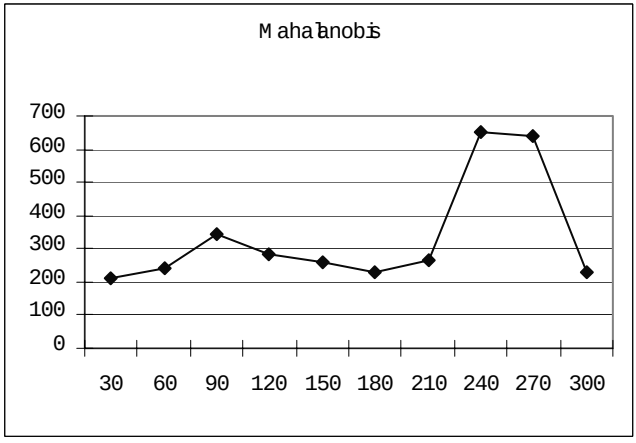

Figure 7.8 The changes of Mahalanobis distance at various resolutions.

Figures 7.7 and 7.8 show the changes in the J-M distance and Mahalanobis distance at each resolution, respectively. It is found that the spectral separability does not change up until a resolution of 150m, which was determined to be the resolution of action in the previous step, but that changes in spectral separability become evident at lower resolutions. In particular, the spectral separability increases at the resolutions of 240m and 270m. At these resolutions, the attribute information is clearly classified making these resolutions the adaptive resolutions (or the optimum resolutions) for representing the attribute changes of the study image.

7.4.3 Evaluation of the Procedure Proposed

7.4.3.1 Comparing Classification Accuracies of Images at Different Resolutions

In order to determine if the resolution of action and the adaptive resolution accurately reflected the image characteristics, the image of the study area was classified by land cover types and the classification results were then evaluated (Figure 7.9).

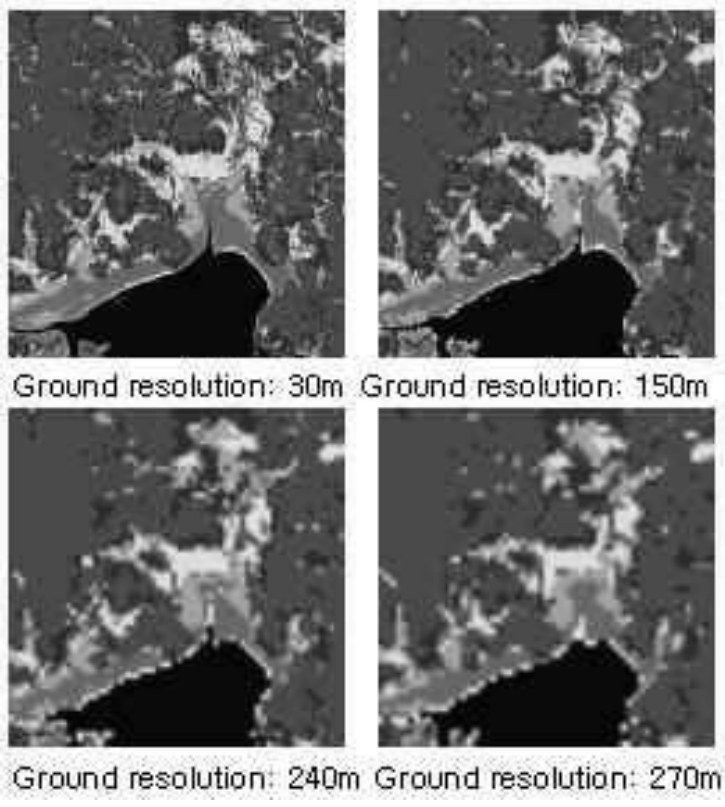

Figure 7.9 The land cover classification at various resolutions.

For the purposes of classification accuracy analysis, the topographic map, forest map and aerial photos of Suncheon Bay area were used to prepare a reference map in Arc/Info vector coverage format, which can be converted into raster data with various resolutions. The reference map had 4 classes, which were water body, tidal flat, agricultural area and forest. In order to measure the image classification accuracy by resolutions, a variety of resolution images were compared to the raster reference data for each resolution. An overlay analysis was conducted on the images at each resolution and the overall accuracies and Kappa Indices were calculated (Figures 7.10 and 7.11).

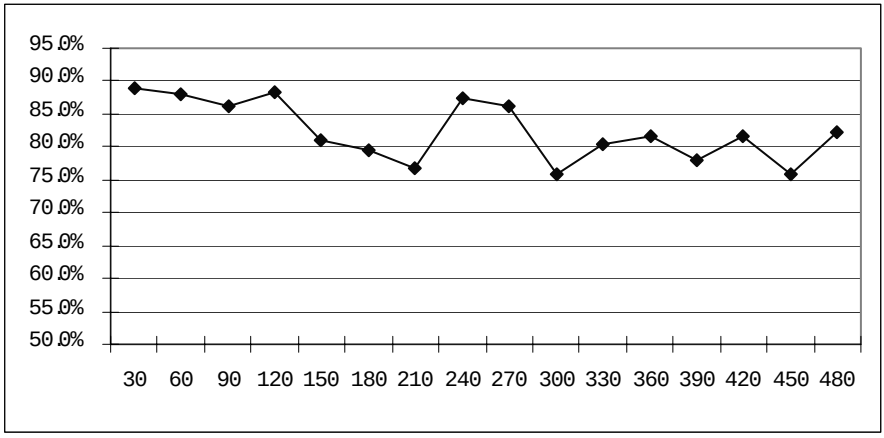

Figure 7.10 Changes of accuracy by spatial resolution.

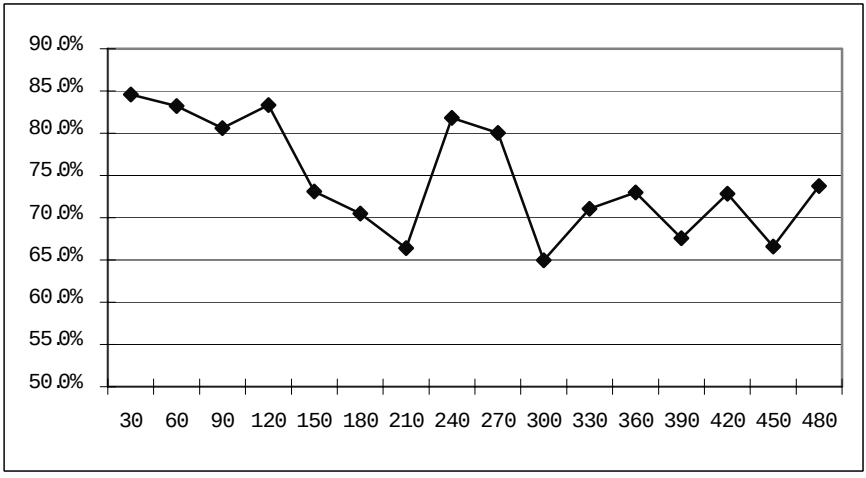

Figure 7.11 Changes of Kappa index by spatial resolution.

The changes of image classification accuracy by resolution were compared to the image characteristics revealed by the procedure for exploring the optimum resolution. The following results were discovered. First of all, there are sharp drops in accuracy at the resolutions of 150m and 300m. These resolutions could be the resolutions of action. They were obtained from the measurement of the spatial autocorrelation of the images of variances (see Figures 7.6 and 7.11). This result is expected to provide the basis for revealing the usefulness of the spatial autocorrelation measurement for the images of variances. Second, the classification accuracy increases at the resolutions of 240m and 270m, the adaptive resolutions to represent attribute information properly, which were selected using the method of the spectral separability measurement (see Figures 7.7, 7.8 and 7.11). In other words, the classification accuracy improves at the adaptive resolutions, which are found at resolutions lower than the resolution of action. In this vein, it can be said that the J-M distance and Mahalanobis distance can be used in the procedure to explore the optimum resolutions.

7.4.3.2 Correlation Analysis Between the Accuracy and the Index

Next, in order to evaluate the indices that reflect the image characteristics by resolutions, the correlation between these indices and the classification accuracies were analysed. Spearman's rank correlation analysis was more suitable than Pearson's product moment correlation analysis in this case because of a small amount of data.

Table 7.1 shows the correlation analysis between the 3 indices, measuring the textural indices of satellite imagery, i.e. local variance, fractal dimension and spatial autocorrelation of images of variances respectively, against the classification accuracy by resolutions.

Table 7.1 Spearman's rank correlation coefficient between the textural indices and the classification accuracies

	Local Variance	Fractal Dimension	Autocorrelation of the images of variances
Correlation	-0.273	-0.200	-0.717

Compared to the low correlations of the classification accuracies with the local variance and fractal dimension, the spatial autocorrelation index exhibits a higher negative correlation. The negative value means that the classification accuracy declines as the spatial autocorrelation index increases. For instance, according to the earlier analysis in this study, the sharp decline in classification accuracy seen at the resolution at the apex of the spatial autocorrelation is a direct reflection of this negative correlation (see Figure 7.6).

Table 7.2 shows the correlation analysis between the 3 methods for measuring the spectral separability, divergence, the J-M distance and Mahalanobis distance respectively, against classification accuracy.

Table 7.2 Spearman's rank correlation coefficient between the indices of the spectral separability and the classification accuracy

	J-M distance	Mahalanobis distance	Divergence
Correlation	0.636	0.588	0.042

Whereas the J-M distance and Mahalanobis distance show a relatively high positive correlation with the classification accuracy, the correlation of the divergence is very low. In other words, with the correlations near 60%, the J-M distance and Mahalanobis distance can be accepted as the indices of the spectral separability. However, for divergence, it does not represent the changes in attribute information by resolutions as an index of the spectral separability.

7.5 CONCLUSION

Analyses of geographical or spatial phenomena can yield different results depending on the spatial data scale selected by a researcher. The scale is also an important variable in research in remote sensing and geographical information sciences, which calls upon quantitative methodologies for the understanding and analysis of spatial processes and patterns. In particular, the spatial resolution determines the scale in such studies that utilise remotely sensed data. This resolution is a decisive factor in the interpretation of the geographical information contained in the satellite imagery.

The aim of the present study was to investigate the proper procedure to select the optimum resolution for satellite imagery. In the first step, the textural characteristics of the original image were analysed and the resolution of action was explored. At this point, Moran's *I* for the spatial autocorrelation of the images of variances was used. The resolution of action, the resolution at which the image characteristics change, was the one where the image's classification accuracy dropped sharply. By exploring the image's resolution of action, the resolution boundaries to maintain the image characteristics were found.

In the second step, the adaptive resolution was explored in order to extract the image's attribute information accurately. In this step, the indices of the spectral separability for the training set were used. It was ascertained that the J-M distance and Mahalanobis distance were the good indices for estimating the accuracy of attribute information. Therefore, the resolution where the J-M distance and Mahalanobis distance were high was the one with the high image classification accuracy.

The procedures for exploring the optimum spatial resolution proposed in this investigation have the following advantages over existing methods: First of all, whereas the procedure to select the optimum resolution in existing methods is vague, the method proposed here searches for the resolution of action first and

then offers clearer criteria. Second, it allows the exploration of the resolution that clearly represents the attributes. It can be said that the resolution at which the spectral separability increases is the one where the image's attribute information accuracy is high.

Lastly, this research must be followed by studies of more diverse land covering types, and images with various sensors. Further studies should be able to provide generalised rules that will serve as a clearer foundation for selecting the optimum resolution.

CHAPTER EIGHT

Visualisation for Coastal Zone Management

Simon R. Jude, Andrew P. Jones and Julian E. Andrews

8.1 INTRODUCTION

8.1.1 Coastal Management in the United Kingdom

The United Kingdom has an extensive coastline of over 12,000km in length that is formed by a number of environmental processes and today is subjected to a range of natural and anthropogenic pressures. Coastal management in the UK is underpinned by the development and implementation of Shoreline Management Plans (SMPs). Introduced in 1995 to provide long-term sustainable coastal defence policies and management objectives for sediment cells or sub-cells, SMPs are developed through co-operative discussions between the numerous organisations involved in managing the coastline (Purnell, 1996; Potts, 1999). SMPs can encompass a range of management options including 'do nothing', 'hold the line' of existing defences, 'advance the line' of existing defences or 'retreat the line' (Ash *et al.*, 1996). However, whilst they define the long-term management objectives, individual management schemes remain subject to economic and environmental appraisal as and when they are proposed.

Amongst the key challenges facing coastal zone managers are the need to widen public consultation and strengthen public participation during the selection of management options, and the requirement to improve the information dissemination process once decisions have been made. Shoreline Management Plans are complicated documents for those without prior technical knowledge of coastal processes, and the method in which they are prepared has been criticised for lacking adequate scope for public participation. It has been argued that this has led to suspicion amongst local communities regarding the beneficiaries of the plans (O'Riordan and Ward, 1999). Traditionally, SMPs and environmental and economic appraisals have only been disseminated to a limited number of organisations and interested individuals. The dissemination has generally been paper-based, and two-dimensional maps have been used to illustrate the plans. The

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

government realises that wider access to information contained within SMPs will be required in the future if they are to gain support for the plans, as the policies outlined in the SMP must be seen to be acceptable to the general public (O'Riordan and Ward, 1999; Potts, 1999). Indeed, a recent government review of the SMP process identified the difficulties associated with facilitating public participation as being very significant (MAFF, 2000). In line with this, the review called for innovative new communication techniques to be developed and incorporated into future SMP documents and dissemination programmes (MAFF, 2000).

The problems found in the United Kingdom are mirrored elsewhere. For example, the European Union Demonstration Programme on Integrated Coastal Zone Management recently noted that stakeholders should be more involved in the development and implementation of coastal management plans (CEC, 2000a). This view is now reflected in recent EU recommendations promoting participatory planning in coastal management and encouragement to develop systems that allow the monitoring and dissemination of coastal zone information (CEC, 2000b).

There is a clear need for the further development of new methodologies that will help enable interested individuals and organisations to be informed of shoreline management decisions in the most inclusive manner possible (Belfiore, 2000; King, 1999). Indeed, King (1999) has specifically called for the use of *electronic* methods to facilitate communication between coastal managers and the public, whilst many others have highlighted the need for research to exploit the potential of GIS in educating, promoting and involving the public in coastal planning and decision-making (Bartlett and Wright, 2000). Certainly, traditional GIS packages are already widely used by organisations involved in coastal management and these systems are frequently cited as one of the tools associated with best practice (e.g. Bartlett, 1994). However, GIS does not provide a universal solution despite its potential for assisting informed decision-making (O'Regan, 1996; Bartlett, 2000). Ultimately a traditional GIS and its output are oriented towards experts with knowledge of complicated terminology, as opposed to the layperson who often has the most to lose from management decisions. These limitations are compounded by the fact that coastal decision-makers are themselves often overwhelmed by the complexity of many GIS applications (Green, 1995). Consequently, the GIS based coastal management systems that have been developed are often simply employed to produce thematic maps of coastal areas for SMPs, and much of the potential of the technology remains unrealised.

8.1.2 VRGIS - a Possible Solution?

One technology with the potential to widen communication in shoreline management planning is Virtual Reality GIS (VRGIS). A VRGIS is in many aspects similar to a traditional GIS, but it encompasses Virtual Reality visualisations as a key output and interaction method. The virtual reality (VR) aspect of VRGIS has evolved mainly as an interface technology within which user interaction issues are of key importance. The more traditional GIS acts as a data storage and manipulation technology.

The important role of visualisation in environmental decision-support has been recorded by a number of authors who have highlighted the need to develop

such techniques to assist in the public presentation of complex environmental process models (Bishop, 1994; Bishop and Karadaglis, 1997). The recent development of VRGIS provides an opportunity to further develop public involvement in coastal zone management by providing the functionality to produce realistic virtual reality visualisations of different shoreline management outcomes. These may prove to be a significant advance on traditional methodologies. Using a case study of the north Norfolk coast in eastern England, this article reports on a research project that is developing an integrated VRGIS methodology for the assessment, visualisation and public communication of the environmental impacts of several proposed real-world management schemes.

8.2 METHODOLOGY

8.2.1 The Case Study Area – The North Norfolk Coastline

The north Norfolk coast is a relatively undeveloped low-lying barrier coastline that began to form in its current state around 6,000 to 7,000 years ago (Andrews et al., 2000). Because of its relatively undeveloped nature, the coastline has high scientific, economic and recreational value, reflected by the whole zone being protected by national and international legislation. Management of the coastline is complicated, with numerous statutory and non-statutory bodies involved in overseeing a wide range of sites including a number of nature reserves. The coastline has been studied widely and benefits from an extensive monitoring programme managed by the UK Environment Agency. The development of a first generation SMP began in 1993 and was published in 1996 (Environment Agency et al., 1996).

The SMP covers a very large area. Therefore, a number of smaller project-level study sites were identified through consultation with a range of statutory and non-statutory organisations involved in managing the coastline. In order to illustrate this work, a single scheme at Brancaster West Marshes is described here (Figure 8.1, see colour insert following page 164).

8.2.2 Brancaster West Realignment Scheme

With sea level predicted to rise by up to 88cm by 2100 (Houghton et al., 2001) there is considerable concern regarding the potential for future active management of the coastline because of its vulnerability to North Sea storm surges (Thumerer et al., 2000). A possible option to accommodate future rises includes allowing reclaimed freshwater marshes to revert back to their natural state, a process known as managed retreat, setback, or coastal realignment. Coastal realignment has triggered considerable concern and debate amongst the public (Clayton, 1995), although the European Habitats Directive does require such schemes to offset habitat losses by creating new habitats elsewhere along the coast.

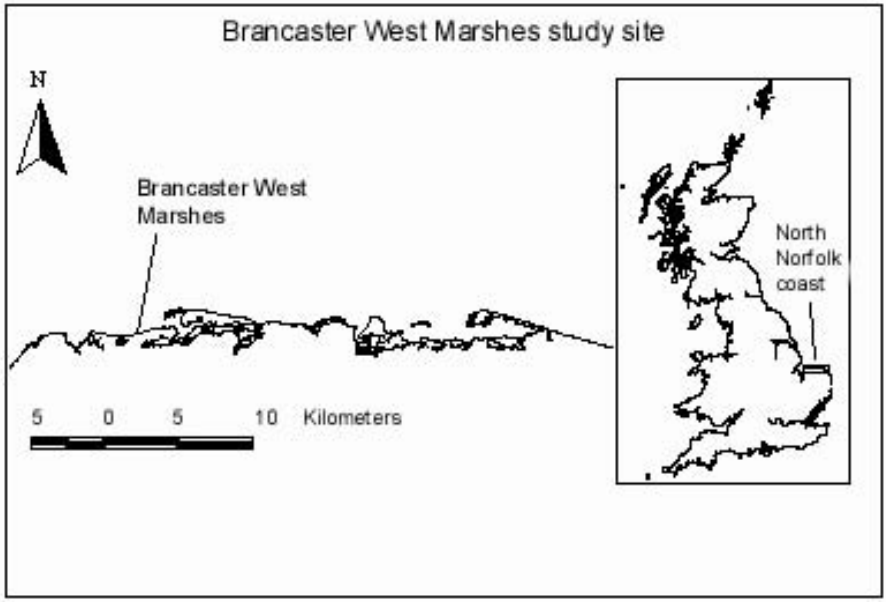

Figure 8.1 The location of the Brancaster West Marshes study site.

Brancaster West Marshes is a site currently under consideration for coastal realignment. The Marshes comprise approximately 40ha of freshwater grazing meadows forming a Site of Special Scientific Interest (SSSI) and a Special Protection Area (SPA) under the European Union Birds Directive (Tyrrell and Dixon, 2000). The site is flanked by earth flood embankments with its frontage protected by defences strengthening the natural dune frontage. The latter were constructed in 1978 to provide protection against storm surges but have degraded to such an extent that the Environment Agency has proposed a managed realignment scheme in which the frontage will be removed, with a new defence constructed 300m inland from the original location (Tyrrell and Dixon, 2000). The freshwater marshes to the north of the new defence will subsequently be allowed to revert to salt marsh.

The scheme has attracted considerable attention because it impacts a site protected under the Birds Directive. Furthermore, it could potentially interfere with the defences and frontage protecting the adjacent Royal Society for the Protection of Birds (RSPB) reserve at Titchwell. Additional complications arise from the privately owned defences belonging to the Royal West Norfolk Golf Club to the east, who plan to construct their own defence to protect their practice ground in response to the scheme.

8.2.3 Database Construction

An extensive GIS database was developed using ArcInfo and ArcView GIS packages (Table 8.1). Data was obtained from organisations involved in managing the coast, and supplemented a number of Ordnance Survey products including Land-Line.Plus, and Land-Form PROFILE. Where management plan data was unavailable in a digital format it was digitised, with permission, from management documents.

Database construction illustrated the difficulties associated with integrating data from a range of different organisations. Firstly, identifying data holdings availability was time-consuming and frustrating, with some organisations wishing to charge for data conversion. Secondly variations in the GIS software used by organisations required further complex conversion into a standard format.

Table 8.1 Sources of data.

Dataset	Supplied by	Provides
Aerial photography	Norfolk County Council and Natural Environment Research Council	Colour aerial photography of the site from 1988 and 2001
CASI	Natural Environment Research Council	5m resolution Compact Airborne Spectrographic Imager image with intertidal zone classification
Geology	British Geological Survey	Solid and drift geology
Landcover Map of Great Britain	Centre for Ecology and Hydrology	25m resolution landcover grid
Land-Form PROFILE	Ordnance Survey	10m DEM grid
Land-Line.Plus	Ordnance Survey	Large-scale vector data
LIDAR	Environment Agency	2m DEM grid
Shoreline Defence Survey	Environment Agency	Flood defence location, design and condition
Shoreline Management System	Environment Agency	Coastal monitoring data including beach profiles

8.2.4 Assessment Methodology

Assessments of future changes at the study site were made using information from a range of sources. Data on the coastline's evolution was provided from results of the Natural Environment Research Council's Land-Ocean Interaction Study (LOIS) together with historical mapping and aerial photography of the site. Furthermore, beach profiles collected by the Environment Agency's Shoreline Management System for the frontage over the last 10 years were incorporated into the GIS. This historical data was complemented with assessments of the potential impacts of future sea level rise on the site. Future sea level rise was calculated using the Model for the Assessment of Greenhouse-gas Induced Climate Change (MAGICC) (Hulme et al., 1995) for each of the latest emissions scenarios from the Intergovernmental Panel on Climate Change (IPCC). The results from MAGICC exhibited considerable uncertainty in predicted rates of future sea level rise. Therefore, for the purpose of the research, the assessments were based on the IPCC's IS92a scenario using the high sea level rise predictions calculated by MAGICC (86cm by 2100). The assessment of sea level rise also accounted for isostatic changes in the land level and used mean isostatic adjustment rates as predicted for eastern England by Shennan (1989).

The estimation of how the combined sea level rise and isostatic adjustment would affect the study site was undertaken in ArcInfo using an Arc Macro Language (AML) script that calculated a new Digital Elevation Model (DEM) for each year between 2000 and 2100. Sources of elevation data employed for this included 2m resolution LIDAR data provided by the Environment Agency and Ordnance Survey Land-Form PROFILE 10m resolution products. This methodology allowed the applicability of different sea level rise scenarios to be quickly assessed before they were used for creating VR visualisations.

8.2.5 Large-scale Data Preparation

Ordnance Survey Land-Line.Plus large-scale digital topological data was used for the basis of the detailed visualisation work. It was supplied in $1km^2$ titles at 1:2,500 scale in line-only format, and thus required conversion to a polygon topology to allow attribute data to be incorporated. All editing took place in ArcInfo GIS, where the tiles covering the study site were appended and cleaned to produce a line coverage of the study site. Unfortunately the data was produced in such a way that automated polygon topology generation methods that have been applied for urban areas such as those used by Lake et al. (2000) are unsuitable. This is because not all polygons are completely closed and, although the data is provided with seed points relating to polygons, they fail to cover every land parcel. Hence, where required, polygons were closed and seed points were generated manually.

Once the polygon coverage was created, attribute data was added. Attributes were assigned to each polygon from three separate data sources. For the intertidal zone, 5m resolution Compact Airborne Spectrographic Imagery (CASI) was available from the LOIS Project. This imagery was georeferenced and converted to a grid format using ERDAS Imagine before being used to assign attributes to the

polygons. Land-based polygons falling outside the intertidal CASI coverage were classified from aerial photography and landcover data obtained from the Centre for Ecology and Hydrology Landcover Map of Great Britain. In total, 38 different landcover classes were used.

Following construction of the polygon dataset, extensive fieldwork was undertaken to both ground-truth the coverage and to collect digital photographs for use during the production of the visualisations. Plans for the realignment scheme were obtained from the Environment Agency and were digitised to create a new coverage reflecting proposed future state of the site. The Environment Agency dataset was appended to Land-Line.Plus to allow evaluations of the areas of loss to be calculated, and for the individual environmental indicators to be assessed.

8.2.6 Production of Visualisations

Visualisations of the scheme were produced using two techniques. Firstly interactive visualisations were produced using ArcView 3D Analyst Extension to provide 'fly through' Virtual Reality Modelling Language (VRML) experiences, and secondly, static visualisations were produced by exporting the GIS results into World Construction Set, a photorealistic-rendering package. Whilst the virtual fly-through is the most common output of VRGIS, the experience it provides does not necessarily equate to the way members of the public are able to best perceive landscapes. Hence the two methodologies were chosen so as to allow an assessment to be made of their respective roles in widening public understanding of future coastal management schemes. All the visualisations were created using a 1GHz AMD Athlon-based PC with 512MB RAM running Windows 2000.

8.2.6.1 ArcView 3D Analyst

The production of visualisations using ArcView 3D Analyst involved the creation of a Triangulated Irregular Network (TIN) DEM using the Land-Form PROFILE data, over which the Land-Line.Plus polygon dataset was then draped to create a 3D scene. Sea defences and buildings were added as separate coverages, allowing them to be extruded from the DEM to produce 3D surface features. This process involved obtaining sea defence height information from a database of Environment Agency defences. The absence of true height information in Land-Line.Plus meant that, for buildings, a height of 3m per storey was assumed. Sea defence heights were extruded from Ordnance Datum whilst buildings were generated using the DEM as the base elevation. For the production of visualisations of the site following the realignment scheme, the DEM was reprofiled in those areas where change was deemed likely to occur, then it was converted to a TIN. Finally the Land-Line.Plus-derived coverage representing the future site state was used as the drape.

3D Analyst allows the attributes of the resulting visualisation to be queried, and facilities enabling the user to navigate around and zoom in and out of the 3D scene in real-time are provided. For the purpose of this project, static images of the environments were created. Each scene was also exported to a VRML file for use in any Web viewer.

8.2.6.2 World Construction Set

In contrast to ArcView, World Construction Set allows photorealistic visualisations to be generated, and has the advantage for many GIS users that ASCII DEMs and ArcView shapefiles may be imported and used as the basis for these visualisations. However, one drawback, at least for UK users, is that input data must be reprojected to decimal degrees.

The first stage in the production of the visualisations involved the importation of the DEM data into the package. World Construction Set permits terrain features to be generated using Terraffectors. Terraffectors create terrain from two-dimensional vector representations. Their advantage is that a cross-section profile of a study area may be created to represent real world features in which the ability to specify the height or depth of the feature in relation to the underlying DEM is implicit. Area Terraffectors, based on vector polygons, were used to generate representations of the site's sea defences from defence heights and cross-sections as provided by the Environment Agency Shoreline Defence Survey from 1999. They were also employed to create creeks and pools. Despite its poorer vertical resolution, the smoother Land-Form PROFILE data was chosen as the underlying DEM in preference to the Environment Agency LIDAR dataset because Terraffectors were found to work better with that source.

The second stage in visualisation generation involved importing the individual ArcView coverages for which new environment effects were to be created. By splitting the original landcover classification dataset into separate ArcView shapefiles for each landcover type, different features could be assigned different ground effects. For example, grasslands were given a surface texture representing long meadow grass. Later 3D vegetation and trees were included, although the limited selection of pre-generated foliage features and 3D objects in World Construction Set required the creation of new objects from photographs of the study sites. Finally, 3D buildings were added. Their addition involved a multi-stage process where the building polygons were converted from an ArcView shapefile coverage to a DXF file, allowing a package called SoftCAD to be used to create a 3D building. This enabled them to be to converted into a 3D object that was useable in World Construction Set.

During each stage of the visualisation generation process, preview renders were used to test the result of parameter changes and, where necessary, adjustments were made to each feature. Once a satisfactory result was achieved, final rendered images were produced using a number of virtual camera locations that best represented the change that would occur at the site.

8.3 RESULTS

The results of the assessment of the impacts of the scheme revealed that, although there will be a predicted loss of 10.2ha of freshwater grazing marsh following construction, this Figure will most likely be offset by an increase in salt marsh area of 6.3ha and 1.6ha for water channels and creeks. However, what is less certain from this analysis are the impacts on biodiversity that this change may bring about.

The results of the visualisations are provided in Colour Plates 8.1 to 8.4 (following page 164). In each case the same viewing location is used to illustrate

the changes at the site following construction of the realignment scheme. The immediate difference between the ArcView 3D Analyst and World Construction Set images is the level of detail, the former being more stylised in comparison to the latter. For example the ArcView 3D Analyst images do not contain the extensive colours, textures and 3D features found in the World Construction Set images. Likewise, the limited VRML functionality in ArcView 3D Analyst results in crude representations of the defences, produced by extruding the defence shapefiles, whilst the Terraffectors available in World Construction Set rendered their detailed cross-sections. This trade-off in detail does, however, have important implications for the rendering times for each method with the ArcView 3D Analyst 3D scenes being continually updated in real-time as the scene was explored, whilst the static rendered images of World Construction Set took approximately 1 minute to render a preview image so it is likely to be some time before explorable World Construction Set environments can be produced.

8.4 DISCUSSION

One of the key criteria for the choice of study area here was that extensive coastal monitoring data was available from a range of organisations. In particular, it was very important that large-scale digital data, plus detailed management plans and information, were available for the chosen study site. Without such information, it would not have been possible to produce assessments and visualisations of future environments that would stand up to public scrutiny. However, even here there were problems in gaining access to some key documents. For example, whilst the Environment Agency Regional Office housed the Shoreline Management System GIS, the project manager for the Brancaster West scheme was based at the local office. This led to difficulties when trying to locate up-to-date plans for the scheme.

The primary drawback associated with the methodology at present is the lack of widespread availability of large-scale digital data in a suitable format. Although Land-Line.Plus represents the best available source, the time-consuming editing required to produce a suitable polygon coverage may prove extremely costly within an organisational context. Despite this limitation, once the data was finally cleaned it lent itself extremely well to use in the visualisation software. Few difficulties were encountered during the GIS analysis stage of the work although problems were identified relating to the interoperability of data between ArcView and World Construction Set. The primary difficulty came from the requirement for ArcView shapefiles to be projected in decimal degrees as opposed to the UK National Grid. Further problems were also typified by the laborious process required to create and import buildings due to the need to convert files to suitable formats. Such findings reflect a general problem relating to the incompatibility of GIS and VR software formats (Williams, 1999).

The two methods presented in this paper were chosen to represent alternative techniques that may be suited to different purposes in coastal management. The 3D Analyst visualisations are more dynamic and interactive, allowing the user to query the results. They may be more suited to those directly involved in the decision-making process and who wish to obtain quantitative information from

them. Conversely, World Construction Set provides extremely realistic static images. These may be more suited to inclusion in management documents, such as environmental appraisals, where they could be used as an alternative to photomontages. With calls for SMPs to be distributed electronically (MAFF, 2000), both techniques lend themselves well to dissemination via the Worldwide Web. World Construction Set images could be displayed as scaleable bitmaps, whilst the virtual environments from ArcView 3D Analyst can be easily converted into VRML files, enabling the user to explore the policy impacts for themselves.

The two visualisation techniques do pose a number of questions that reflect the numerous challenges facing the application of VRGIS. The concepts of visualisations and virtual environments are relatively new and as such it has been argued that, until they are more widely used, knowledge of how best to design them will be lacking (Batty et al., 1998). This leads to the question of how the public, as opposed to experts, relate to visualisations and whether simple visualisations like those produced by 3D Analyst are more effective than detailed photorealistic visualisations at conveying complicated information? There are obvious difficulties when trying to compare the applications of visualisation presented here with research using high performance graphics workstations by some other authors (Bishop and Karadaglis, 1997). However, although improvements may be made using customised software on high performance hardware, any practical application in coastal management is likely to be constrained by costs incurred in software, hardware and training. This work has illustrated that effective visualisations may be created using off-the-shelf software running on a high-powered desktop PC.

It is obvious that visualisation techniques on their own will simply produce pretty images that are of little use if not employed properly by coastal managers. VRGIS will clearly only achieve its full potential for coastal management if it is integrated into the planning process (Zube et al., 1987; Lange, 1994). It could potentially be used from the beginning of the SMP or project planning stage, assisting communication between management organisations during the development of alternative options. Later during the decision-making process VRGIS has an obvious use in public consultation and participation. However, such advances will only be achievable if the underlying planning process is opened up to the public to allow their participation, which in the United Kingdom would require major changes to coastal planning legislation. What visualisation techniques should *not* do is, as Lange (1994) points out, be used to sell a particular scheme to the public. This would be a wasted opportunity; visualisations have the potential to *promote* the discussion of alternatives in initiatives to identify the optimal solutions to coastal management problems.

Virtual Reality GIS should not be seen as an immediate and universal solution to coastal management problems because at present there is a lack of research understanding concerning the methods that can be used and the effect of the different contexts in which they may be applied (Zube et al., 1987). As Williams (1999) notes, VRGIS has the potential to enhance conventional GIS but should not be viewed as a replacement. This research is, however, investigating the potential application of the assessment methodology and visualisation techniques in the SMP and planning process. Focus groups and participation seminars have

been undertaken to gain feedback both from coastal managers and planners who may adopt these methodologies. Further surveys are being organised with members of the public, who have the most to gain from the use of visualisation techniques as a means of communication and a participatory tool. In this way it is hoped to explore the potential difficulties of applying the methodology in more detail. A second strand of the work will also assess how the visualisations could be used in choice experiments to determine if they may be used in decision-making contexts such as that of extended cost-benefit analyses. It is hoped that this project will illustrate the potential of VRGIS in participatory coastal management.

In conclusion, we believe that this research highlights the potential of GIS and VRGIS as an integrated tool to assess, visualise and potentially value future coastal landscapes through the use of high quality, yet disparate, data related to management of the coastal zone. It also illustrates how VRGIS may communicate, educate, inform and involve the public and stakeholder groups in coastal management decisions by presenting information in a recognisable and understandable format. We firmly believe that the application of VRGIS can stimulate meaningful discussion and dialogue between groups traditionally associated with conflicting opinions. Coastal Zone Management can only benefit from its application.

8.5 ACKNOWLEDGMENTS

The authors would like to thank all of the organisations that provided input into the research and the Environment Agency, Ordnance Survey and Suffolk County Council for providing access to their GIS data. The research was completed whilst the lead author was in receipt of an ESRC/NERC Interdisciplinary PhD Studentship.

CHAPTER NINE

Application of a Decision Support System in the Development of a Hydrodynamic Model for a Coastal Area

Roberto Mayerle and Fernando Toro

9.1 INTRODUCTION

Recent advances in numerical modelling of physical processes and field survey technology nowadays allow the development of numerical models with extensive data sets. As a consequence, model developers are facing new challenges to handle the increasing amount of data and its analysis.

Furthermore, model development and application concerning coastal areas are heavy time demanding tasks that need tools to assist the researcher. Most of the time they involve analysis of field measured data and its comparison with numerical model outputs. Even though there are good tools for specific tasks, there is a lack of them for integrating measured and modelled data.

An application of a Decision Support System (DSS) in the development of a hydrodynamic model for a coastal area is presented. Description of the DSS components, their interaction, and its GIS capabilities to handle spatial data are also given.

9.2 DEVELOPMENT OF HYDRODYNAMIC MODELS

A hydrodynamic model is the mathematical representation, with the assistance of numerical algorithms, of flow and wave situations to study them more effectively. However to obtain reliable information, development of numerical models must include evaluation of results. This process is time-consuming and involves comparison of numerical model outputs with measured data. Moreover, a unique model development procedure can be restrictive due to the large amount of variables involved in the physical process. The number of variables and their levels of significance depend on the objective of the study. In spite of these difficulties a general trend for the development of hydrodynamic models can be defined and is presented next.

Figure 9.1 shows the phases and steps in the development of a hydrodynamic model. The model development consists of several phases (i.e. sensitivity analysis, calibration, validation and application) in which the modelling experts fine-tune

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

the numerical and physical parameters to reproduce the field conditions. Each of these phases has several steps that share information with the other phases.

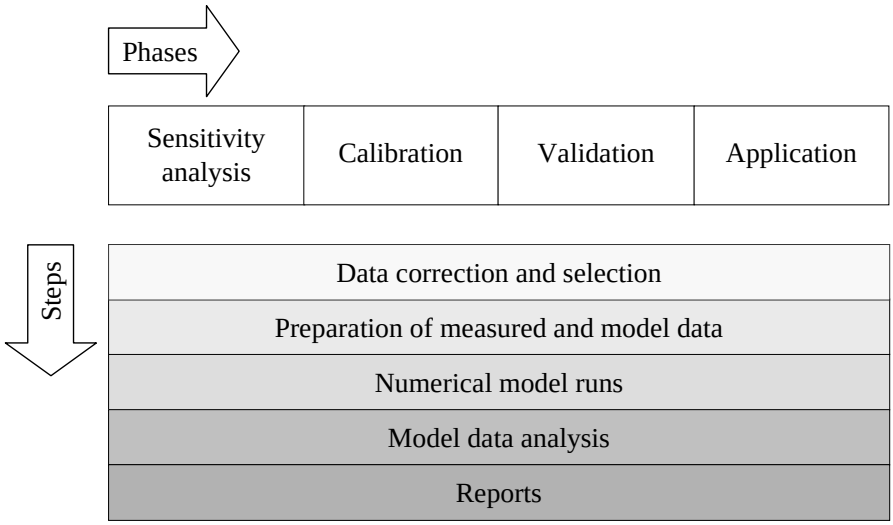

Figure 9.1: Phases and steps in the development of hydrodynamic models

The "*sensitivity analysis*" evaluates the response of the model to changes of the physical and numerical parameters. The numerical parameters are set and the physical parameters having an effect on the results are selected. Physical parameters are adjusted to represent the conditions in the studying area during the "*calibration*". During the "*validation*" the model ability in reproducing the field conditions, within certain level of accuracy, is checked. The model "*application*" is the last phase in the model development and is performed by the end users to make decisions. The validated model is then used in hindcasting, nowcasting and forecasting situations.

Regardless of the model development phase, each of them has several steps as indicated in Figure 9.1. The first one is the "*data correction and selection*" in which the measured data is corrected, selected and stored in a database. This is usually data that needs to be processed to fit the model formats. In situ measurements are in the form of time series at a certain location or recordings at a certain area for a given time. The "*preparation of measured and model data*" includes the creation of the model grid and definition of some default (but logical) numerical and physical parameters. The measured data preparation includes reformatting of the data to be used as initial conditions and boundary conditions for the model and to enhance easy comparison with the model results. "*Numerical model runs*" is the core of each phase and refer to determination of the change in the numerical model outputs caused by changes in input data. "*Model data analysis*" is the step in which the model results are analysed by means of the experience and judgement of the model developer, and compared with other model results or measured data. The data analysis is an iterative process with the model runs and gives feedback to the model developer whether or not to choose new

parameters to run the model again. This is a procedure in which software tools are needed to speed up and facilitate model development. Therefore, a "*Decision Support System*" (DSS) that assists the model developers is of vital importance. And finally, the "*reports*" document the work that has been done and summarises the experience and conclusions obtained. These written reports are used as reference in the future phases of the model development.

9.3 A DECISION SUPPORT SYSTEM FOR MODEL DEVELOPMENT

The handling of information for hydrodynamic model development is a difficult task as a consequence of different sources, types and formats of the data and the increasing amount of data involved in such activities nowadays. An efficient way to retrieve, analyse and store information accurately and speedily is crucial for the good performance in the model development process.

A Decision Support System (DSS) for development of hydrodynamic models is an interactive computer-based system intended to help modellers use data from measurements and models to simplify and speed up model creation. It helps to retrieve, summarise and analyse data. It comprises three integrated components: "*interface*", "*database*" and "*models*". Figure 9.2 shows the components of a DSS for development of hydrodynamic models, with the input and output data.

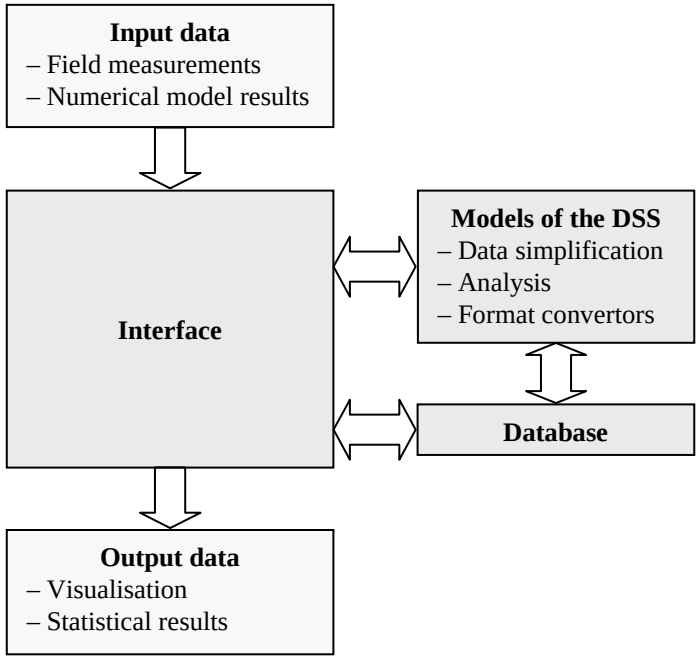

Figure 9.2 Components, input and output data of the DSS

The proposed DSS centres on the model development of depth-integrated (2DH) flow models with field data applied to coastal areas. The DSS has been tailored to handle primarily data such as water levels and current velocities.

The input data to the DSS, from measurements and numerical model outputs, is fed to the system through the interface and is stored in the database component of the system. The GIS application, as a DSS generator, is used to handling spatial data in conjunction with the database. The instructions to the system are given by the decision-maker through the interface that passes the type of analysis to be made by the model components of the DSS. Finally, the output data is presented in the form of statistical tables or visualised in plots and Figures.

The "*interface*" component is the part of the DSS that interacts with the user. It should be user-friendly and usually includes graphical components and it is then called a "*Graphical User Interface*" (GUI). The front end of the system is a graphical interface created customising ArcView 3.2a GIS software (ESRI, 1996).

The "*database*" is the collection of data that is organised so that its contents can easily be accessed, managed and updated. The size and effort spent in the database depend on the amount of available information. It is the data source for the DSS that processes and presents the information. The importance of the database in the system relies on the versatility for the selection of the data for analysis rather than in the storage capacity. In the case of the DSS, its capabilities are implemented using the GIS software generator, with tables connected under the concept of relational database.

The "*models of the DSS*" use the data provided by the database and allow the user a direct opportunity to explore the data relevant to the problem. The model components of the DSS take care of evaluating, analysing and correlating the information from different sources available in the database and reduce the information to make it easy for the user to understand the physical process. The distinction between the models of the DSS and the numerical models should be made clear here. Whereas the latter ones are software tools used to solve partial differential equations for the hydrodynamics in coastal areas, models of the DSS are software tools to link and analyse numeric output and in-situ measurements. The model components are mainly programmed as Matlab (The MathWorks, 2000) functions grouped in a software library that makes the DSS a versatile system open for new types of data analyses, new types of data sources and makes their maintenance easier.

Figure 9.3 makes a parallel between the model development steps in which the DSS assists the researcher and the DSS components. The DSS interface is used in all steps of model development and even in earlier stages during the data acquisition to visualise information. The database component is used all along the development steps and it is queried according to the model development phase that is being analysed. The data simplification, analysis and conversion are performed by the DSS models and is made during the data preparation to run the model and during the evaluation of the numerical model outputs.

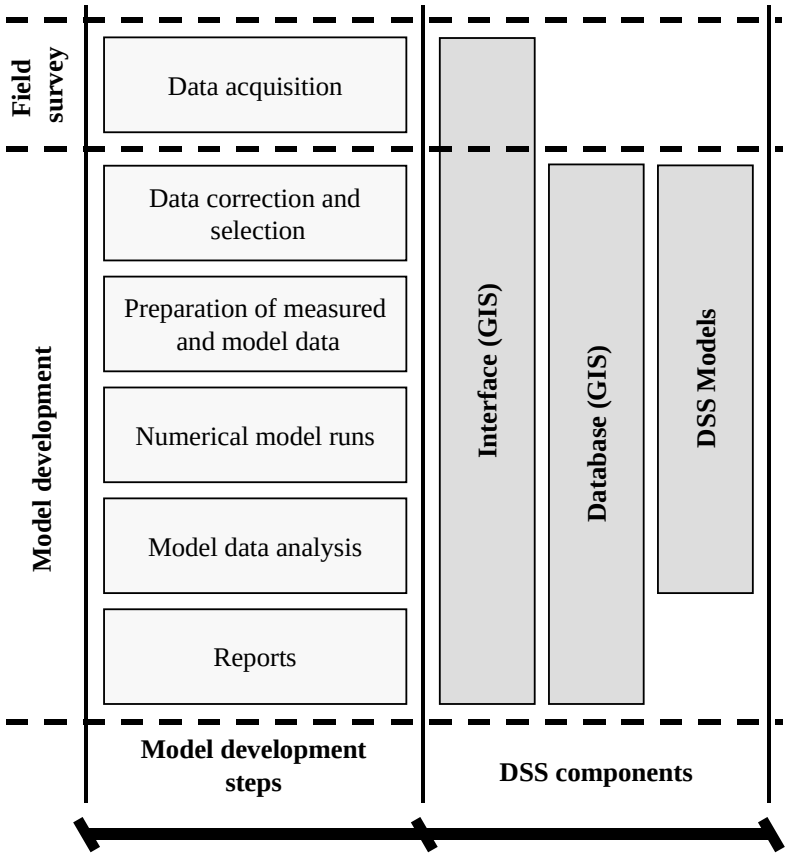

Figure 9.3 Model development phases and DSS components

9.4 APPLICATION

This section presents the application of the DSS during the development of a hydrodynamic model for an area on the German North Sea coast. The multiple possibilities of the DSS for data handling and its versatility to the needs of the user are shown.

The in situ measurements presented herein were collected as part of the project "Predictions of Medium Scale Morphodynamics" (Promorph) (Zielke et al., 1998) and were used for the development of the flow model (Palacio et al., 2003).

The domain of interest is the Meldorf Bight and the adjacent tidal channels covering an area of about 600km^2. Around 50% of the area of investigation is dry during the ebb phase and almost the whole domain is submerged during the flood phase. Figure 9.4 shows the area of investigation, model boundaries and location of in-situ measurements. The tidal channels have a maximum depth of about 20m. Tidal range is around 3.0 to 3.5m. The calibration of the flow model is carried out

using measured water levels at several gauge stations and velocity measurements over several cross-sections obtained by means of acoustical profilers.

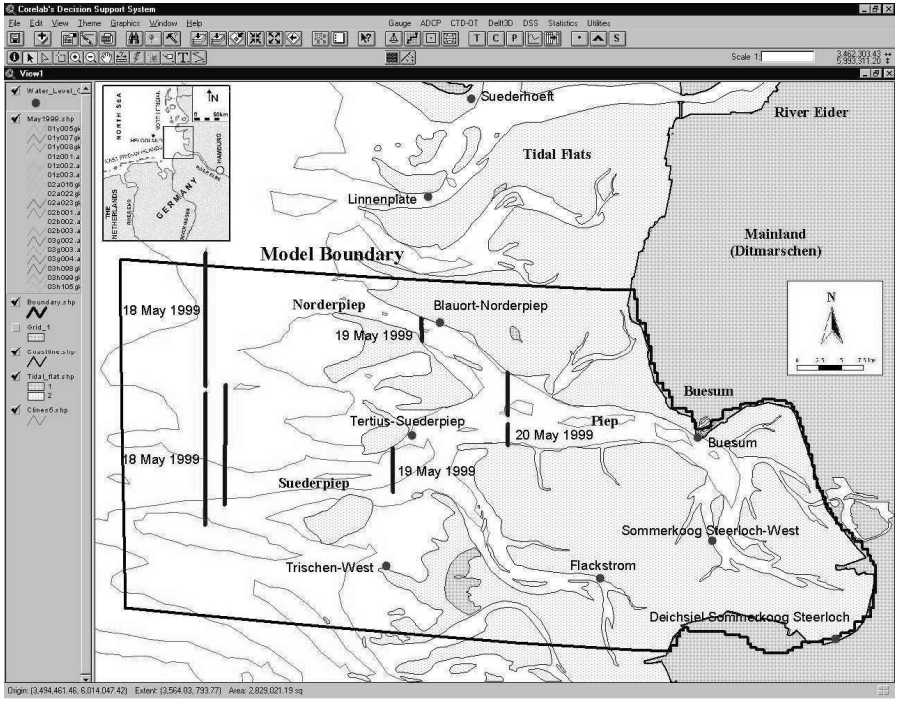

Figure 9.4 Area of investigation, model boundaries and in situ measurements

9.4.1 Data Acquisition

The acquisition of field data describing the model domain is necessary for the model development. Data may be collected from the relevant authorities, research institutes or measured in field campaigns. Here the following data sets were used:

- bathymetry in the tidal channels and tidal flat areas,
- continuously recorded water level measurements from gauge stations,
- atmospheric pressure and wind data,
- current velocity measurements.

Figure 9.4 shows the GUI for the study area with location of the water level gauges and some of the cross-sections selected for current velocity measurements.

An example of measured current velocity along a cross-section is shown in Figure 9.5. This type of plot can be animated when having several cross-section plots in a period of time.

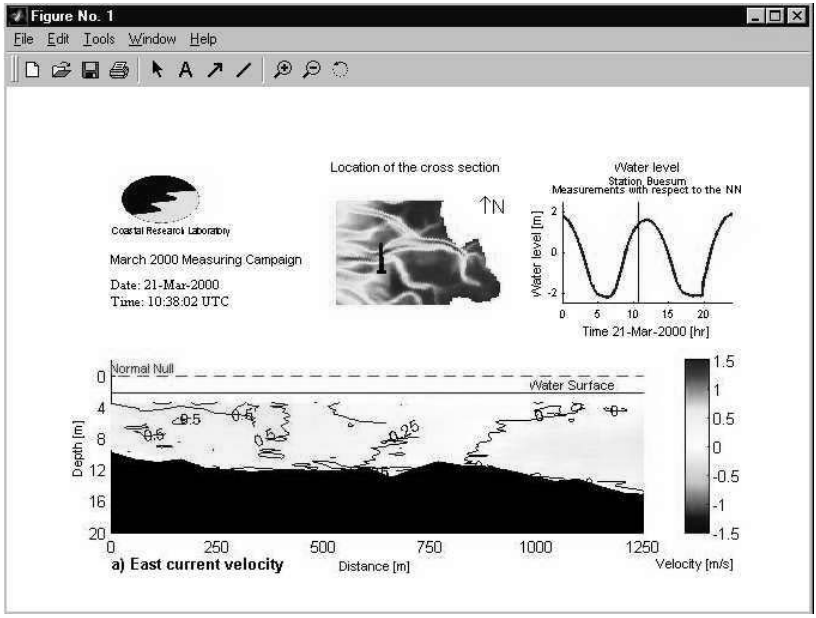

Figure 9.5 Measured current velocity transversal to a cross-section

9.4.2 Data Correction and Selection

Among others, the following corrections are incorporated with the collected measurements:

- the European time used during the recordings is referenced to UTC,
- referenced locations using differential GPS are projected onto the same reference system of the model grid,
- the depth during the measurements is usually referred with respect to the water surface. Due to the changes in the water surface in time accompanying the tide, all data is corrected and referred with respect to a fixed reference level (e.g. mean sea level) to allow comparison of data at different periods of time.

In addition to data correction and projection, some additional data is generated for later use with numerical model outputs; that is for the calculation of the depth-integrated velocity out of the 3D velocity measurements.

In situ measurements are stored in the DSS database and can be accessed by the user. The database tables are used in conjunction with the GIS map layers in such a way that the database can be queried selecting objects in the map views.

Data once entered in the DSS database are available for visualisation and selection for comparison and analysis during model development. The first step in the data selection is to display an inventory of the data showing which in situ measurements and the covered measuring period are available. The time interval considered for model development can be chosen as the time period for which simultaneous measurements of several of the required quantities are available. Or, on the other hand, it gives an idea of the missing field data in the selected interval.

Figure 9.6 shows the in situ measurements available in 2000 in the Meldorf area. The vertical axis shows the available magnitudes in terms of water levels and current velocities and the horizontal axis corresponds to the time axis. Such a Figure enhances detection of the time intervals when data sets are available for the model development. The periods selected for the model development are indicated in the Figure.

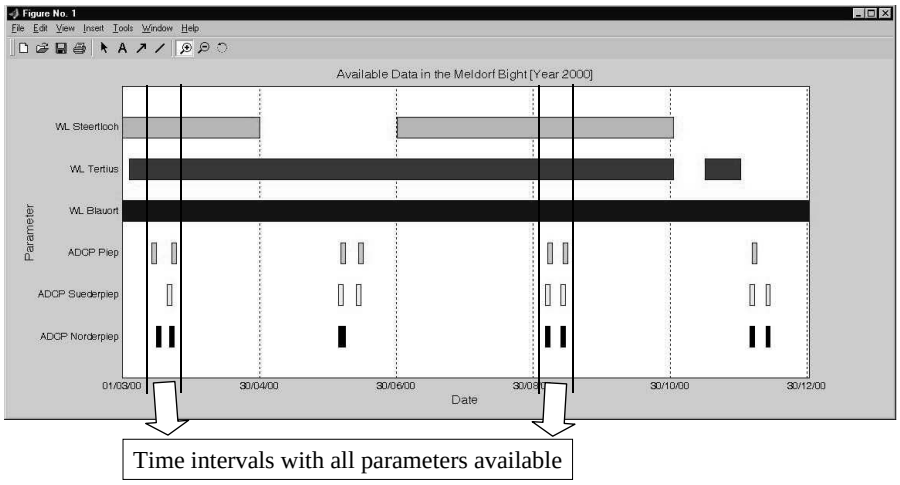

Figure 9.6 Available data in the domain area.

9.4.3 Preparation of Measured and Model Data

The model set-up, grid generation and bathymetry interpolation are done with the software tools of the hydrodynamic model.

A curvilinear grid, adjusted to the bathymetry of the domain, was created, covering an area of 600km^2, with around 35,000 cells and a resolution from 60m (inner part of the model close to the main tidal channels) to 180m (in areas close to the model boundaries). The model has three open boundaries (North, South and West). Along these boundaries the boundary conditions are specified as a function of imposed water levels. Since the bathymetry in the area was obtained from measurements done at different periods, one of the functionalities of the DSS is the selection of the appropriate bathymetry from different data sets. Besides it could also be used in updating the model bathymetry regularly.

The selection of the simulation periods is based on the intervals with available data sets that are going to be used as initial and boundary conditions for the model. These periods can be selected among the intervals shown in Figure 9.6. In the calibration and validation phases additional in situ measurements are needed for the comparison with the model results.

9.4.4 Numerical Model Runs and Model Data Analysis

Subsequently, the DSS assists the modeller in the statistical analysis and comparison of the measured data and/or the numerical model outputs depending on the model development phase being performed, i.e. sensitivity analysis, calibration, validation or application.

9.4.4.1 Sensitivity Analysis

Here the behaviour of the numerical model outputs with respect to the physical and numerical parameters is checked. The aim is to define the numerical parameters and to Figure out the physical parameters to be considered in the calibration of the model. The analysis is done at several locations all over the domain and periods of time that represent the main flow conditions; for instance, in case of tidal dominated areas, tidal phases and tidal cycles as well as periods with calm winds and during storms are considered.

For the Meldorf Bight Model the evaluation was made analysing the computed water levels and current velocities. For the comparison of the modelled water levels, the DSS makes an analysis of the variation of "*amplitude/phase*" with respect to several physical and numerical parameters. The differences in height (amplitude) and time (phase) between the peaks of two time series are computed. This analysis is used for harmonic magnitudes that have a cyclic behaviour, e.g. when evaluating water level data sets. The analysis of the water levels combines data from several locations and periods of time.

Figure 9.7 shows the GUI with a table that summarises the effect in the water levels for different time steps in the model set-up at several locations. The table includes for each location (record) and parameter (field) the number of records, mean, standard deviation and RMS-Error. The aim is to identify an appropriate time step that gives sufficient accuracy in the model results in order to minimise the computational time of the simulation. Different time steps were considered. A period of 30 days was used in the analysis to consider the effect of spring and neap tide. The selected time step is 0.50 min.

For the analysis of the data and the statistical computations the data can be organised in many different data sets. Figure 9.8 shows the DSS interface with the windows, in which the conditions for statistical analysis and selection of the data sets are set.

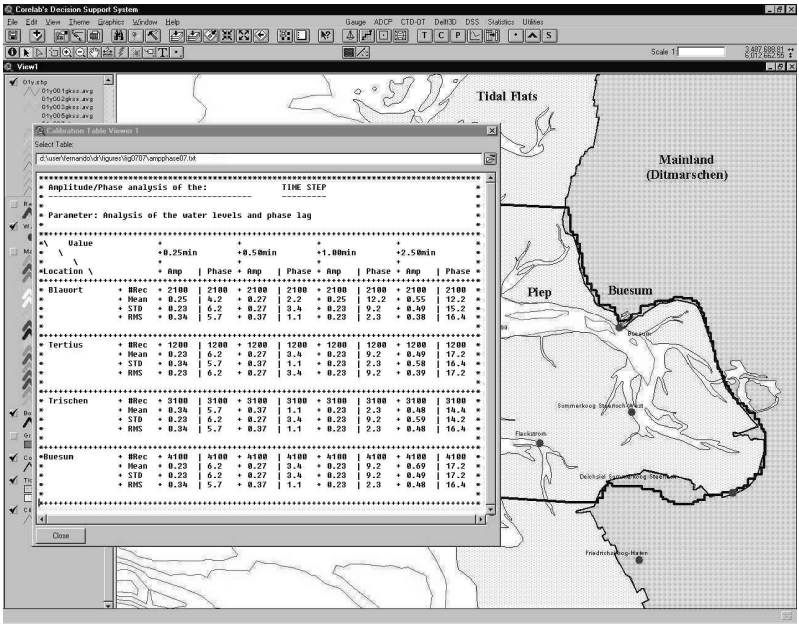

Figure 9.7 Summary of the sensitivity analysis of the time step

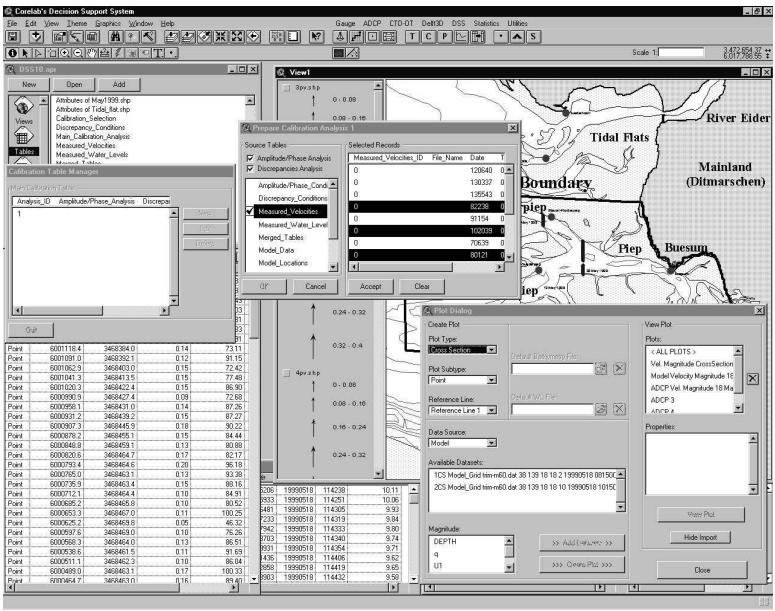

Figure 9.8 DSS interface with input data windows for the statistical analysis

9.4.4.2 Model Calibration

Physical parameters are adjusted to represent the conditions in the studying area during the model calibration. The evaluation was made analysing water levels and flow velocities. Only the calibration of the bottom roughness in terms of Chezy coefficients in the whole domain is presented. Bottom roughness with constant values of Chezy coefficient were considered.

For the comparison of the flow velocities, the DSS makes a "*discrepancies analysis.*" The *discrepancies analysis* computes the differences between the model results and measured data, and performs some statistics with these differences. This analysis can be performed organising the data by locations or velocity intervals (data sets are grouped in several classes according to the velocity magnitude from the minimum to the maximum velocities available in the data sets).

Figure 9.9 summarises the statistics of the analysis of depth integrated velocity for these three types of bottom roughness and several intervals of flow velocity. The table includes some values such as mean, standard deviation and value of the parameters RMS-Error and Relative Mean Absolute Error (RMAE) (van Rijn, 2001) for the flow velocity differences (modelled - measured) used in the analysis. The best option is obtained on the basis of these statistical parameters. In this case there are not significant differences between the three options; however, there are slightly better results with a Chezy coefficient of 60 $m^{0.5}/s$ for the bottom roughness.

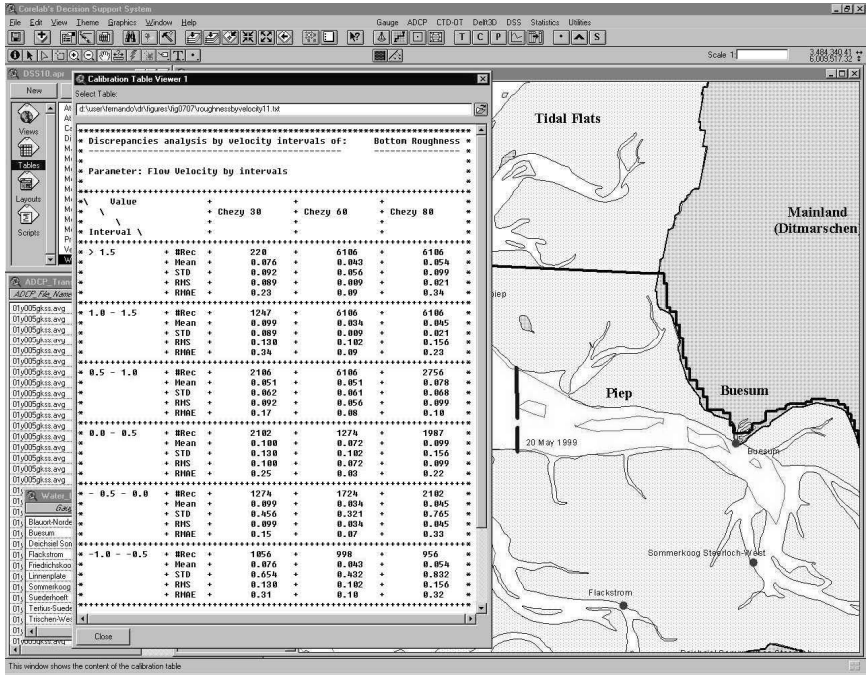

Figure 9.9 Summary of the model calibration of the bottom roughness.

9.4.4.3 Model Validation

During model validation, the model performance to reproduce the field measurements is determined. As in the model calibration, measured and modelled data are compared and therefore the same DSS tools can be applied. The data sets used in the validation are different from those used in the model calibration. The tools presented in section 9.4.2 are employed for selection of additional measurement data.

Figure 9.10 shows a comparison of modelled and measured flow velocity, integrated over the depth, at a cross section within the model domain.

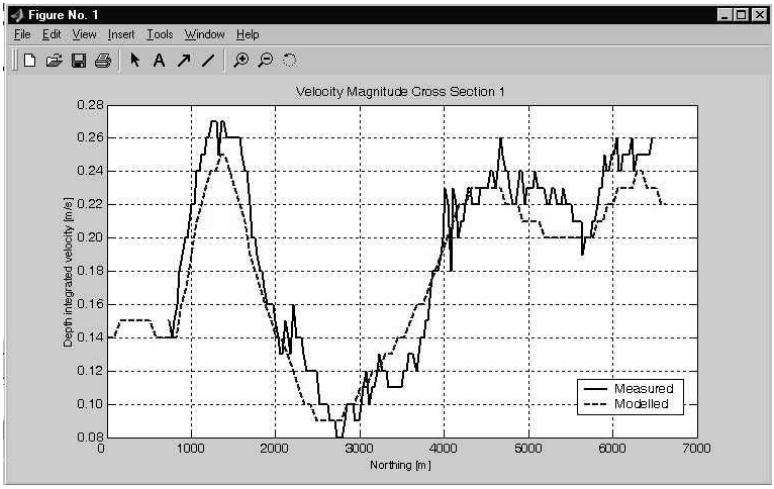

Figure 9.10 Velocities comparison during the model validation.

9.4.4.4 Application

The model, once validated, is used for forecasting flow conditions following several "if" scenarios; this allows to study a problem and possible engineering solutions (e.g. determine water levels for different wind conditions for the design of dikes). In this phase, all the DSS tools already described are available for handling existent and additional data that might be collected after the model validation.

9.4.5 Quasi-Real Time Validation

Another application of the DSS during the data acquisition might be the comparison of the measurements with the model results previously prepared. The steps involved in the quasi-real time validation (Mayerle and Toro, 2002) are as follows:

- prior to the measuring campaign, model simulations are carried out (for different parameters) for the period in question. For this, open sea boundary conditions on the basis of astronomical constituents can be used,

- the model results covering the measuring period are stored and brought to the field,
- during the cross-sectional measurements, the measured current velocities (using acoustical profilers) are transformed into depth-integrated values,
- comparisons between 2DH model results and measurements are done just after the completion of a cross-section,
- after the measuring campaign is achieved (12-13 hours covering one entire tidal cycle), the results taken at all the cross-sections and covering the entire measuring period are analysed and improvements in the model and/or the measuring strategy can be considered on the basis of the statistical analysis. Figure 9.11 shows the DSS in use covering a cross-section along one of the main tidal channels. Figure 9.11a shows the research vessel during the ADCP measurements. Figure 9.11b displays the resulting velocity field from the simulations. In Figure 9.11c a researcher using the DSS during the measurements is shown. Comparisons of modelled and measured current velocities, integrated over the depth, are shown in Figure 9.11d.

9.4.6 Reports

Usually a large number of graphs are created to visualise the model at several locations and certain periods of time. The DSS has been linked to MS Word and MS Powerpoint to summarise these graphs and document the conclusions of the work that has been done.

Figure 9.12 shows several plots of the flow velocities from the Meldorf Model during a tidal cycle already imported into a report. Animation of the behaviour of the velocity field during the tidal cycle can be created with this sequence of Figures.

9.5 CONCLUSIONS

Progress in field measurements and advances in numerical modelling are generating a large amount of data creating new challenges for its handling and analysis. This brings acutely the necessity of software tools to assist the researcher during development of hydrodynamic models.

The use of GIS technology in the model development brings many new capabilities and commodities to the model developer for spatial data handling and easy interaction with a relational database. This chapter shows the application of GIS as a software generator to develop a DSS that assists the modeller in integrating measured data and model results for the development of hydrodynamic models.

The structure of the DSS gives flexibility to the researcher regardless of the methodology of model development and the criteria of analysis for comparing numerical model outputs and field measurement data. It has also flexibility for coupling alternative extensions for new data sources and types of statistical analysis. The DSS also allows the storage and processing of the measured data at

the end of a measurement campaign allowing the analysis of the data and to reprogram further measuring campaigns, if necessary.

New technologies, like telemetrics, increase the possibilities of the DSS to use it in quasi-real model validation situations in which the model is prepared *a priori* and is brought to the field to compare the numerical model outputs with the measurements that are being taken. After the completion of a measuring campaign the results taken at all the cross-sections and covering the entire measuring period are analysed and improvements in the model and/or the measuring strategy can be considered on the basis of the statistical analysis.

CHAPTER TEN

Decision-Making in the Coastal Zone Using Hydrodynamic Modelling with a GIS Interface

Jacques Populus, Lionel Loubersac, Jean-François Le Roux, Frank Dumas, Valerie Cummins, and Gerry Sutton

10.1 INTRODUCTION AND CONTEXT

There are many kinds of coastal water quality issues. They arise from various sources of inputs to the coastal zone that are either chronic or accidental. Pollution of seawater mostly results from a) point source and diffuse pollution originated from agricultural, industrial and urban activities, or b) pollution from maritime activities, e.g. waste oil as well as all types of toxic substances being dumped into the sea, including radioactive ones (Kershaw, 1997).

Toxic phytoplankton blooms are a new plague. Although they are not the direct result of human behaviour, they are probably linked to human activities, and particularly contaminated ballast water. These harmful disruptions have severe effects on shellfish stocks, entailing long production shutdowns. Problems also currently exist with open sewers discharging into places designated for shellfish production or into recreational waters (Boelens *et al.*, 1999).

After flooding, there is run-off pollution from agriculture and urban areas and nitrate concentrations and bacterial counts increase remarkably. The increase in nitrate concentrations can lead to dramatic eutrophication, whereas pathogenic bacteria can make aquaculture products hazardous to human health (Lees, 2000). Other activities or phenomena such as dredging, deep water sludge disposal or landfill seepage are concerns for water quality and marine living resources (Sullivan, 2001).

While hydrodynamic modelling results and the handling of geo-referenced information are becoming more readily available to coastal management stakeholders within GIS (Geographic Information Systems), there is still a lack of direct interfacing of model results with baseline mapping data (BASIC, 2001). This paper discusses solutions to bridge this gap and illustrates them with two case

0-41531-972-2/04/$0.00+$1.50

studies where effective model outputs are being used for improved environmental management and decision-making.

10.2 HYDRODYNAMIC MODELLING BASICS

Mathematical models (Garreau, 1997) can solve geophysical fluid mechanics equations using a number of simplifying assumptions. In essence, knowledge of the bathymetry, wind tide and currents are used to predict water levels and concentrations of conservative elements over space and time.

The ability of these models to accurately and reliably reproduce the important features of complex systems has improved considerably along with rapid growth in understanding of the underlying physical phenomena, and the ability to quantify them in terms of valid mathematical formulations. The widespread and affordable availability of high-powered computing facilities has also contributed to this development, given the heavy processing loads involved in running all but the simplest models.

Confidence in the predictive capacity of models is governed by the quality of fit between modelled output data and real field measurements. Standard practice in building a typical coastal model entails a number of discrete steps, the first of which involves reconstructing the morphology of the area of interest in the form of a digital terrain model. The next step involves adding water to the system, and then setting it in motion through replication of vertical tidal fluctuations and horizontal wind friction. Together these forcing factors create gradients, which in turn drive horizontal current flows. A range of assumptions is usually made in order to simplify the system, and allow it to run effectively. It is recognised that models do not strive to exactly reproduce in detail all the features of a natural system; however the aim is to arrive at a situation where the model is capable of reliably reproducing the principal features through an iterative process of validation and calibration.

10.3 GIS FOR COASTAL ZONE MANAGEMENT

A Geographic Information System (GIS) is a computer-based information system used to digitally represent and analyse geographic features. It is used to input, store, manipulate, analyse and output spatially referenced data (Burrough and McDonnell, 1998). A GIS can be distinguished from database management systems or from visualisation packages through its specialised capability for spatial analysis. The use of GIS for coastal zone management has expanded rapidly during the past decade and references are numerous (Durand, 1994; Populus, 2000; Wright and Bartlett, 2000). For optimum efficiency, geo-referenced data should be properly stored in geo-databases built on spatial data model design (Prélaz Droux, 1995). Some of the greatest challenges currently faced by those handling coastal zone data are a) the land-sea interface, with different mapping references in both horizontal and vertical modes, b) water dynamics and the related temporal issues, and c) 3D display requirements.

10.4 TOOLS AND DATA

10.4.1 Technical details of regional and local models

MARS-2D is a bi-dimensional model using a finite difference method called ADI (Salomon, 1995). A broad regional model, extending between 40˚N and 65˚ N and from 20˚ W to 15˚ E with a 5 km grid, is used as a framework in which to embed further models of smaller extent for areas of interest along French Atlantic and English Channel coasts. Commonly, the embedding system has up to 5 levels allowing phenomena to be examined at resolutions from 1km down to 50m. This type of model is suitable for applications in areas whose waters are typically well mixed (e.g., coastal or mega-tidal areas). The model is designed to solve for tidal and wind driven currents and the transport of dissolved materials.

MARS-3D (Lazure, 1998) is a fully finite difference model, in both vertical and horizontal orientations, which uses a time splitting method based on MARS-2D for the barotropic mode. Good coupling between 2D and 3D modes has largely been achieved through the use of iterative methods. MARS-3D is used at resolutions ranging from 5 km over regional areas of epicontinental seas, down to 100 metres over detailed areas, narrow bays and estuaries. It is currently run operationally at the regional scale (with a 5 km mesh) on all French seaboards. Table 10.1 gives an overview of MARS model features.

Table 10.1 Comparison of MARS-2D and MARS-3D main features

Model	MARS-2D	MARS-3D
Area	English Channel, Bay of Biscay	English Channel, Bay of Biscay
Grid and time step	From 50m up to 10km	~ 5km, 5 – 20 minutes
Period of time	From days to decade	Year to decade
Applications	Tide currents, dissolved matter, salinity under homogenous conditions	Tide, currents, temperature, salinity, transport of dissolved matter
Type	2D Finite difference	3D Finite difference

10.4.2 The modelling system

A modelling chain has been developed at Ifremer over a period of many years. The system has a series of pre-processors and tools for the graphic display of results produced by the MARS computation kernel.

This mathematical model uses some simplified hypotheses to solve the equations that govern how marine currents and sea levels evolve. In order to function, the process requires an input water level along the edge of the area of interest. These boundaries are usually unknown locally, since they are dependent on tidal and weather conditions, which are themselves usually derived from modelling over a much larger area. Thus, the modelling process advances through the generation of a series of sequentially nested models. An initial general model covering a large area of the continental shelf and the Channel is followed by a succession of intermediate models of increasingly smaller scope, but higher resolution. Boundary conditions for the wide-area model are resolved using world tide models, into which modelled meteorological forcing factors have been assimilated. The modelling chain can be summed up as follows:

- A generated link calculates the position, extent and resolution of each sub-model, from the large-area model to the detailed high resolution model based on computational and hydrodynamic design criteria. Computational efficiency is optimised by maintaining a maximum resolution ratio (mesh size ratio) of between four and five between any two consecutively nested models. Hydrodynamic criteria are observed as far as possible in the design through avoidance of islands or zones with violent currents, although at present the system only works when model boundaries are strictly aligned to parallels and meridians. This link of the chain has a user-friendly graphic interface and generates a descriptive file of the entire nesting process.

- The second link in this computation chain is a software program which calculates an interpolated bathymetry for each nested model. The link also has a graphic interface developed in UNIRAS, which restores a depth for each calculation link in a file. The bathymetry used for the large-area model has been validated, and is essentially taken as fixed. However, it is updated on an occasional basis, as new information becomes available. The MARS-2D computation kernel is used in both case studies below, where prevailing tidal currents have a relatively homogenous vertical structure, providing a good approximation of the mean current fields pertaining in the study areas.

- Lastly, a range of graphic tools are used to display the resulting modelled outputs which are written in NETCDF format (Rew and Davis, 1990). NETCDF is a widely used self-documenting format, which also provided a suitable platform upon which the ArcView portal was subsequently developed.

10.4.3 Reference mapping data

Currently, coastal practitioners must refer to common baseline or reference data, i.e., primary data to which secondary (or more application-related) data will be subsequently linked (Allain, 2000). The coastline, bathymetric data, and major administrative boundaries are examples of such baseline data that could be readily

provided to a wider public under optimal conditions of accuracy, updating, and scalability to suit various needs.

However, it is noted that the bathymetry of inter-tidal areas, and other near-shore zones, is often less easily available or poorly defined. Such paucity of data is usually associated with the high cost of acquisition and restricted accessibility. Bathymetric data for the two study sites under consideration was available from the French hydrographic service at a scale of 1:50, 000.

ArcView™ was the main GIS platform used for the studies, within which the Spatial Analyst™ extension facilitated a number of operations on raster images such as recoding, resampling, changing extent, computing statistics and the use of algebraic image combination functions. Existing ArcView functionality also facilitated interactions between raster and vector data layers drawing on the attributes of file features attaching to vector data sets. However a major hurdle remains in the efficient handling of large numbers of raster data layers that typically accrue as the output from multiple model runs.

10.4.4 An Integrated GIS/model interface

The primary rationale behind the creation of a GIS/model interface was to allow a) consultation and display of results contained in the output files produced by the MARS hydrodynamic model; and b) extraction of these results to import them to ArcView. The concept was initially tested through the development of ModelView (Loubersac *et al.*, 2000), a prototype interface the functionality of which was successfully demonstrated in the case of hydrobiological contamination in the Bay of Marennes-Oléron, France.

As a further development, in order to broaden the scope of application a platform-independent stand-alone interface, MODELCON, was designed for use in conjunction with a range of GIS packages. In order to ensure optimum compatibility with standard software packages and other GIS (e.g. Excel, MapInfo™ etc.), MODELCONV extracts NETCDF files to a standard ASCII format. The MODELCONV interface was developed in JAVA, with Microsoft's Visual Studio 6 environment and the JAVA library to access NETCDF files (NETCDF JAVA version 2), ensuring maximum portability in anticipation of future use on Unix systems or via the Web.

10.4.5 A Geographic conversion module

An additional processing module was developed in order to address specific geoprocessing requirements beyond those available in the standard version of ArcView. This module operates as an ArcView extension and was implemented in Avenue. It enables the user to perform a range of geodesic processing operations on point, multipoint, polyline and polygon data, as well as 2-D and 3-D related measurements (pointM, multipointM, polylineM, polygonM, pointZ, MultipointZ, PolylineZ, PolygonZ).

This module also allows data to be projected or unprojected, i.e. as geographic co-ordinates (latitude, longitude), or projected Cartesian co-ordinates including 3-D (X, Y, Z). Other operations that are supported include:

- switching between geodesic systems: WGS 84, NTF and Europe 50;
- switching ellipsoids: Clarke 1880, IAG GRS 80 and Hayford 1909;
- switching projections: Lambert (various), Transverse Mercator (UTM).

10.5 CASE STUDY ONE: SHELLFISH PRODUCTION IN THE GOLFE DU MORBIHAN, SOUTHERN BRITTANY

10.5.1 Water quality issues in the Golfe du Morbihan

The Golfe du Morbihan is located in southern Brittany, France. Enclosing an area of 125 km^2, with many islands and extensive intertidal flats, the basin connects to the open ocean via a 1km wide channel. Its perimeter is highly indented, and is traversed by numerous streams and rivers. The main anthropogenic pressures related to two main cities, Auray (11,000 inhabitants) and Vannes (50,000 inhabitants), are augmented by very significant seasonal tourist populations. Important natural shellfisheries (*Venus* spp.) are commercially exploited, and the gulf also supports a valuable oyster farming industry. Both rely on suitable water quality being maintained within narrow sanitary limits. In general, water and shellfish quality criteria are set by the EU Shellfish Hygiene Directive (Lees, 1995). However, at national level slight differences are found in the interpretation of shellfish hygiene *E. coli* guidelines, specifically in stating what proportion of samples must fall under the concentration thresholds and in the treatments required prior to human consumption (BASIC, 2001). In France, these values are defined by the modified decree n° 94-340 of 28 April 1994, as shown in Table 10.2 below. Shellfish farmers must take different measures for depuration with respect to these categories.

Table 10. 2 French shellfish hygiene categories

Categories	**Level of contamination in faecal coliforms***			
	300	**1,000**	**6,000**	**60,000**
A	≥ 90%	≤ 10%	0%	
B	≥ 90%		≤ 10%	0%
C	≥ 90%			≤ 10%
D				> 10%

* per 100g shellfish

10.5.2 Microbiological modelling

Faecal coliforms (FC), of which *Escherichia coli* is a major component, are good indicators of bacteriological contamination levels in seawater and shellfish. EU health standards for recreational waters and shellfish harvesting zones are based on organism counts. These bacteria mainly come from rivers and streams which receive waste water from various sources including surface runoff and soil outwash, sewage treatment plant discharges (especially in heavy rainfall situations, when function is impaired by lower residence time) and unauthorised discharges. Other direct sources are storm water drain systems discharging directly into the sea and diffuse contamination in the vicinity of moored boats.

Coliform bacteria do not tolerate exposure to solar UV radiation, and thus have a limited life span in seawater. Their survival time will vary depending on their metabolic state and environmental conditions. Bacterial survival times are positively influenced by the following:

- lower winter temperatures which can slow down bacterial metabolism and extend survival based on slower rates of consumption of energy reserves;

- increased turbidity values, linked to levels of suspended solids. Turbidity has a dual effect, as a potential food source and as protection against solar UV (ultraviolet) radiation. Turbidity is usually higher in winter, due to greater discharge and sediment resuspension.

In general modelling applications, bacterial survival is represented by the term T90 (being time at which 90% of the bacteria will have disappeared), which assumes an exponential rate of decline in numbers. Values for T90 are normally established on an empirical basis, and those used in the current study were based on experience at local sites (Guillaud, 1997).

10.5.3 Simulation descriptions

In order to characterise coliform distributions under a range of environmental conditions, a series of MARS 2-D model simulations were undertaken in which the following parameters were varied:

- Tidal conditions. Simulations were made over a period of three weeks under realistic tidal conditions, i.e. of sufficient duration to capture both spring and neap cycles.

- Seasonal influence. This was investigated by varying discharge volumes, i.e. coliform flux.

- Weather conditions. Three sets of commonly prevailing conditions were selected, in accordance with wind statistics derived from data supplied by the French meteorological office. These were 1) zero wind (baseline condition), 2) westerly $8 m.s^{-1}$ and 3) north easterly $8 ms^{-1}$.

- T90s. A summer value of 10h, with 24h for winter was chosen in accordance with local measurements.

- The impact of major malfunctioning of water treatment plants in heavy rainfall periods. This was modelled by doubling the amounts of bacteria discharged over a 24-hour period, which is typical of what can occur during a summer storm. The objective was to investigate the impact of episodic events on coliform distribution, particularly with respect to existing zonation patterns.

The above scenarios were investigated through a combined series of seven simulations (two seasons under three different conditions, plus one exceptional situation type). In order to assess the validity of the simulations, the resulting coliform concentration distributions were then categorised according to EU shellfish farming criteria (Table 10.2). Model-derived zonation patterns were found to be in broad agreement with existing zonation plans based on both tissue sampling and water quality monitoring network samples.

10.5.4 Simulation results

Having established the overall validity of modelled results, priority was given to locating the zones likely to be subject to the highest contamination. These were found to be in upper reaches of the main rivers and in the bay of Vannes (Figure 10.1). Observations performed during model runs indicated that once steady state conditions are attained, the spring/neap tidal coefficient has little influence on subsequent coliform concentrations. The impact of a constant, moderate wind (8 m/s) on contamination plumes was imperceptible, both in summer and winter. In the summary of results, only the baseline “no wind” situation is referred to.

T90 was found to exert the greatest influence on coliform concentration, and when set to 24hours gave rise to the highest levels of contamination. This is reflected in the final model run for which a 24h T90 linked to winter discharge rates was chosen.

10.5.5 Comparison between the actual classification and a simulation

Figure 10.2 shows the results of zonation categories based on samples collected by the water quality monitoring network (Ifremer, 2003). Zonations are based around 30 such samples per site that are routinely collected over the course of each year at low water during each spring tidal cycle (theoretically least favourable situation). Dots indicate the locations of effluent discharge sources. Figure 10.2 clearly shows the main water body of the gulf officially ranked as category A, whilst the estuaries and their outlets (north and northeast) are in the B or D categories. It is notable that no estuarine areas have been zoned in the C category and have instead been allocated to category D as a precautionary measure in respect of the EU Shellfish Directive. This precautionary designation takes into account the obvious

risk of contamination near urban and port areas, as well as the impact of reduced salinity on mariculture products in upper estuarine reaches.

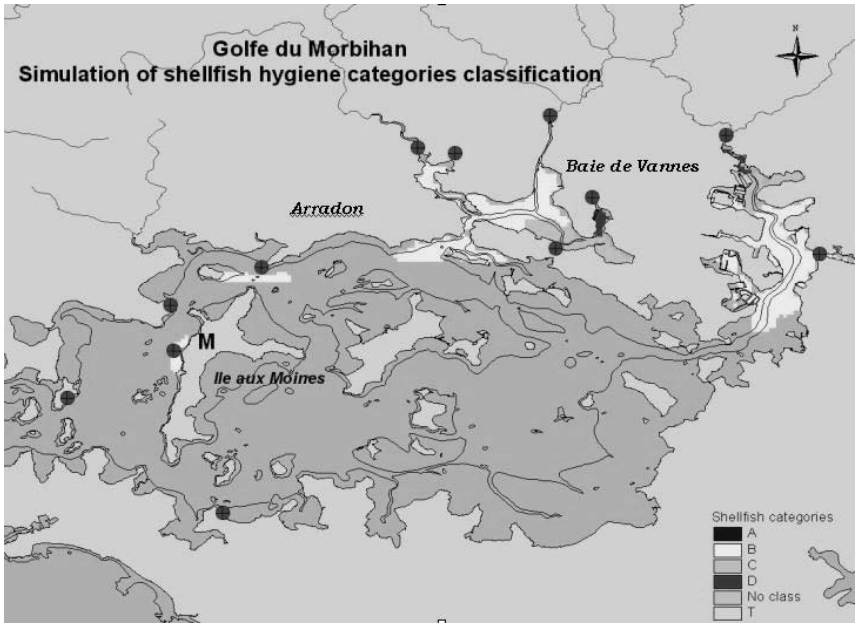

Figure 10.1 Screen capture from GIS showing the Golf du Morbihan. Coloured areas denote EU shellfish classifications based on simulated coliform concentration distributions

Comparing the results highlights the good consistency between simulation results and those obtained from monitoring network observations. Whilst the general configuration of zonation categories (Figure 10.1) based on simulations is broadly consistent with the official classification scheme (Figure 10.2), the former logically appears to give rise to a less conservative regime under which the estuarine areas in the north and northeastern gulf are designated as category C, rather than the precautionary official D designation.

This may be explained by the relative shortness of the period simulated (3 weeks), whereas the official designations are based on an annual monitoring cycle. Other reasons may be that the coliform flows used for the simulation did not include the annual maxima (in the case of water collection and treatment plant malfunctions). Furthermore the actual T90 may exceed the 24h value used in simulations, especially in naturally turbid upper estuarine areas, or as a consequence of winter storm induced sediment resuspension.

By comparing the Figures where the discharge points are identified by a dot symbol, we also note that the model, which minimised coliform concentration levels as seen above, reveals two B category zones in the outer Bay area. These can be seen in Figure 10.1, located to the north and to the west of the Ile au Moines (the island is indicated by an M on the map). Their coincidence with

effluent discharge points (dots) suggests the logical cause of reduced water quality in these areas. This result highlights the valuable insights that can be obtained through the use of realistic simulations based on numerical models in identification of localised water quality issues, which may then be addressed through the allocation of additional monitoring resources. In this case, priority was given to the northern most area (associated with effluent discharge Arradon) owing to its proximity to significant shellfish farming areas, resulting in the establishment of an additional hygiene monitoring station.

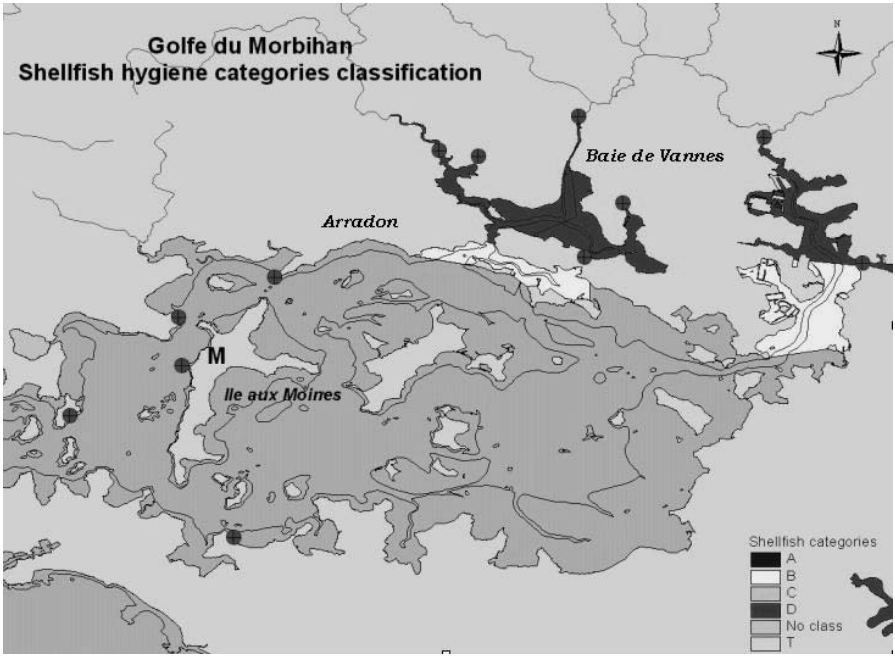

Figure 10.2 Screen capture from GIS showing the Golf du Morbihan. Coloured areas denote EU shellfish classifications based on measured coliform counts.

10.6 CASE STUDY TWO: THE WRECK OF THE *IEVOLI SUN*

10.6.1 Context of the case study

The Italian chemical tanker, *Ievoli Sun*, sailing from Rotterdam to Genoa sank around 9 am local time on 31th October 2000 in the central English Channel, approximately 9 nautical miles north of Les Casquets (Channel Islands) and 20 nautical miles west-north-west of the French Cap de la Hague off the north coast of Normandy (Figures 10.3 and 10.4).

Figures 10. 3 and 10.4 *Ievoli Sun* being towed a few hours before she sank (French Navy sources).

The vessel was carrying three chemical products: 3998 tonnes of styrene (Vinylbenzene), 1027 tonnes of Methyl ethyl ketone (MEK or 2-Butanone) and 996 tonnes of Isopropyl alcohol (Propanol-2). Although the latter two products are considered to be practically non-toxic for aquatic life, styrene is known to be hazardous for the marine environment and for humans. According to the Group of Experts on the Scientific Aspects of Marine Pollution of the International Maritime Organisation (GESAMP, 1989) styrene is bioaccumulable with a propensity to affect edible marine resources. Moreover, it is dangerous for human health when in contact with skin or when inhaled. It can cause major environmental problems due to its persistent irritant toxic odour, which can force the closure of beaches.

French Naval investigations in the aftermath of the sinking showed that the wreck was lying on her port side, and subsequent remotely operated vehicle (ROV) surveys confirmed that the hold was ruptured with a consequent release of styrene into the marine environment.

The wreck was located close to the Channel Islands, in an area of high biodiversity, and in close proximity to shipping lanes, cross-channel traffic, fisheries, aquaculture, and beaches. Neighbouring coastlines are rugged and highly indented, with many sensitive and vulnerable sites, and are under the jurisdiction of several different regional authorities, including those of the Channel Islands.

A rapid response team including experts in pollutant chemistry, ecotoxicology, modelling, fishery science, aquaculture and digital mapping was assembled within two hours of the sinking. The prime objectives of this group were to establish a baseline for environmental contamination, and devise a plan for coastal environmental monitoring in the subsequent hours. This meant being able to characterise the fate of pollutants in the water mass and identify sensitive areas and fish species likely to be affected. Thus the main requirements were (Loubersac *et al.*, 2002):

- to rapidly compile various forms of multi-thematic information from multiple sources;

- to provide simulations of pollutant dispersion at sea for several scenarios in the shortest possible time;

- to standardise these compilations and simulations and make them easy to display, communicate and update for simultaneous use across several decision centres.

10.6.2 Simulation of pollutant behaviour using MARS-2D

The MARS modelling suite (Salomon *et al.* 1995; Garreau 1997) was used to rapidly derive a 500m horizontal mesh hydrodynamic model centred on the wreck position. A 2-D horizontal model was adopted to simulate the local hydrographic regime, where dissolved substances were likely to become well mixed owing to the strength of prevailing tidal currents which are relatively consistent throughout the vertical extent of the water column. Actual wind fields supplied by the French meteorological office were also assimilated into the model.

Simulations were run to reproduce the evolution of instantaneous and residual tidal current fields, tidal trajectories and concentrations of the dissolved fraction of the spilled products. The following three scenarios were considered assuming maximal dissolution of the styrene in seawater: a) a single total discharge of 4,000 tonnes, b) simulation of 4,000 tonnes of the product leaking from the wreck over a period of 3.5 days, and c) simulation of continuous discharge of 20 $l.min^{-1}$ over 25 days (closely matching observed leakage rates).

10.6.3 Setting up a customised GIS

A GIS was established for the wreck site and surrounding maritime region, in which functionality was tailored towards handling and visually representing marine and coastal data. The main steps in this process were:

- Building a reference geographic data set (Allain *et al.*, 2000) in order to ensure stakeholder interoperability;
- Conversion of all data into decimal degree geographic coordinates, and establishing a common vertical reference frame for marine and land-based topographies;
- Adoption of a uniform map template for all data layers optimised for a standard working scale of 1:50,000.

10.6.4 Results

The *Ievoli Sun* sank in an area in which strong tidal currents and an irregular seabed give rise to intense vertical mixing. Under these conditions it is reasonable to assume that styrene escaping from the wreck became rapidly dispersed throughout the water column. A 3-D perspective view showing the spatial extent of dispersed styrene as it appeared after 10 days of simulated advection is illustrated in Figure 10.5. This simulation was based on scenario c) with the following assumptions: *i)* the matter coming from the wreck dissolved completely, *ii)* there was no chemical modification over time, and *iii)* an average current was responsible for the transport of these dissolved substances.

The image presented in Figure 10.5 was produced by merging modelled data with those from the GIS mentioned above, using ArcView 3D Analyst. This image corresponds to the situation on the 9th November at 2 am (10 days after the spill), taking into account the atmospheric forcing data provided by the French meteorological service. The concentration limits indicated on this Figure are 0.30 ppm (parts per million or mg/l) (darkest), 0.15 ppm (lightest), and 0.05 ppm (medium-grey) in the raised area.

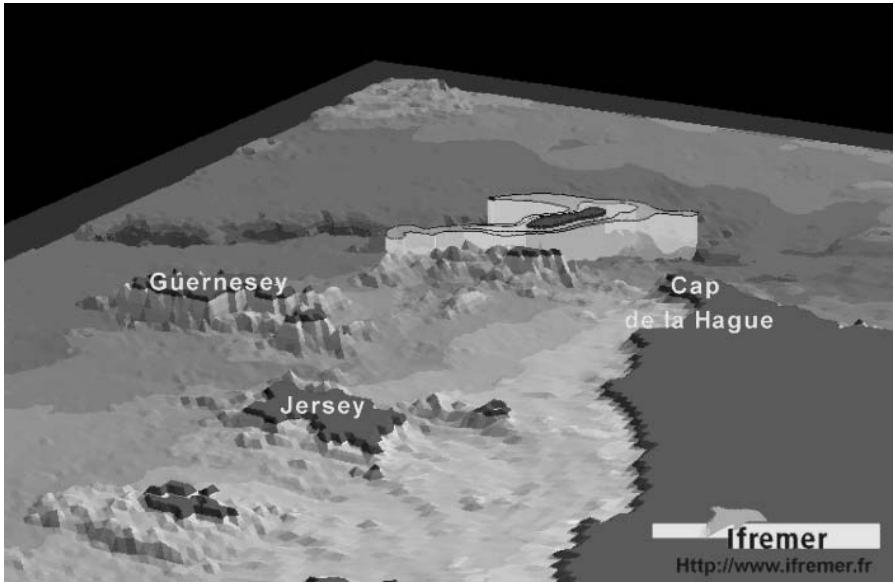

Figure 10.5 3D perspective representation of the plume of dissolved pollutant dispersion after 10 days.

Dispersion of a continuous discharge of 20 $l.min^{-1}$ was also simulated for the period between 30th October and 24th November, incorporating actual wind measurements up to the 19th November and forecasts for the remainder of the simulation period. Plate 10.1 shows the situation at the end of the simulation (24/11/00 at 0600) with contaminant concentration expressed in parts per million (ppm). While the bulk of the dilution patch is located along an axis running East North East – West South West across the wreck site, a distinct branch can be seen extending southward towards the island of Alderney. However, seeing the very low flow simulated, the concentrations of dissolved product in the water column remain extremely low, since the highest concentrations reached in the simulation did not exceed 0.056ppm. However it should be noted that the overall concentrations remained below 0.056ppm throughout the water column; such low values are however consistent with expectations given the low rate of discharge.

10.7 CONCLUSION AND PERSPECTIVES

An operational model of the Golfe du Morbihan was constructed, which successfully reproduced the hydrodynamic regime of the study area to within acceptable tolerances. The model has also been used to effectively simulate patterns of bacterial dispersion, the results of which were generally in accordance with officially established shellfish zonation patterns, based on the sampling regimes of local water quality monitoring networks. Time-series of computed concentrations for specific locations can be extracted from existing model runs, and can be selected to correspond with monitoring sites. The approach thus provides a means of optimising sampling programmes to make best use of available resources, and to improve responsiveness to episodic events with potential consequences for health.

The present arrangement and state of development of these modules allow a user to work effectively with a given number of grids generated as output from a limited number of modelled scenarios. Future developments aimed at automation would reduce the time needed to process and import results, while maintaining the traceability of actions run and all the metadata required to understand and analyse the simulation results. To this end, future efforts will be concerned with improvements in the following areas:

- Ensuring that model-run relevant metadata which is integral in NETCDF files is fully maintained throughout the processing chain;
- Transforming the tables that MODELCONV generates into Arcview grids;
- Implementing batch processing tools, both on the MODELCONV level and to select user-defined time steps, and on operations between variables to generate more synthetic results than in ArcView, and to import a series of files and automatic captioning for them.

The effectiveness of the *Ievoli Sun* pollution response can be attributed to the favourable platform upon which it was based. Pre-existing tools could be activated within 48 hours, facilitating rapid delivery of environmental maps incorporating hourly forecasts of styrene slick position and concentration. Prudent diagnoses of the potential effects on marine life could then be made in the light of various leakage scenarios. Integration was made possible by providing consistent geo-coded information on the land-sea interface, through a GIS interface closely connecting these data and simulations issued from digital models. Integration of consistent geo-coded information on the land sea interface with model simulated outputs within a GIS environment has resulted in the creation of an active interface for pollution response decision makers that incorporates up-to-the-hour scientific assessments.

A further logical extension of this work would be to jointly use hydrodynamic, sedimentological and biological modelling combined with GIS. Links with catchment models to allow regional-scale assessments of human activities (e.g. agriculture) and natural events (e.g. flooding) should also be considered. Planned future work will incorporate sedimentological and biological

process modules into the existing hydrodynamic modelling/GIS schema, thereby increasing the diversity of assessments that can be made. Critical coastal management issues including bacterial and viral contamination of bathing waters, occurrence and impact of harmful algal blooms, eutrophication, and definition of coastal water masses (e.g. in relation to the EU Water Framework Directive) could then be addressed.

It is anticipated that schema will ultimately be extended in order to incorporate links with catchment models, thereby allowing regional scale assessments of human impacts (e.g. agriculture) and natural events (e.g. flooding).

CHAPTER ELEVEN

Towards an Institutional GIS for the Iroise Sea (France)

Françoise Gourmelon and Iwan Le Berre

11.1 INTRODUCTION

As far as coastal zones are concerned, many challenges faced by the scientific community and policy makers, planners and managers justify adoption of a transdisciplinary approach based on bio-chemical, geophysical and socio-economical factors (Burbridge and Humphrey, 1999). GIS are well-established computer-based systems for storing, retrieving, analysing, modelling and visualising the vast amounts of spatial data that may be collected by several providers (Fabbri, 1998). Nevertheless, the implementation of a coastal database is a complex process which requires institutional support to guarantee the multidisciplinary approach, the sustainability of the project in terms of raising funds and human resources, and to promote relationships with other institutions working on the same area (De Sède and Thiérault, 1996).

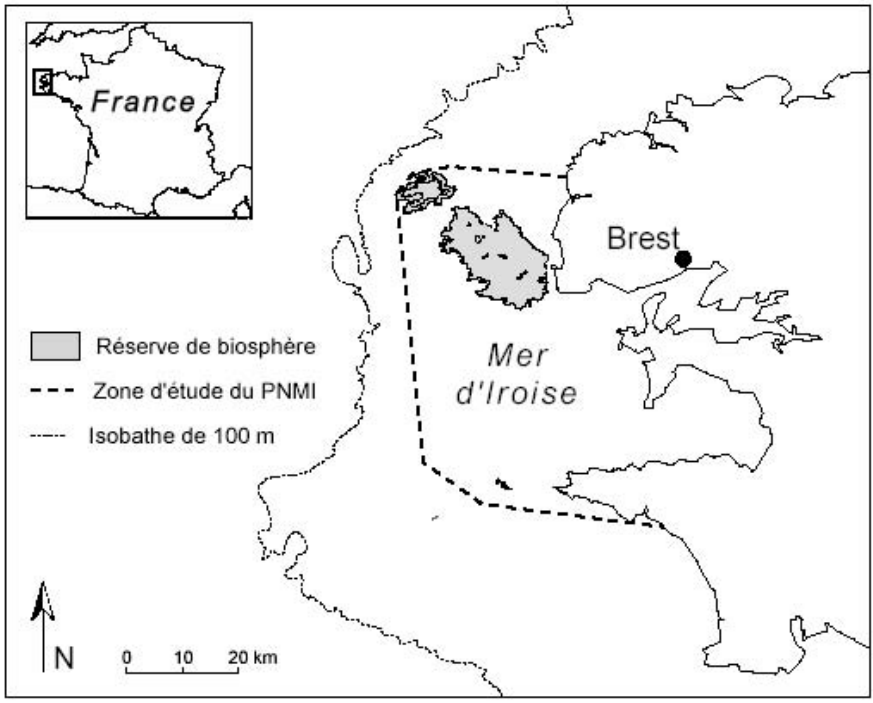
The major pollution caused by the *Erika* disaster, coupled with the catastrophic storms which reached the Atlantic coastal zone at the end of 1999, has led the French authorities to propose creation of a national coastal GIS. The implementation of such a project is complex, witnessed by the lack of any decision about which reference geographical data for the coastal zone to adopt (Allain *et al.*, 2000). In fact, coastal data are scattered among many organisations. They are produced for lots of purposes and therefore are available at various scales, typologies and formats. In spite of these difficult conditions, there are a number of smaller, independent GIS projects at work on the French coastal zone (ENR/OELM, 2000; Guillaumont and Durand, 2000).

This contribution describes the GIS implemented by Géosystèmes laboratory (CNRS, European Institute for Marine Studies) on the coastal zone of Finistère (western Brittany, see Figure 11.1) during the last ten years. In the beginning, the GIS was conceived as a support tool for monitoring and managing the Biosphere Reserve of Iroise, but today, it also serves as a powerful tool for carrying on integrated research on the coastal zone of the Iroise Sea, especially within the framework of the European Institute for Marine Studies (Institut Universitaire Européen de la Mer, IUEM). This latter institute brings together a number of

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

separate marine research teams from the University of Western Brittany, Brest, dealing respectively with oceanography, geology, biology, chemistry, geography, economy and law. The development from a GIS dedicated to scientific applications towards an institutional support is described below.

Figure 11.1 Study area



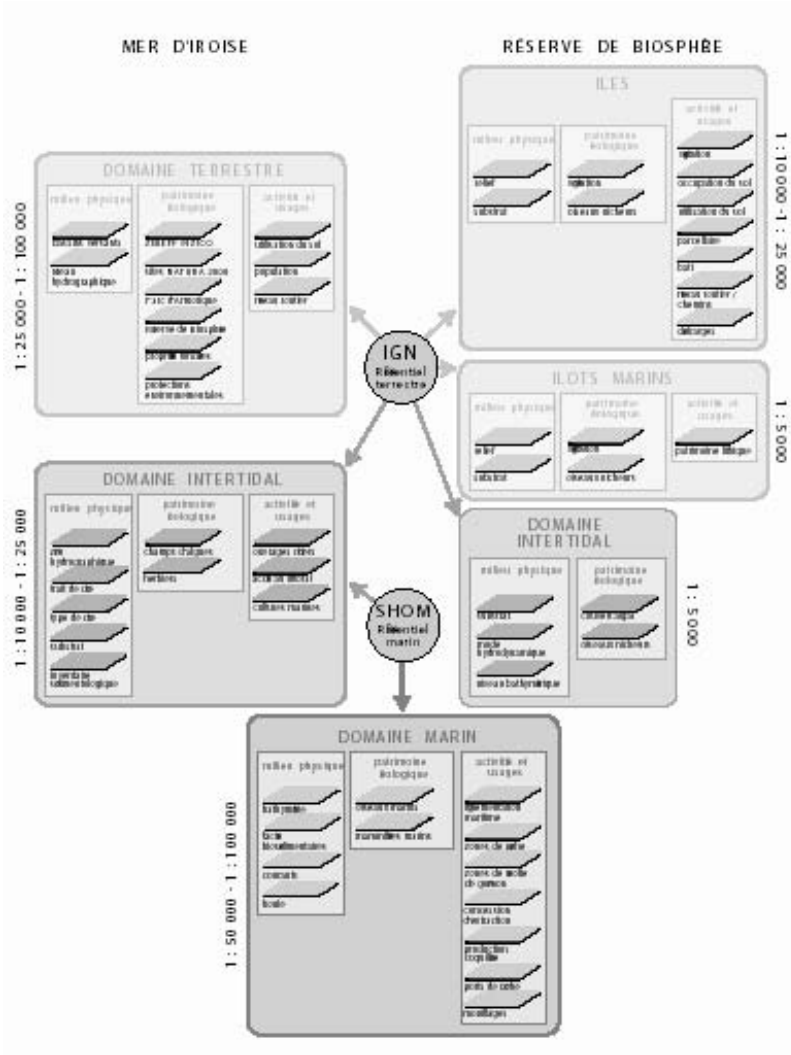
11.2 THE DATABASES

Nowadays the GIS supports two complementary databases, called *SIGouessant* and *BIGIroise*, that were originally developed with separate objectives and data (see Figure 11.2).

The *SIGouessant* database deals with the Mer d'Iroise Biosphere Reserve at a local scale. The biosphere reserve label is allocated to representative terrestrial and coastal areas by the UNESCO Man and Biosphere (MAB) programme. The conception of such an area is based on three main functions: conservation of biodiversity and landscapes; sustainable use in regional units; and logistic support for research, monitoring, education, information and involvement of the local population. In this context, many thematic studies have been performed on the Mer d'Iroise Biosphere Reserve to increase knowledge of dynamic terrestrial and marine processes, and to study the aftermath of human activity such as tourism, management and fishing on biodiversity. The objectives are to provide a basis for land management recommendations as well as for wildlife management

programmes. The *SIGouessant* database has been developed since 1990 as a support to the long term ecosystemic approach, and to provide data for scientific and management investigations (Gourmelon *et al.*, 1995). The geographic reference data is provided by orthophotographs produced by the French National Geographical Institute (IGN - Institut Géographique National). The thematic layers describe physical, natural and social parameters with the same classification systems and scales, collected at various dates thanks to continued monitoring.

Figure 11.2 Database organisation



The *BIGIroise* database is an extension of *SIGouessant* to the whole coastal area of the Iroise Sea. Its initial aims were to produce a synthetic environmental

mapping through combination of multiple data sets available for the coastal zone (Le Berre *et al.*, 2000). The database uses marine geographical information produced by the French hydrographic service (SHOM – Service Hydrographique et Océanographique de la Marine), and is built up according to the environmental planning methods developed and proposed by the Unesco MAB committee (Journaux, 1985). After the collection of existing digital data, and the digitisation of other data sources (atlases, maps, etc.), 34 thematic layers, concerning physical, biological and socio-economical parameters for marine and terrestrial areas of the Iroise Sea have been integrated in the GIS (see Figure 11.2).

After ten years of functioning, this GIS has become an adopted tool for data inventory, environmental analysis and decision-making, which have been described by Crain and Mc Donald (1984) as three development stages of a GIS.

11.3 OVERVIEW OF IROISE GIS APPLICATIONS

11.3.1 State of the knowledge

After the development of a set of tools for data processing and analysis, using techniques such as association, combination and generalisation, the resulting databases have been used to compile a baseline assessment of the state of knowledge regarding the marine and terrestrial environments of the Iroise coastal area. This has allowed the production of an atlas for public communication (Gourmelon *et al*., 1995), and the creation of a synthetic map showing the potential conflicts of interests in the Iroise Sea (Le Berre, 1997). These documents are used to support discussions among the stakeholders.

However, this inventory of existing knowledge also shows that the quality of available data is heterogeneous — especially in terms of exhaustiveness and age — though strong efforts to collect and structure data on the Iroise Sea have been made by a number of scientific and institutional organisations. One of the main difficulties lies on the compatibility of marine and terrestrial geographical reference data. Although the compatibility is essential for database coherence, we are still waiting for a national consensus (Alain *et al*., 2000) on this issue. Other difficulties come from the lack of knowledge about the marine environment. The structure and the functioning of the Iroise Sea ecosystem remains barely understood. Moreover, except for some legal aspects, scarcely any geographical information dealing with human activities is available.

GIS offers many functions that may be used to bypass these problems: For example, the database can help define sampling strategies to be used for collecting additional marine biological data; and it may also provide relevant data for the implementation of theoretical models of ecological population distribution, based on the applications developed for the US Gap Analysis project (Davis *et al.*, 1990). The population models used for Iroise Sea are based on physical parameters such as bathymetry, sedimentology, and hydrodynamic features (marine currents and waves) and have been tested successfully on seaweeds and on the bottlenose dolphin (*Tursiops truncatus*, see the next section, below). Furthermore, integration

with remote sensing allows the production of synoptic and multi-temporal data that are particularly useful for marine studies, because of the variety of the sensors used for recording parameters such as water colour, sea surface temperature, shore morphology, etc. (Van Zuidam *et al.*, 1998).

11.3.2 Environmental issues

GIS is now widely used for applications relating to terrestrial studies and management issues. In landscape ecology especially, the capabilities of GIS are successfully used to perform spatial and statistical analysis of many environmental components, and for modelling real-world processes (Haines-Young *et al.*, 1993). In the islands and the islets of Iroise Sea, many similar GIS applications are concerned with exploring relationships between vegetation and land-cover changes, fauna (rabbits and nesting birds) and human activities. For example, land-cover and land-use changes of Ushant island over a 150-year timeframe have been studied, using field studies, aerial photographs and the 19th Century land registry (Gourmelon *et al.*, 2001) as primary sources of data. Over this period, the island underwent a drastic transformation from rural landscape to extensive shrubland. Only traditional extensive sheep breeding is actually maintained. Within a GIS analysis, the relationships between sheep grazing and land-cover have been established, and scenarios of land-cover potential related to changes in the intensity of sheep grazing produced. The scientific results have provided an objective framework for further assessment of fallow land management.

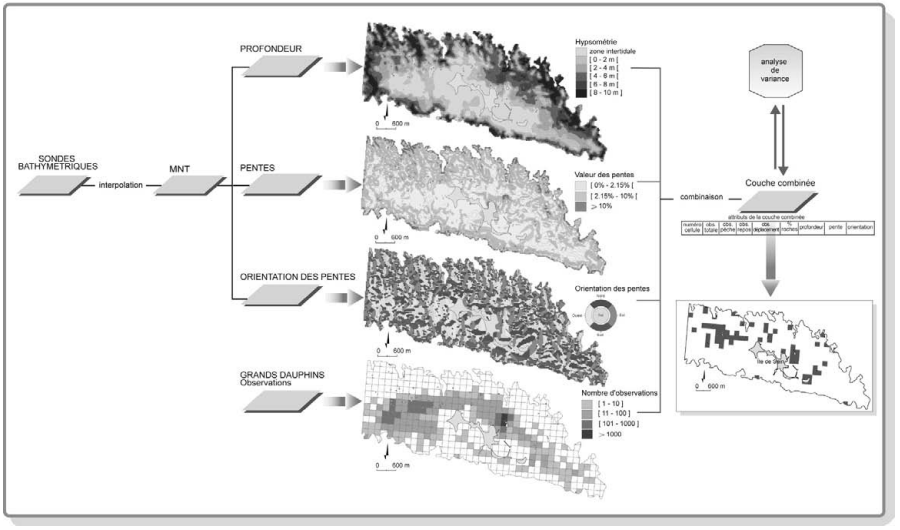


Figure 11.3 Investigating factors influencing spatio-temporal distribution of bottlenose dolphin (*Tursiops truncatus*)

In contrast to these successes on-shore, the implementation of GIS is more difficult in the marine environment due to the peculiarities of maritime space-time

scales, which tend to be generally wider, more complex and less well-known than those of terrestrial ecosystems. A regional approach to marine environments is often required, and data collected at several spatial and temporal scales need to be integrated, for example data relating to the dynamic component of biological and hydrological parameters that may occur daily (like tides), seasonally or annually (like lunar and biological cycles), or that may only be noticeable over several years and decades, such as long term changes (Holligan, 1994). This complexity implies a need to link the GIS to models for the production of dynamic data, i.e. hydrodynamic modelling, and for the analysis of the functioning of the whole system and its subsystems (Capobianco, 1999).

As has already been mentioned above, within the Iroise Sea one area of data analysis aims to investigate the environmental factors that may influence the spatio-temporal distribution of the bottlenose dolphins (see Figure 11.3). In France, the increasing interest in natural heritage has encouraged development of resource management efforts that maintain a high degree of biodiversity. In this context, a Marine National Park project has been proposed for the Iroise Sea, which would include both the areas of coastal bottlenose dolphins. A spatial and temporal approach to the dolphin habitats is required to define a conservation strategy based on habitat features, more than on spatial distribution of groups. Such an approach has been developed in the United States through the Gap Analysis Program conducted by the U.S. Geological Survey (Davis *et al.*, 1990), and is being adapted for the Iroise Sea. Within this wider framework, a more localised study is focusing on a particular group of dolphins observed around Sein Island, and which has been monitored since 1992 (Gourmelon *et al.*, 2000). The annual and seasonal distributions of this dolphin group reveal some preferential sites inside its vital area. Investigating the factors leading to this perceived spatial determinism requires that spatio-temporal parameters be considered, and is thus well-suited to GIS analysis. Meanwhile, at a more regional spatial scale, a classification of bathymetric parameters has been performed to produce a sea-floor stratification that may be compared to observations of bottlenose dolphin distributions (Le Berre *et al.*, 2002). At both scales, local and regional, strong relationships appear between bottlenose dolphin distribution and topographic sea-floor features. The GIS is subsequently used for dolphin habitat suitability modelling, based on logistic regression. This methodology provides a means of mapping the dolphin distribution, and providing useful information for the future National Marine Park. Nevertheless, distribution of prey with depth of slope and hydrodynamic activity is probably of prime influence. The next step of this research will be the introduction of physical and biological modelling in the GIS. The synergy between numerical models and GIS is necessary for the production of dynamic data useful in such an investigation.

11.3.3 Contribution to integrated coastal zone management

A large part of the Iroise coastal zone belongs to protected areas of various types (natural reserves, hunting reserves, biosphere reserve, proposed national marine park, etc.) for which there is a strong need for scientific long-term monitoring, and also of concrete strategies and policies for management. In such contexts, maps are

essential, both for decision-making by field staff, and also for information communication aimed at the stakeholders involved (decision-makers, managers, scientists, etc.). The integration of data from various sources within a consistent framework, as provided by a GIS, improve their accessibility and their availability. GIS also provides efficient functions for rapid production of thematic or synthetic maps and other visualisations, designed for different purpose. Above all, GIS shows great potential for the design and the production of good quality maps tailored to specific uses, such as decision-support during a specific critical event such as an oil-spill, particularly if the mapping process is automated. For instance, in the environmental monitoring programmes implemented for the Iroise sea, the GIS is used for the preparation of sampling strategies, for the detection of spatial changes, for the assessment of future evolution, and for impact simulations.

The assessment and simulation of impacts or changes that affect coastal areas are generally made within the scope of management strategies and policies (Capobianco, 1999). Spatio-temporal modelling, coupled with geographical databases may be very efficient for the production of realistic syntheses of an ecosystem's evolution after different disturbances. In such an integrated and multidisciplinary context, the design of operational tools for decision support depends on the upholding of links between numerical geographical information and other databases, on the integration of spatio-temporal modelling and on the production of user-friendly interfaces that facilitate access to information.

In order to test the ability of *BIGiroise* as an operational tool, the geographical information available for the tidal zone of a limited part of the Iroise Sea was used as a test bed for the development of a model dedicated to oil spill contingency (Le Berre, 1999). It takes into account the relevant data for assessing the sensitivity of coastal areas in order to prepare and to plan the strategies of intervention and to provide useful information for the monitoring of damaged sites (see Figure 11.4). In a practical way, shore sensitivity is assessed through morpho-sedimentary, ecological and socio-economical indices (Michel and Dahlin, 1997) but, for the production of a relevant information for operational needs, vulnerable areas exposed to the pollution risk must be identified. The assessment of risk requires that meteo-oceanic and physico-chemical features of the pollutant be taken into account. This can only be achieved within a spatio-temporal model. In this operational context, the GIS may provide information, especially maps, useful for helping decision-making, but this is only a part of a more comprehensive facility that should be implemented. An efficient system for such purposes requires significant extensions such as oil spill drift models, links with thematic databases (i.e. about pollutant composition) and the production of users interfaces (Howlett *et al.*, 1997).

11.4 PLAN FOR AN INSTITUTIONAL COASTAL ZONE INFORMATION SYSTEM

The research programme described herein demonstrates the contributions and the limits of the GIS implemented for the Iroise Sea. The major issues are now its timelessness and the improvement of its ability to produce a better knowledge of environmental and socio-economical processes in the aim to provide useful

information for decision-making. It implies in a next step an integration into a more efficient framework (see Figure 11.4). An integrated environmental coastal zone management system, for assessing coastal zone changes and functioning, should integrate remote sensing, modelling, GIS and GIS-based decision support systems (Van Zuidam *et al.*, 1998).

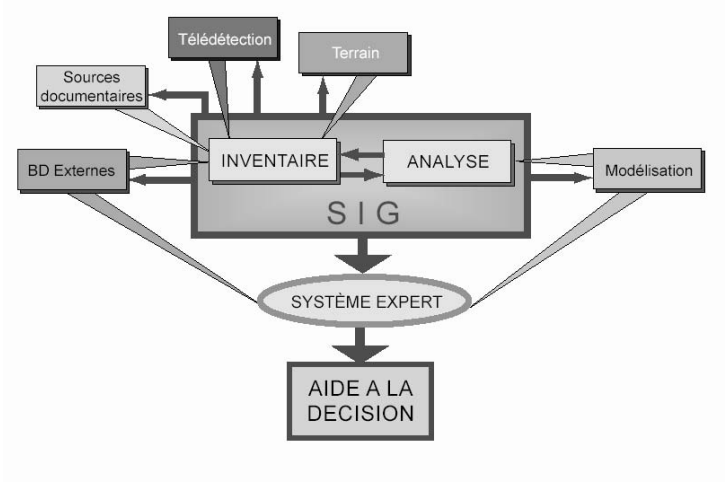

Figure 11.4 Development of an operational GIS

11.4.1 Context and objectives

The GIS developed for the Iroise Sea is an essential component of the infrastructure established to support environmental research programmes conducted by the "Géosystèmes" laboratory. The GIS is used for scientific analysis, to improve the protocols for field data collection, and in some cases to provide decision-making information such as maps and statistics. Due to its environmental characters, the Iroise Sea is the core area of most of these research programmes, sometimes spanning several decades. A proposal has been submitted by the component research units within the laboratory, to the national authorities, to establish a Coastal Domain Observatory with the aim of recording and monitoring long-term changes in a western European coastal area strongly influenced by both climate fluctuations and anthropogenic impacts. The proposal is currently undergoing evaluation for possible funding. In this context, a Coastal Environment Information System (Système d'Information des Environnements Côtière, SIEC) connected with an intensive computing centre is planned, to reinforce the synergy of the Institute, especially by providing facilities for gathering remote sensing data, image processing, GIS and dynamic modelling.

This common service will have five main functions:

- **Collection of data and integration of existing datasets** produced by the IUEM, concerning physical, biological and anthropogenic parameters, and creation of a consistent GIS database, based on the geographical reference information approved by the French National Committee for Geographical Information (Conseil National pour l'Information Géographique, CNIG, see http://www.cnig.fr);
- **Develop and maintain global data exchange conventions** in order to make geographical reference information produced by organisations such as IGN, SHOM, Ifremer or Météo-France available to the IUEM research teams;
- **Information production** by the digitisation of maps, or by data processing of numerical data (interpolation, image analysis, etc.);
- **Metadata production** for supplying a catalogue to assist internal and external data exchange and diffusion between data producers (laboratories, institutions) and users (laboratories, marine professionals, policy and decision-makers);
- **Education and training** of the IUEM staff and students in Geographical Information Sciences.

The feasibility of this joint project has been tested from an inventory of the whole data produced in the IUEM research labs.

11.4.2 The first stage: data dictionary and metadata production

Within the IUEM, the needs for data cataloguing are both external and internal. For internal uses, the maintenance of an up-to-date description of datasets is a guarantee of its long-term viability, and may improve collaboration and exchanges between research teams as it avoid redundancies in research projects. As a research institute, IUEM is an important data producer and user, and has a strategic need for being identified as a data provider by different kinds of external users, especially in a context of the growth of data and information communication across the World Wide Web. The Institute's data broadcasting policy within the SIEC implies a strong compliancy with existing metadata standards, in order to guarantee their robustness and encourage their exchange (Bartlett *et al.*, 2000).

At present, two major metadata standards are used by the international community of geographic information providers: the European standard (CEN/TC 287) and the International standard (ISO/TC211). Correspondence between these two is not perfect, especially in terms of data ownership rights, but the general hierarchical structure of the data descriptions allows the conversion from one standard to the other. As the contribution and established collaborations of the IUEM to international research programs takes place mainly at the European level, the European standard has been adopted for SIEC. The metadata are integrated and managed with Report V2.0, a CEN/TC287-compliant metadata software system developed by the French Ministry of Equipment. At the laboratory level, although the geodatabase was developed initially with ArcInfo software (where ArcCatalog is compliant with the ISO standard), Report is also used for producing and

managing the metadata catalogue until such time as ArcCatalog can take into account the European metadata standard.

In fact, the conversion of standardised metadata to specific formats stays unavoidable when supplying information to Web geodatabase repertories or clearinghouses such as Bosco (http://www.bosco.tm.fr, for French coastal data) or EDMED (http://www.sea-search.net/edmed/welcome.html for data produced during MAST research programs) for example. The need to be able to undertake this kind of specific task will be taken in account when developing the SIEC structure.

11.5 CONCLUSION

The experience acquired after ten years of coastal GIS development shows that even if the databases are useful in many scientific and management applications, their prospects depend on a better standardisation of geographical reference data and their metadata, and on a better integration of the GIS into environmental coastal zone management systems. In the future, data collected and used in Brest will be transferred into the SIEC, a coastal environment information system planned at the IUEM level. In this long-term framework, specific funding and a proper organisational context will be allocated to this information system. Currently, the inventory of data available to the concerned laboratories, and the metadata production, are continuing. The next steps of this joint project will concern the design and the implementation of this multidisciplinary coastal GIS (Muller *et al.*, 2000). From specific scientific applications, the GIS now has to evolve towards an institutional system designed and developed by a team based on future users and data providers.

11.6 ACKNOWLEDGEMENT

The authors would like to pay tribute to the late François Cuq, Director of the Géomer (Géosystèmes in the past) CNRS laboratory and of the Coastal observatory of the European Institute for Marine Studies, who died in May 2003, for his strong involvement in the birth and the growth of a GIS team of geographers in Brest, and for his huge contribution to the development of applied geomatics to coastal zone management in France.

CHAPTER TWELVE

Cultural Intermixing, the Diffusion of GIS and its Application to Coastal Management in Developing Countries

Darius Bartlett and R. Sudarshana

12.1 INTRODUCTION

Whether viewed as system or as science, the origins and development of GIS are essentially rooted in Western (largely "Anglo-Saxon") geographies, sciences, and technologies. Indeed, Coppock and Rhind are even more specific, and point to the "dominant contribution of North America to the development and implementation of GIS up to the mid- and late-1980s" (Coppock and Rhind, 1991). In addition, the overwhelming majority of international scientific journals and educational texts in the discipline similarly originate in Europe and North America. They are also mostly anglophone, although recent years have seen the gradual emergence of a corpus of GIS literature in non-English, though still predominantly European, languages (e.g., for the French language, see Collet, 1992; Didier and Bouveyron, 1993; Pantazis and Donnay, 1996; Pornon and Hortefeux, 1992; as well as references in Bourcier, this volume, Populus *et al.*, this volume, and Gourmelon and Le Berre, this volume).

While the origins of GIS and most other Information and Communications Technologies (ICT) lie in the West, they are increasingly being applied to other parts of the world, and their diffusion may be seen as a step towards the eventual creation of global information infrastructures. This transfer of GIS and ICTs, as well as the know-how to apply them, is generally heralded as a "good thing" (Nag, 1987; Taylor, 1991; Hastings and Clark, 1991; Yeh, 1991; Salem, 1994; Alhusein, 1994; Metz *et al.*, 2000; Nwilo, this volume), and a growing corpus of literature attests to the benefits that can accrue to receiving countries from the acquisition and application of spatial information technologies.

Less well-publicised is the potential for cultural and other impacts on non-western societies as these tools and technologies become more widespread. In this paper, we explore some of the issues that we believe merit closer study in this

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

regard, drawing by way of example on the use of GIS for coastal zone management in the Indian sub-continent.

12.2 GIS DIFFUSION TO THE NON-"WESTERN" WORLD

The process of technology transfer is arguably as old as humanity itself. In the past fifty years, however, it has gradually gained increasing importance as an element in the quest for sustainable development, reduction of vulnerability to environmental hazard, and the opening up of new markets. In short, technology transfer may be seen as a cornerstone of globalisation.

Based on our own experiences in a number of technology and know-how transfer initiatives, as well as a critical review of the literature, we have come to the conclusion that much technology transfer, particularly from north to south, and from west to east, appears often to be predicated on a number of important, though often untested assumptions.

1. **Technology transfer is driven primarily by philanthropic notions of serving "the public interest."** In reality, much transfer of technology is driven by very different forces, such as the marketing efforts of large (mostly Northern) corporations, including GIS vendors, or the interests of donor governments seeking to obtain or retain political power and influence, pursue military strategies, influence global geopolitics, etc. These latter forces are rarely motivated by altruism, and may frequently seek to attach political or other conditions to the transfer: Alhusain (1994), for example, argued that the implementation of GIS in many developing countries is "still in its primitive stages… due to many wrong practices common in these countries… One of the most serious practices in these countries is that many of them - with some exceptions - are non-democratic societies." In order to help overcome these perceived deficiencies, he advocates that the transfer of GIS and other technologies should be explicitly linked to political change: "International organisations such as ISPRS and the UN… can play very important role in encouraging the process of transferring the IGIS (Integrated GIS) technology to developing countries … *and, particularly, the democratic practicing [sic] within these societies should be highly appreciated and encouraged*." (Alhusain, 1994, emphasis added).

2. **The notion that "new" technology equals "better" technology** and, linked to this, an implicit equation suggested between acquisition of technology and generally improved quality of life. This can lead to the acquisition of technologies becoming seen as a desirable and worthwhile goal in its own right, rather than as a means to an end. Thus the allure of GIS may be as much based on the wish to acquire a high-visibility "status" product, linking the owner with the developed world, as well as being a route towards accelerated national development. As Apfell-Marglin (1996) explains it, "The First World is 'developed' and the Third World is 'developing' or 'underdeveloped'. In these phrases the *telos* of development stands revealed and the superior results are there already, luring everyone 'forward.'" Particularly in recent years, uneven diffusion and take-up of spatial information systems, as well as the

Internet, and other Information and Communication Technologies, have led to the expression of fears among sections of the developing world that the technology "connects people who mostly belong to developed nations [and] excludes the major population from the developing nations" and even that "the developing countries will suffer from unequal distribution of scientific knowledge" and might thus be deprived of opportunities for development (Shanmugavelan, 2000). This fear of "being left behind" adds to the pressures on decision-makers in developing countries to embrace new technologies.

3. **Technology transfers will, indeed should, only consist of one-way (generally North-South or West-East) flows.** As currently practiced, the diffusion of GIS to the developing world exemplifies and reinforces this belief. However, there is in practice no reason why this should be the only pathway available, and there may be circumstances in which a reverse flow – that is, a transfer of ideas, technologies and methods, from South to North or from East to West - could be not only possible, but perhaps even desirable. The countries of the South may be less developed than those of the North, but they are not totally lacking in their own expertise, wisdom and ways of doing things: as the late president of Tanzania, Julius Nyerere, argued in a 1968 speech, "Knowledge does not only come out of books… We have wisdom in our own past and in those who still carry the traditional knowledge accumulated in that tribal past…we would be stupid indeed if we allowed the development of our economies to destroy the human and cultural values which African societies had built up over centuries" (quoted in Swantz and Tripp, 1996).

4. **Delivery of knowledge and capabilities to the recipient country is sufficient**, and subsequent diffusion of these tools or techniques within the country can be left to take care of itself. In practice, greater focus on internal diffusion is needed, especially from the often more cosmopolitan and progressive urban centres to the traditionally more conservative, and particularly undeveloped small towns and rural settings.

These observations, we believe, carry potentially important implications for the manner in which GIS is diffusing to, and being applied to assist coastal management tasks within, particularly developing world countries. The two areas where we believe these issues to be especially relevant are in the formalisation and representation of conceptual models of the coast within GIS databases; and in the incorporation of GIS within the decision-making process. Each of these will be examined in more detail in the remainder of this paper.

12.3 CONCEPTUAL MODELS AND REPRESENTATION OF SPACE

GIS consists of a nested and interlinked series of conceptual, logical and data models (Peuquet, 1984) that unite the human user, the computing hardware and software, and the data and operations being performed, into a more-or-less integrated and synergistic whole. The resulting system is a metaphor which we

hope embodies all the elements and properties of what we perceive as important in the real world, while discarding the unimportant (Bartlett, 2000).

Measurement, description and apportionment of land appears to have always been an important feature of human society, to the extent that spatial thinking is probably a fundamental element of human intelligence (Chrisman, 1997). The *representation* of geographic information in some (carto)graphic form may also be seen in the histories of civilisations the world over (e.g. Noble, 1981; Thrower, 1996; Burrough and McDonnell, 1997; Godlewska, 1997; Harley and Woodward, 1989; Wilford, 1981). The Chinese, under Yü Kung, and the Greeks, under Anaximander, were reputedly making detailed maps and surveys as early as the sixth century B.C. (Thrower 1996). The diffusion of Buddhism from northern India into China was also taking place at about this time, and there were regular trading links and exchanges between China, India and the Roman Empire along the "Silk Road", as well as perhaps by sea. It may be assumed that much of the early European cartographic thinking that was emergent at this time was derived from, or at least influenced by, eastern philosophies and ideas.

The intervening centuries, however, have seen the ascendancy of western map-making. This cartography, while it almost certainly borrows unconsciously from other traditions, is nonetheless rooted firmly in western science, western world-views and western ideas of effective information communication. The net result has been the effective globalisation and hegemony of a cartography based on Euclidean distances, Cartesian space, the conceptual separation of time and space, and cartographic design rules based on western aesthetics. It is this cartography, enhanced through the application of Boolean logic and implemented through the medium of binary arithmetic, that we find embedded in the representation of geographic space within current GIS. These European (and, partly by derivation North American) scientific-cartographic paradigms have thus become the *de facto* worldwide standard for geographic data modelling, to the effective exclusion of all possible alternative models (Bartlett, 2000).

12.3.1 Geography, GIS and metaphysics

While the metaphors and paradigms embedded in GIS are thus western in origin, the applications of GIS are increasingly extending to other cultures and traditions. Little attention appears to have been given, until now, to the implications underlying this essentially top-down convergence of western technologies with non-western thinking and modes of practice.

White (1967) has observed that human ecology is "deeply conditioned by beliefs about our nature and destiny - that is by religion," while Robinson (1982, quoted in Singh, 1999) reminds us that, "geographers and most other researchers, consciously or unconsciously, have tended to assimilate a scientific perspective which in turn is based partly upon certain metaphysical assumptions concerning the nature of relationship between man and environment." In practice we implicitly know that western perspectives on science, which are largely based on Judaeo-Christian ethics and the application of Newtonian physics and mechanics, are merely subsets of an enormous range of possible world views and approaches to human ecology. There are fundamental and very important differences in the "metaphysical assumptions" and views of human-environment relationships,

between the major religions and cultures of the world. Ipso facto, alternative world views and mental maps must also exist although, given their diverse cultural and geographic origins, these "maps" may take very different form and appearance from the types of cartography more usually encountered in the West. For example, if the late Bruce Chatwin's hypotheses are to be believed, even the Aboriginal "songlines" may represent a set of "musical maps" of the Australian continent, and a mapping of space relayed through oral tradition rather than via any graphic medium (Chatwin, 1988).

As is well known, coastal zone management remains an area of potential GIS application where major challenges are encountered. Many of these difficulties are due to pervasive inherent weaknesses in the conceptual and data models used by these systems, that mitigate against effective multi-scalar representation of highly dynamic objects with indeterminate boundaries. Although progress is being made towards resolving these issues, it is perhaps worth asking whether any solutions or insights to better representation of coastal space might be found through exploring alternative, non-western perspectives and conceptual models, and seeking to embody these within our computer representations? Such an exploration would require knowledge of computer technology to be interfaced with concepts and methods drawn from the social sciences including, perhaps, cultural and social anthropology. To the best of our knowledge, no such collaboration between these very distinct disciplines has yet been undertaken.

The Indian sub-continent would appear to be a particularly promising place to begin such research. As well as being an ideal "laboratory" for testing and further refining any leads that might suggest themselves, due to the extent, diversity and importance of the coastal zone, in India the predominant Hindu-Buddhist philosophies interface with western, Judaeo-Christian traditions, and the products of these, in virtually every sector and aspect of daily life. India is also a land of strong contrasts between traditional, frequently feudal-based rural societies on the one hand and, on the other, a burgeoning Information Technology sector – including its own space programme and orbiting remote sensing platforms – to match anything in the West.

12.4 THE APPLICATION OF GIS TO COASTAL ZONE MANAGEMENT

One of the primary reasons for wishing to model coastal space in a GIS framework is so that the technology may be used for enhanced decision-making and territorial management. Humanity has always had a close relationship with the coast, with at least 40% of the world's population now living within the coastal zone (Carter, 1988; Bartlett, D.J. and Carter, R.W.G. 1990). The oceans, and especially the continental margins, provide resources, living space, industry, and the locale for a growing leisure and tourism activity, all of which may contribute significantly to the social and economic development of society. The coastal zone may also be an important milieu for confrontation and intermixing of cultures, particularly as a growing global population competes for ever scarcer resources, and as globalisation brings yet more "exotic" coastal regions – often located within the developing world – into easy reach of leisure- or adventure-seeking holiday-makers, especially from the more affluent nations of the world.

Finally, the coastal zone is one of the world's more hazardous regions in which to live and work (Carter, 1988). Specific dangers include the risks of flooding and shoreline erosion, which are themselves often caused or exacerbated by extreme weather events (hurricanes, cyclones) or geotectonic disturbances (e.g. tsunami arising from earthquakes) (Burton *et al.*, 1993; Smith 1996). On top of these lie the indirect impacts and second-order consequences of disaster, arising through disruption of economic and social systems. The nature of these consequences may vary between urban and rural areas, as well as between developed and less-developed countries but, wherever they occur, their effects can be far-reaching and severe (Smith, 1996). Continued growth of world population, allied to recent warnings about possible near-future changes in global climate and accompanying rises in sea-level, increases in storm frequency and impact, etc., suggest the coast is likely to become more, rather than less, hazardous in the future (e.g. Titus, 1987; Carter, 1988; Devoy, 1992).

12.4.1 Western approaches to coastal management

The challenge of coastal management is to reconcile human and non-human uses of the shore. Unfortunately, this goal has more often remained elusive than achieved, prompting Carter to remark that humanity "has an uneasy relationship with the coast. Throughout history, we have tried to ignore it, adjust to it, tame it or control it, more often than not, unsuccessfully" (Carter, 1988). Until comparatively recently, coastal management in the West (and in those countries influenced by western thinking) has tended towards increasing reliance on engineering methods, and the application of various technologies – including GIS – in order to resolve specific problems.

This technocentric approach finds several echoes in Western (Judaeo-Christian) approaches to nature generally, and traditionally sees nature/the world as being provided for human use. It is based on an essentially linear view of time, and on reductionist thinking where the progress of science is directed towards ever deeper understanding of ever smaller parts of the picture, with comparatively little attention being given to the whole (Koestler, 1969). We find that this philosophy of "nature to be commanded" has impacted on the terminology used to define and delineate coastal management objectives with, for example, recurring use of the language of conflict and expressions such as "protecting the coast", "armouring the line of the shore", "defending the beach", and even "reclaiming land" (when, in many cases, what is being referred to is not a re-taking of that which was once lost to the sea, but instead a carving out and colonisation of new territories we never had in the first place!). Carter conveys the flavour of this ethos very well when he quotes Sir John Rennie's Presidential address to the Institute of Civil Engineers, London, in 1845: "Where can Man find nobler or more elevated pursuits than to interpose a barrier against the raging ocean (Carter, 1986)?"

While this particular sentiment was expressed one and a half centuries ago, it is still encountered regrettably frequently to the present day, and inevitably makes its way into the strategies, algorithms and models adopted when applying GIS to the coast. In the West, most coastal management problems are likely to be articulated in the language as alluded to above; the questions for which answers are sought will be framed by the assumptions and beliefs espoused by the society

the coastal manager is part of; and the science policies adopted in order to resolve the situation will likewise be determined largely by the cultural and institutional contexts. Thus, traditional applications of GIS to coastal management have likewise drawn heavily on civil engineering and CAD-based approaches, the goal of which is most frequently to "stabilise" the line of the shore. Social, cultural and, indeed, environmental aspects of the problem have often tended to take a subsidiary role.

12.4.2 Eastern approaches to coastal management

In the East, and especially in India, the situation is much more complex. Many Asian countries were under European (in the case of India mainly British) rule for a few centuries, and the pre-existing feudal system of resource use was confronted with bureaucratic administration based on European principles. Thus we see a convergence of "East" and "West". Under colonial influences, management decisions were made, and resources categorised, largely on the basis of revenue unit polygons. Such units have spatial expression, and are relatively easy to represent in a traditional GIS. However, operating according to a completely different geography, the feudal system still exists or has re-emerged (in some places in the form of Mafioso-style organised crime) in many parts of post-colonial India, and decisions concerning the fate of a resource are now no longer expressed as per-revenue units that are easily interfaceable with GIS. Debt repayment systems based on lines of bartering, species segregation, accounting of fish catch instead of geographic accounting, *etc*., are all local values that stand distinctly different in comparison to the pattern of accountability in the west. The complexity of applying GIS to such management contexts lies in the fact that the local governments attempt to keep records in the Western pattern, while resource management is grossly influenced by indigenous, informal and feudal beliefs inaccessible to the procedures of modern information systems.

One of the basic assumptions underpinning both Western-style coastal management, and also implementation of a GIS, is the laminar structure of environmental management process. This philosophy of "layers" projects the nature of the problem, as well as the knowledge, decisions and actions needed to solve it, in a stratified manner. Within GIS, these "layers" are most frequently recognised in the thematic stratification of information. They also, however, find expression in the institutional contexts that frame uses of the technology. The layers in an organisation are generally distinguished by expertise, experience, hierarchical influence and a divisional or departmental approach to achieving work objectives. They can only be established and interlinked by the social process of *co-operation*. But whereas co-operation is a frequently encountered social value of Western society, *subjugation* and conflict at a human level are the dominant social values of the East, arising from the roots of the civilisations concerned.

This carries important implications for the use and transmission of information, since the co-operative laminar approach depends more on mechanical and modular interpretation of information through an iterative process, while the subjugative approach lends itself to single-window interpretative mode based more on human bias, instincts and an individualistic ethos. Hence, it may be argued that

machine-based knowledge and decision-making will always find less acceptability in the East in comparison to the West. This applies in particular to the process of automated information extraction, e.g. by GIS, which finds broad acceptability in the Western mind whereas manual charting and information extraction methods are much more common in the East. Again, in the latter, responsibility for the validation of information and interpretation is hierarchical, and finds its acceptance once more in the unquestioned or less questioned 'subjugation' social ethos.

As was seen above, human affairs in Asian society tend to be based strictly on a feudal approach to responsibility and authority, and thus based on an ethos of domination by one group or individual over another. When it comes to human-nature interactions, however, a somewhat different ethos prevails. Here, when compared to Judaeo-Christian philosophies, Eastern traditions appear to give far greater emphasis to a fundamental interconnectedness of things; they place great stress on the importance of cycles (and also see time as a circular rather than a linear concept); and teach a need to accept and adjust to change rather than resist it. In short, they would appear to be much more inherently compatible with the goals of sustainability and integrated coastal zone management.

Assuming that the GIS has to cater to the process of coastal decision-making, such issues again become important, and it is once more necessary to debate on the background social realities of decision-making. We know that decisions are either made on a Long Term Perspective (LTP) or with a Short Term Perspective (STP). LTP aims at qualitative values in deliverables and is prompted by slowly emerging needs, with fewer and diminishing contingency methods built in to the system of delivery. However, STP has the urge and need to cater rapidly and in a quantitative manner, since speed and precision of delivery may be critical to sustainability and survival. These contrasting perspectives are also discernible between East and West: Western societies tend to be more stable and secure, and hence can afford both the resources and the time required for longer-term planning. In less-developed countries, however, the concerns and the priorities are usually very much more immediate and focused on issues of survival and daily sustenance. These will inevitably have implications for the design of appropriate information systems. Hence, system modelling and both the design and implementation of a GIS needs to be very meticulous and detailed under the LTP mode while it only has to be at a practically manageable level to yield the effective STP that is vital to many Eastern societies. It is also a reality to work with STP in many politically less stable social systems. Such being the case, there is a need to revisit basic GIS principles and practices for the East, to cater to faster but less precise (i.e. gross) decision-making.

12.5 CONCLUSION

Ultimately, integrated coastal zone management should be *informed* coastal zone management. This evidently requires access to appropriate, timely and reliable data and information which, in turn, suggests an important role for GIS and other suitable information technologies. However, it is worth bearing in mind the cautionary message of Henry Nix who, in his Keynote address to the 1990 AURISA conference, pointed out that:

> *"Data does not equal information; information does not equal knowledge; and, most importantly of all, knowledge does not equal wisdom. We have oceans of data, rivers of information, small puddles of knowledge, and the odd drop of wisdom"* (Nix, 1990)

If we truly desire to know the coast, and manage its resources wisely, we urgently need to look beyond the confines of our current technologies and our scientific (and social) paradigms.

We do not intend to suggest here that Indian, or for that matter any other, cultures and philosophies hold *all* the answers to solving current problems of coastal GIS. Nor do we wish to suggest that GIS and other "Western" technologies have no role to play in the developing world. Instead, it is the intention of this paper to argue for a greater receptivity to other ideas and approaches; a greater willingness to step outside the boundaries of western-dominated methods of science; and finally, a greater appreciation that introduction of GIS as part of wider technology transfer programmes needs to be carefully attuned to the cultural and other social contexts of the receiving communities. We believe that if the diffusion of GIS around the world is conducted in a spirit of genuine collaboration and desire to share experiences among and between cultures, then nature, as well as humanity, is likely to be the richer for the endeavour.

12.6 ACKNOWLEDGEMENTS

This paper evolved out of discussions between the authors that took place during and subsequent to a workshop on "Subtle Issues in Coastal Management" (Sudarshana *et al.*, 2000), which was held in Dehra Dun, India, in February 2000. Darius Bartlett gratefully acknowledges generous funding from the Embassy of India, Dublin, which was crucial in enabling his participation in this workshop.

CHAPTER THIRTEEN

The Use of GIS to Enhance Communications of Cultural and Natural Resources and Contamination

John A. Lindsay, Thomas J. Simon,
Aquilina D. Lestenkof, and Phillip A. Zavadil

13.1 INTRODUCTION

Five Pribilof Islands, volcanic in origin and remotely located in the Bering Sea, are home to Aleuts and the breeding grounds to 70% of the world's northern fur seal population and numerous seabird species. The once uninhabited islands were first occupied by the Russians in 1786 and later became controlled by the U.S. Government. At the time of the Russian incursions into the Aleutian Islands, some have estimated the Aleut population at 15,000-18,000. First Russia and then the U.S. relied on the forced labour of Aleuts relocated to the Pribilof Islands from the Aleutian Islands chain to harvest sea otters, fur seals, and arctic fox. From their first arrival and through much of the 20th century, *Unangan* (people) or Pribilof Aleut people relied on the islands' and Bering Sea's natural resources, including fur seals, sea lions, whales, arctic fox, walrus, sea bird species, and a variety of plants for customary traditional purposes and subsistence. Even today natural resources are vital to the survival interests of *Unangan* on the Pribilofs. *Unangan* of St. Paul and St. George Islands are the world's single largest ethnic Aleut community whose world population approximates 3,200 individuals. Fur seal, endangered Steller sea lion, introduced reindeer, halibut, crab and other marine invertebrate species, and plants, such as crowberry, continue to play a significant role in customary traditional practices, economic development, and the maintenance of cultural and ecological harmony.

Settlement terms under the Alaska Native Claims Settlement Act (ANCSA) of 1971 required the National Oceanic and Atmospheric Administration (NOAA), as the most recent of the former federal land managing agencies for these islands, to transfer more than 95% of the land area to the local Aleuts. A 1976 Memorandum of Understanding and a 1984 Transfer of Property Agreement (TOPA) incorporated the details of the property transfer between NOAA and various local entities. The settlement and subsequent legislations including the Pribilof Islands Environmental Restoration Act of 1995 and the Pribilof Islands Transition Act of 2000 required NOAA to restore the islands' environmental

integrity compromised by U.S. Government activities supporting its commercial fur sealing enterprise. Environmental concerns included numerous releases of petroleum fuel products associated with the disposal of used oil, overfilling of storage tanks, corrosion of storage tanks, pipelines, and barrels, as well as landfills for household wastes, construction and demolition debris, scrap metal and junked vehicles, boats, barges, and aircraft. In addition, military activities during World War II contributed to soil and groundwater contamination. More than ninety sites on the two inhabited islands, St. George and St. Paul, required evaluation and potential restoration in order to complete the land transfer. The islands' remoteness, approximately 2,200 statute miles from NOAA's base of operations in Seattle, Washington requires a minimum of eight hours in travel time. Weather extremes involving fog, snow, and wind frequently cause flight cancellation. Improving communications through such multimedia technologies as Internet, GIS, and video were identified early as absolutely critical to the restoration project's success.

In the context of public land transfer to private sector entities and the restoration of lands and structures located within a National Historic Landmark and District, the National Historic Preservation Act (NHPA) further mandates NOAA to mitigate for these actions. Mitigation efforts at a minimum will provide a historical legacy associated with the federal ownership period for the benefit of future generations. The legacy is expected to include a book, video documentaries, and a detailed Geographic Information Systems (GIS) project. This chapter focuses on the GIS project. The NOAA Pribilof Islands Environmental Restoration Project Office (PPO) entered into collaboration with the St. Paul Tribal Government's Ecosystem Conservation Office to build a GIS project that included not only extant conditions, but also traditional cultural and natural resource features. This chapter presents an ongoing project that began in 1999, the conclusion of which is not expected for several more years.

13.2 GIS APPLICATION

The environmental restoration project began nearly two decades ago. Numerous written reports included site locations and analytical results from hundreds of soil samples. Unfortunately, site boundaries and sample point locations have not been easy to recover because of poor referencing and a relatively monotonous environment that becomes overgrown with waist high vegetation or eroded by violent winds. A decision was made at the outset to map all features using differential global positioning systems (DGPS) and a GIS. This approach would allow the relocation of sites and sampling points in years distant if necessary, as well as aid in other efforts, such as defining the vertical and horizontal extent of contamination, and the calculation of volumes of soils requiring excavation. The PPO also recognized the importance of mapping historical, natural, and cultural resource features, such as gravesites, to aid the communities in their future management of the islands, and subsequently to comply with the NHPA and the Coastal Zone Management Act.

Alaska's high latitudes and the islands' remoteness challenge GIS application. Normally available geo-referenced base maps, such as topographic quadrangles and nautical navigation charts, are scarce, small scale, or nonexistent.

Early project acquisition and prosecution of DGPS data acquired with Trimble Pro XRS and corrected with post processing layered over existing electronic versions of nautical charts revealed positional errors requiring exhaustive research to rectify.

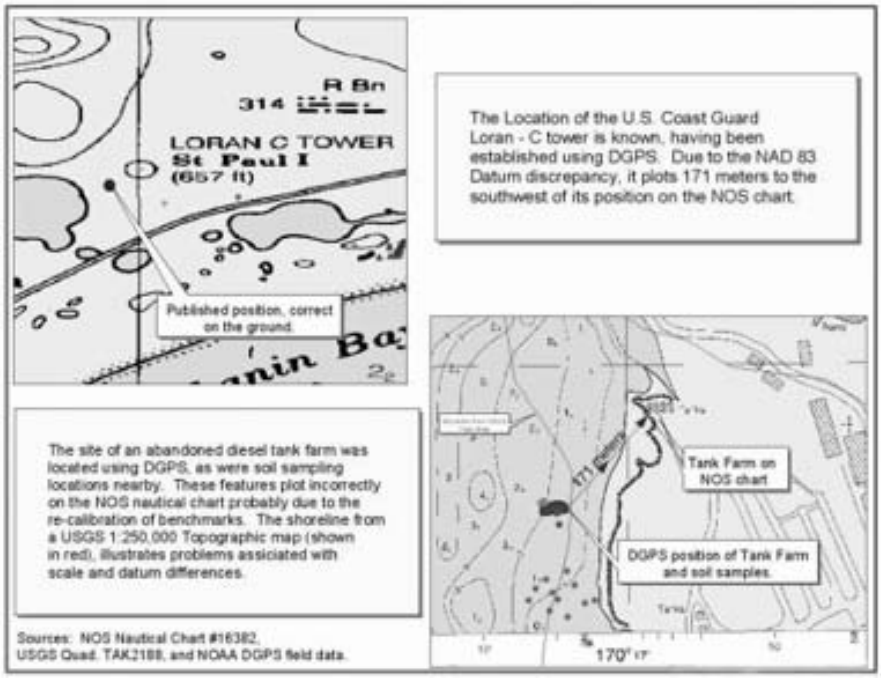

Figure 13.1 Errors in previous mapping projects.

The project resurveyed the two principal islands, St. Paul and St. George, to first order following National Geodetic Survey protocols. The results revealed a transcriptional error in an earlier version of the cartographic process that translated into an approximate 180-meter error (Figure 13.1). New benchmarks were installed on the islands, and NOAA/NOS issued new nautical navigation charts in March 2001. The chart scale, however, was still too small (1:50,000) for practical use. The NOAA project entered into a cost share collaboration with the US Geological Survey to provide Digital Elevation Models (DEMs) at 1:24,000 scale, topographic quadrangles at 1:25,000 scale with 10-meter contour intervals, and Digital Ortho Quarter Quads (DOQQ's) at 1:12,000 scale using pre-existing (1993) colour aerial photography. In an effort to acquire recent high-resolution imagery, NOAA contracted with a satellite vendor to provide 1-meter panchromatic and 4-meter multi-spectral imagery. The PPO is considering the application of interferometric synthetic aperture radar (IFSAR) imagery of the islands for use in establishing hydrographic controls to further improve island charting and to monitor long-term Aeolian erosion processes that have a potential to impact current restoration efforts. These products, when combined with historical maps and project data, will provide a comprehensive view of the islands and their changes over time.

The Pribilof Islands GIS mapping project uses ESRI's ArcView version 3.2. Federal Geographic Data Committee compliant metadata allows rapid data searches. The project focuses on several coverages and features (Table 13.1). As noted above, base maps include NOAA navigational charts as well as airphoto- and satellite-derived DEMs. Historical maps acquired from various sources including libraries and published reports dating back to the late 1800's provide a reference for changes occurring over more than a century. Changes of interest include fur seal, sea lion, and walrus rookery and haul out locations, as well as building and off-road trail locations. The maps are scanned at 1200 dpi and overlaid on registered and rectified base maps. The PPO uses Trimble Total Station RTK (real time kinematic) 5700 DGPS survey equipment to provide real time horizontal spatial accuracy of ±1 cm and vertical accuracy of ±2 cm. Acquired data is used for contouring and creation of 3-D models of landfill activities, excavations, contaminated soil stockpile volumes, and potentially for plotting seabird nests on cliff faces combined with laser spotting technology.

Table 13.1 Pribilof Islands GIS coverages and features

Coverage	Features
Geographic	Islands and land masses
Geologic	Soils, stratigraphy
Chemical	Soil and water
Demographic	Buildings, roads, debris sites; historic and current video and still images
Topographic	Cinder cones, landfill relief, DGPS ground surveys, aerial and satellite imagery
Biological (fauna and flora)	Fauna, flora, rookeries, haul outs, migration patterns, historic and current video and still images
Oceanographic	Bathymetry, currents, ice pack
Archaeological	Habitations, burial sites, historic and current video and still images

The authors' previous experience with marine GIS projects (e.g. Lindsay *et al.,* 1999; Butman and Lindsay, 2000) revealed the robustness of ArcView GIS. Using hotlinks the GIS project is enabled to include multimedia features, such as still, raster (laser line scan), and video imagery and sound recordings. The PPO uses Canon XL-1 digital and Panasonic 720p High Definition (HD) electronic media cameras and digital still cameras to document field activities. HD is down-converted to standard definition. Standard Def and digital videotape postproduction relies on MacIntosh G4 editing suites with Final Cut Pro software and DVD Studio Pro authoring software. Real GIS data are imported into a Hewlett Packard X4000 with XSI animation software to create textured, lighted, and animated production quality 3D models for viewer friendly but scientifically accurate renditions of real data. Historical video on Betacam and VHS tapes are converted to digital format using the same hardware and software. The GIS project itself and video mini-documentaries are placed onto DVD (digital video disk) using super drives. (Please note that any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.)

13.3 ENVIRONMENTAL RESTORATION

The U.S. Government initiated environmental restoration activities on the Pribilof Islands in 1983 following the final decision to transfer island lands from the public to the private sector. Former operations managers, residents, and historical reports aided in the identification of contaminant and debris sites. From a mapping perspective the primary emphasis of the environmental restoration activities on the Pribilof Islands has been on the locations of land features, boundaries, and the acquisition of soil and water chemical contaminants data. Demographic land feature focus has been on ownership, including federal land tracts and parcels targeted for transfer under the ANSCA and TOPA, topography, cultural uses associated with waste disposal practices, debris and contaminated waste site boundaries, building locations, utility locations (water, electrical, fuel transfer, cable, telephone and television lines), and grave site locations. Pribilof Islands' soil and groundwater chemistry has typically been evaluated at sites where spills or releases of petroleum products were suspected or known to have occurred, such as landfills and building sites.

A significant commercial infrastructure was built on St. George and St. Paul Islands to harvest and cure northern fur seal skins between 1872 and 1984. Numerous buildings were constructed for brine and salt curing, barrel making, skin packing, and seal by-product production, such as oil and animal meal. Other structures included electrical generation plants, gasoline stations, a radio station, fuel storage and transfer, commercial store, storage and utility buildings, a school, health clinic, quarries, and roads. As the value of the harvesting grew, so did the sophistication of the infrastructure and the use of petroleum based fuels for electrical generation and motorized vehicles. Storage tanks of various sizes ranging from about 500 gallons to 200,000 gallons and fuel lines serviced the islands' energy needs. Until about 1970, these tanks were filled from 55-gallon barrels brought ashore by bidarrahs, a native rowing craft with Russian influenced origins that were covered by sea-lion skins, and eventually by fuel barges with floating transfer lines.

Environmental restoration efforts prior to 1999 lacked either resolve and/or management experienced in restoration; consequently their efforts resulted in restoration of readily visible debris that included six thousand tons of surface debris, thousands of barrels either empty or containing used oil, and some underground storage tanks. Contaminated soils, groundwater, and landfills were left virtually untouched. In addition, initial efforts relied on conventional surveying and mapping techniques that archived features on paper maps without providing adequate geo-references. Subsequent field activities failed to recover site boundaries and soil sampling points. Short field seasons punctuated by years of inactivity resulted in as many as four characterizations at some sites in this treeless and knee-high grass environment in part due to the lack of geo-referencing and unique visual cues such as building foundations, stressed vegetation, soil staining, or surface debris. In an effort to capture these data, the PPO scanned existing paper maps, periodic air photos dating back to 1948, geo-referencing these when possible, and including them in the GIS project along with textual and tabular information. Since 1999, the PPO has relied on DGPS survey systems to log data points and vectors, to catalogue site features, and to relocate sites and sampling points. For the first time Pribilof Islands data was entered into a GIS

project that permitted near real-time project map creation and distribution. Maps were spontaneously created in the field office for planning and discussion purposes. Subsequent maps demonstrated the extent of soil and groundwater contamination, and served to increase the efficiencies of removal action decisions.

For example, diesel fuel contaminated sites are first verified by laboratory soil chemical analyses. Using GIS created maps depicting analytical results, and site historical and current features as guides, a removal or excavation is initiated within the bounds defined about these analytical results. These analyses seldom define within several meters the horizontal and vertical extent of contamination. Therefore, following initial excavation of contaminated soils, the project relies on thin layer chromatography (TLC) soil screening to verify whether remaining soils have diesel fuel contamination. The project has determined that field applied TLC based on standards offers a high probability (>95%) of accuracy within a sliding scale (e.g. 0-100 mg/kg, 100-250 mg/kg). TLC samples and their horizontal and vertical positions can be collected, processed, and the results entered into a GIS within approximately two hours. The sample results are overlaid onto registered and rectified historical air photo(s) depicting the historical structures, such as buildings, fuel tanks and fuel lines linked as sources of the contamination but long since dismantled. The composite photomap allows the cleanup team to substantiate the TLC results in context with the extent of the excavation and likely sources. If the map depicts a sample result with likely low levels of contamination, and no historical source was within close proximity to the spot, the cleanup team has received greater certainty about stopping further excavation. When excavation is considered complete, additional soil samples are taken for fixed laboratory analysis. The photomaps created during these field exercises can be displayed on laptop computer screens, printed on photographic papers, projected onto walls and plasma screens, and transmitted via Internet to far off locations.

High resolution (sub-meter scale) topographic maps of quarries and mineral stockpiles are created with the DGPS and GIS. On the islands, the project is required to purchase sand, scoria, and rock for use as backfill in excavations of contaminated soils, making haul-roads over the tundra, and capping landfills. Owners of the mineral rights require the purchaser to conduct pre- and post-surveys of the quarries to first approve and then verify quantities removed to establish a cost or royalty. The projects survey grade GPS in combination with the GIS are used to create the survey maps.

As mentioned above, the driving force behind the environmental restoration is the land transfer from the American government to local entities. These lands in the form of lots, parcels, and tracts were initially surveyed more than two decades ago using traditional surveying techniques by a separate federal agency. The available plats are in paper form and they are not easily applied in discussions involving numerous individuals and multiple issues that may involve structures, and contamination of soil and groundwater. In addition some shoreline changes have occurred since the original surveys. The project scanned and registered best fits of these plats and entered them into the GIS project for use as overlays with air and satellite photos. These enhanced maps from the original plats, hotlinked to still or video imagery, greatly improved communications between on- and off-island officials.

13.4 NATURAL RESOURCE NAMING CONVENTIONS

On and around the Pribilof Islands, marine mammals and seabirds dominate the environment. Only three terrestrial mammals are indigenous to the Pribilofs; they include the arctic fox, the black-footed lemming on St. George, and the Pribilof shrew on St. Paul. While English naming is the predominant convention followed today, some *Unangan* elders still refer to various species and/or their life stages in either *Unangam tunuu* (our people's language) or Aleut language, or Russian. For example, the arctic fox is called *aygagux* in *Unangam tunuu*. Fur seals are identified by sex and life stage in one or more languages. GIS mapping features can incorporate the various naming conventions applied to these species as appropriate.

13. 5 LOCATION NAMES

Present Pribilof Islands location names are also a mixture of *Unangam tunuu*, Russian, and English. For example on St. Paul Island, Lukanin Bay and beach, also spelled Lukannon, was named after the *promyshlenik* [fur hunter] who along with another, Kaiekov, killed 5000 sea otters during the first year of occupation in that area. Zolotoi Beach is literally interpreted as "Golden Sands" (Martin, 1960). Other present-day place names demonstrate American influence. On St. Paul, Hutchinson Hill acquired its name after Hayward Hutchinson, the first American to secure the commercial rights to the islands' fur seals.

The northern fur seal is the most intensively studied mammal on the islands. Records and maps of rookery locations, and haul out areas date back to the Russian period. Henry W. Elliot and others (*cf.* Elliot, 1881; Townsend, 1896; Osgood *et al.*, 1915) provided some of the earliest American rookery and haul out area maps. Rookery names as with other points of interest varied over time. For example, today's Northeast Point rookery on St. Paul was known during the Russian period as Novastoshnah Rookery while in *Unangam tunuu* it is *Chaxax*.

During NOAA's restoration activities the Aleut community expressed desire for greater recognition for their contribution to the islands' history. Although the literature is not devoid of *Unangam tunuu* place names, such names are uncommon on maps. Leaders on both islands had already begun to ascribe *Unangam tunuu* (Aleut place names) but official maps were wanting. NOAA enlisted the assistance of the U.S. Geological Survey (USGS) to procure digital aerial mosaics of the islands for the construction of base maps and the first large scale (1:25,000) topographic relief maps of the islands. These maps were released as a publication in March 2003. NOAA and USGS encouraged the local residents to document *Unangam tunuu* on these topographic maps and the USGS worked to secure their official status by having the place names reviewed and accepted as Geographic Names by the Alaska Historical Commission.

13.6 POPULATION DISTRIBUTIONS

While the Russian discoverers, beginning with the navigator Captain Gerassim Pribylov, may have recorded various marine mammal population statistics,

locating such records will require more concerted efforts than we have so far undertaken. But early American records clearly indicate that many of the aforementioned species at least once flourished on the islands.

Pack ice is said to influence the comings and goings of a variety of species, but most notably, walrus, arctic fox, and polar bear. Mastodon bones and molars have been recovered from lava tubes on the islands, suggesting either arrival *via* land bridge or pack ice. Purportedly in 1835, long lasting pack ice around St. Paul prevented haul out by pregnant fur seals, which resulted in the loss of both females and potential pups (Martin 1960). The pack ice in the early 1960's is reported by locals to have brought a polar bear to St. Paul, as well as several other times in the past. During 2000, pack ice was responsible for the occurrence of 6 to 7 arctic foxes on Walrus Island, a significant seabird rookery. These foxes are largely responsible for depopulating sea bird colonies, especially murres, on this small rocky island. Presently, NOAA has pack ice distributions in GIS format dating back to 1972. Ice pack incursions about the Pribilofs are being included in the GIS Project. More detailed information can be obtained through a weblink to NOAA's National Environment Satellite Data and Information Service's National Ice Center (www.natice.noaa.gov).

As noted elsewhere, fur seals received the attention of both the Russians and the Americans. Official duties of government agencies from both countries included mapping rookeries and haul out areas and maintaining various population statistics. With the passage of time, the influence of humans and the alteration of habitat has resulted in rookeries being modified or lost. For example, Webster's Point and the Salt Lagoon Rookeries are no more. GIS layering of historical areas is useful for the study of such changes, and the project also takes into account location names as ascribed over time within and between cultures.

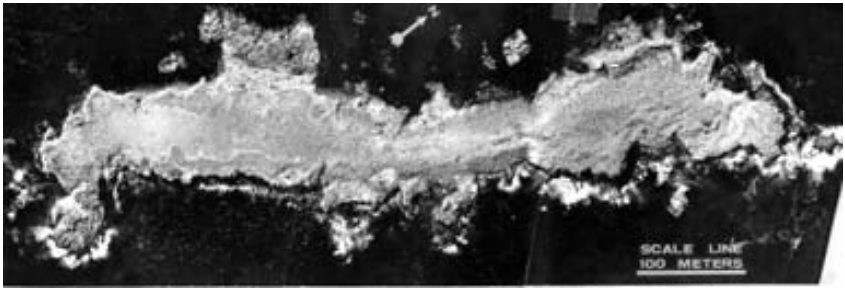

Figure 13.2 1948 aerial survey of Walrus Island.

The NOAA National Marine Mammal Lab has accumulated numerous aerial photographs of seal rookeries on St. Paul. The PPO scanned, registered, and rectified images from 1948, 1967, and the 1980's and included them in the GIS project.

Elliott noted (1875) only "a few sea-lions" bred on Walrus Island, although thousands could be seen among the fur seals at Northeast Point on St. Paul. Osgood *et al*. (1915) reported only two breeding rookeries: one of these was at Sea Lion Neck on St. Paul and the other near Garden Cove on St. George. But they also noted major haul out areas on all five Pribilof Islands. An aerial survey in 1948 found 1,258 adult sea lions on Walrus Island, but the resolution was

insufficient to determine the number of pups if any. The aerial photos have been registered and rectified for inclusion into the GIS project. During a rare visit to Walrus Island in 2000, our contingent observed 109 sea lions of which 11 were pups. During the same period fewer than 10 sea lions were observed on Otter Island. Today, despite the significantly reduced numbers, Walrus Island is the major sea lion rookery in the Pribilofs. Eleven species of seabirds nest on the Pribilof Islands. The red-legged kittiwake, as one example, occurs only in the Bering Sea and it has major rookeries on the Pribilofs. Only one shore bird, the rock sandpiper, breeds on the Pribilofs. The U.S. Fish & Wildlife Service monitors seabird nesting on the islands, but no electronic maps are available to date.

13.7 CULTURE AND SUBSISTENCE

Veltre and Veltre (1981) undertook the first focused comprehensive evaluation of the subsistence natural resources on the Pribilofs, although much of their work was acquired from historical documents dating back to the 1800's. They point out that the sealing industry "had significant ramifications on subsistence in the Pribilofs." Table 13.3 provides a listing of some representative natural resources on or about the Pribilof Islands and the customary traditional uses of each.

Two species have been virtually eliminated from the Pribilof Islands, the Pacific walrus and the sea otter. Neither animal apparently played much of a subsistence role on the Pribilof Islands in part because of their demise by the promyshleniks who sought the valuable ivory and pelts, respectively. Their historical haul out areas are included in the GIS project.

A third species, the Steller sea lion, is close to extinction on the Pribilof Islands as discussed above. Scans of historical maps depicting sea lion rookeries and haul out areas are layered onto the GIS project and verified observations of sea lions on shore will be logged into the project. Today, the sub-adult male sea lion constitutes a subsistence resource and is hunted primarily from the shore. Some hunting does occur on the water at St. George Island, however. Sea lion are hunted for their meat, blubber, internal organs, and fore flipper, although in earlier years the animal provided several customary traditional uses (Table 13.2). Historically, the dried flesh and hides of sea lions along with fur seals has long been a staple on the Pribilofs. The sea lion provided essential meat and clothing, as well as covering for the bidarrah.

The northern fur seal continues to play a major subsistence role on the Pribilof Islands with several hundred being killed on St. Paul and St. George each year. Until recently, the U.S. Government allowed a subsistence take of 2,500 young bachelor males to be harvested each year. Today, the Tribal Governments on each island and the NOAA National Marine Fisheries Service (NMFS) are co-managing the subsistence harvest of fur seal. Locations authorized for subsistence sealing by year and favourite hunting areas are being included in the GIS project. Several recent seal midden locations are being mapped as well.

Links from the GIS maps are used to display more detailed information on the food subsistence value offered by the northern fur seal. A link from the map to a photograph (Scheffer 1948) that laid out the various body parts provides even more detailed information (Figure 13.3).

Table 13. 2 Species list using either Aleut or English name found on or about the Pribilof Islands and their customary traditional use.

Subsistence Resource	Customary Traditional Use
qawax	Hides: baidarkas and bidarrahs (skin boats) Intestines: waterproof garments Throats: boot tops Fore-flipper palms: boot soles Stomachs: oil containers Whiskers: traded to Chinese Sinews from back: "thread" for sewing Gall bladder: healing sores Carcass, liver, lungs, lard: food (Elliott, 1881)
itxayan	Carcass: food
aygagux	Skin: sold for it fur value
kagayax	Eggs: food Carcass: food
chuchiigix	Carcass: food
sikiita	Skins and feathers: parkas Eggs: food Carcass: food
saquudax	Plant stem: food
qayux	Berries: food
Salmonberry	Berries: food
aguganax	Roe: food
waygix	*Body: food*

Today, as in the past, many seabirds have customary traditional uses. Millions of seabirds flock to the islands each year for breeding. Henry W. Elliott was the first American on the Pribilof Islands that accounted for their natural history and cultural subsistence through prolific writings extending over 20 years. He noted that large flocks of *chuchiigix* (*Aethia pusilla*) arrived in the spring and were harvested by *Unangan* with hand scoop nets. *Chuchiigix*, known as the least auklet, make nests in crevices among boulders. *Chuchiigix* are still hunted today by using a long bamboo pole to strike the small birds out of the sky (bamboo often washes up on the shores of the islands). Veltre and Veltre (1981) point out that this is one of the few species that can be hunted by children. Elliott (1881) reported that least auklets were replaced in late July by large flocks of red-legged turnstones that were also eaten by *Unangan*. Unlike the *chuchiigix*, the turnstones bred elsewhere, but they stopped on the Pribilofs to feed on the "flesh flies and their eggs, which swarm over the killing grounds." The killing grounds are not

nearly as extensive as they once were, but whether the abundance of turnstones on the islands was affected is not known.

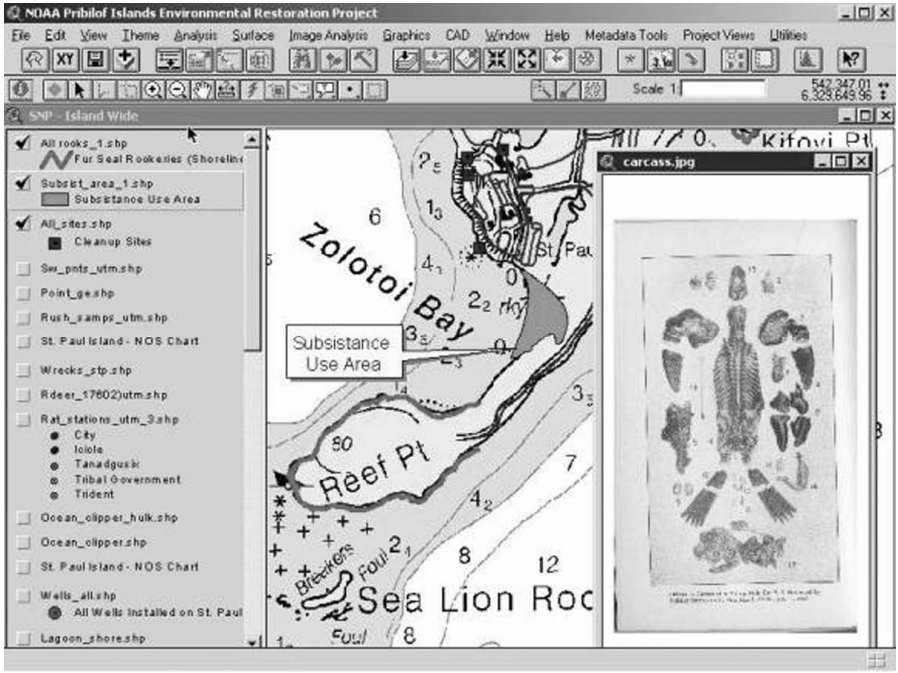

Figure 13.3 Example of hyperlinked media accessible from within the GIS: body parts and subsistence values of a northern fur seal.

Egg gathering was a major annual activity on the Pribilofs, although it is much less so now. Primary egg gathering areas included the steep rocky bluffs and the tabletop flat Walrus Island. According to Elliott, the primary egg-gathering season on Walrus Island was June-July (Elliott 1875). Historical egg gathering locations are included in the GIS project.

The Pribilof Islands are treeless, except for a low-to-the-ground-willow species. Several plant species afforded both cultural and subsistence value. For example, Elliot (1875) commented that only two berry plants, *Empetrum nigrum* and *Rubus chamemorus*, are readily harvested by the Aleuts during the end of August and first week in September. These species are still much sought after and often families spend summer afternoons harvesting the berries. *Saquudax* (wild celery) seemed to have had more importance in the past than it does now. A silent 1930's black and white film archived in the Oregon Historical Society shows Aleut children harvesting *saquudax* and demonstrating how it is eaten. A digitized version can be viewed via a hotlink when the distribution plots for the plant are active in the GIS project.

Heretofore, little documentation logged by the U.S. Government, Aleut community, or Russian Orthodox Church is known to exist as to the burial of deceased islanders. Some gravesites are marked, while many are known only

orally and most are not recalled at all. As a community service and as part of the interest in historical documentation, NOAA received permission from the local churches to develop a GIS project of the cemeteries. Using a survey grade GPS, more than 700 gravesites on St. Paul and St. George Islands were entered into the GIS project. Digital images of each location along with individual statistics (individual names and photo, birth and death dates, and short biographical sketches as available) are linked to the geographic locations. Printed hard copy maps were provided for use by the local churches and municipalities. Using DVD authoring software, the GIS project enhanced with animation and Aleut choir music was transcribed onto a DVD. NOAA provided the respective DVDs to the local church councils. In turn, the St. Paul Island council is relying on the Tribal Government for long-term maintenance of the GIS project. Recently, the Russian Orthodox Church Diocese of Alaska began promoting this GIS application throughout the Diocese.

13.8 LONG TERM NATURAL RESOURCE MANAGEMENT

Currently, Tribal Government of St. Paul's Ecosystem Conservation Office (ECO) is using GIS in combination with traditional ecological knowledge for use in environmental and resource management. Due to the increased human interactions with the Pribilofs' Bering Sea environment, the need to monitor and record these interactions and their impacts on St. Paul and neighbouring islands has become vital. Monitoring of commercial and customary traditional activities, the island ecosystem (i.e. numerous plant and animal species, lands, and environmental changes), in addition to ecological disaster prevention planning are essential in safeguarding customary traditional practices and for protecting and conserving the health of the islands. Critical response planning to prepare the community to effect immediate responses to future ecological perturbations is also vital as competition increases between traditional and commercial interests for the dwindling Bering Sea fishery resources.

The impacts associated with regional oil spills, off-road all terrain vehicle trailbreaking, and commercial fishing along with knowledge about decreasing populations of northern fur seals, Steller sea lions, and various seabird species serve to highlight a need for a balanced harmony between the subsistence users and other interests. Harmonious relations can be achieved through communication, planning, negotiation, and mutual work towards an understanding and respect for differences among groups. To this end, ECO has worked on ongoing development of *Tanalix Amgignax* (Island Sentinel/Guard) Program in coordination with the Pribilof Islands Stewardship Program, PPO, NMFS, and USFWS. This program includes the following elements:

- Promote "caretaking" and stewardship of the Pribilof Islands' many life systems.
- Provide a central forum that actively deals with environmental issues.
- Monitor activities that have potential adverse implications on this area of the Bering Sea environment.
- Promote a proactive position on behalf of all life systems indigenous to the Pribilof Islands Bering Sea area for immediate monitoring.

- Exercise the Aleuts' inherent right to be responsible for the islands' environment.
- Share caretakership concerns and activities with others, expecting visitors to be on their "best behavior" while visiting St. Paul Island and the surrounding sea.
- Promote environmental and cultural awareness.

Some specific *Tanalix Amgignax* activities that also involve GIS include: preventing rats from coming to the island by actively setting and maintaining rat traps in and around the harbour area and sanitary landfill; monitoring the islands' shoreline and interior for natural process impacts (weather and wildlife) and disturbances, such as vegetative changes by overgrazing reindeer, shoreline erosion, and derelict fishing gear (i.e. nets, buoys, line, etc.) that wash up on shore; removal of fishing gear from around fur seals' necks; and sharing the importance of taking care of the Bering Sea environment with the community and visitors alike. Rat trapping locations are entered into the GIS project. If and when any rats are captured this information will be similarly logged into the project. GIS mapping of derelict fishing gear not only provides information to managers for directing shoreline cleaning up efforts, but also documents the periodicity of cleanup efforts along shorelines, the relative quantities and types of debris recovered, and identifies areas where oceanographic conditions work to focus debris.

Tanalix Amgignax Program is a prime example of the use of GIS in bringing together traditional ecological knowledge and "western science." NOAA's contribution to the ECO GIS project will foster the dialogue among the many interests that the *Tanalix Amgignax Program* seeks to bring together.

13.9 CONCLUSIONS

GIS application in the Pribilof Island Environmental Restoration Project afforded insights and opportunities not contemplated at the outset of the project. The use of DGPS technology to simply map contaminated and debris site locations, and sampling points led to numerous significant contributions. One of the more routine contributions involved using JPEG and TIFF files cut from the GIS project to make maps for documents on topics such as site investigations, corrective action plans, corrective action reports, and requests to oversight regulators for no further action. Among other significant contributions came new nautical charts with improved near-shore confidence by local fishers in GPS navigation systems; map overlays of historical northern fur seal and sea lion rookeries for comparison with current and ever changing population and environmental conditions; estimates of shoreline erosion rates; improved control management of shoreline marine debris; near real time mapping of contaminant excavations allowing for on the ground decisions; sub-meter scale topographic maps to assist engineers in landfill closeout design and calculating royalty payments from sand and scoria (used as excavation backfill and capping solid wastes) mining; improved communications among officials who lacked on-island experience yet hold responsibility for land transfers following cleanup; and sorting through conflicting boundary descriptions arising from a variety of official documents over an approximate 25-year period.

A collaborative spirit between the government and Aleut entities grew out of training opportunities provided by NOAA in DGPS and GIS, access to NOAA DGPS equipment for ECO Projects, and contributions of GIS software to the City of St. Paul and ECO. Subsequent collaborative geo-spatial projects further improved overall communications. DGPS and GIS enabled local Aleuts to express their own cultural heritage by applying Aleut location names to the first ever large-scale topographic quadrangles of the islands. In terms of community relations, the most significant contribution afforded by DGPS and GIS came from the mapping of the islands' gravesites. Unwittingly, this single DGPS/GIS exercise offered up as a community service in context with a federal mandate to preserve historical information provided the strongest bond and trust between the islands' Aleut population and U.S. Government agents.

Acquisition of precision geo-spatial data in real time is one of many challenges in the higher latitudes. Geodetic control points, such as those offered by Continuously Operating Reference Stations (CORS), are far and few between in America. Alternatively, one can, as done in this project, survey in a base station to provide short-range control. For long-term applications base stations must be maintained against vandalism, climatic events, and curious animals such as foxes that chew through cables. Repeater stations serve to overcome multipath interference such as caused by hilly terrain and buildings. Once these obstacles are overcome, real-time DGPS in combination with GIS provide the investigator with tremendous power to work multiple field situations near real time as well as providing for long-term documentation.

CHAPTER FOURTEEN

GIS Applications In Coastal Management: A View from the Developing World

Peter C. Nwilo

14.1 INTRODUCTION

Geographic Information Systems have revolutionised the way spatial data/information is acquired, stored, managed, and displayed. In the past the acquisition of spatial data was done mainly with analogue theodolite and levels, and the recording and storage of these data were done in analogue manner. Data management was a very cumbersome exercise and the display was in the form of paper maps. Recent developments in information and digital technologies, communication and satellite technology, and improved computing speed and computer hard disk space, have impacted tremendously the way spatial data is acquired, stored, managed, and displayed. The development has created a revolution in spatial information technology in a way never experienced before. Today, virtually every human activity is spatial. Some schools of thought stipulate that in countries such as the United States and the United Kingdom as much as 75-80% of all the activities is spatial. There is correlation between geospatial information technology development and economic development. Developed countries of the world are associated with high spatial information technology development. Conversely, poor economic development is associated with low spatial information technology development as witnessed in developing countries of the world.

The development of Geographic Information Systems and associated technologies has created and is still creating employment opportunities all over the world. It has also led to changes of curricula of training institutions, and new training opportunities are being created. Transfer, sharing access to and development of spatial data standards have become major issues. We now discuss spatial data infrastructure as a major requirement for development, as has long been done with regards to other infrastructures such as roads, rail and waterways, electricity, and water supplies.

Geographic information has been employed in several fields such as management of disasters, vehicle tracking systems, forestry, utilities management, oil exploration, environmental management, health management, census, and

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

mineral resources development, governance (EIS Africa, 2002) and – the focus of this paper – coastal management.

14.1.1 Coastal Areas

The coast is an area that witnesses a substantial amount of physical and economic activities. It is a zone of great significance in the sense that intense agriculture, business and recreational activities take place here. Settlements have been established in these areas and international trade and communication originated in the coastal fringes (Nwilo, 1995; Nwilo *et al.*, 1995). The coastal zone houses about two thirds of the world's population and this percentage is expected to increase to 75% by the year 2020 (UNEP, 1992; Hanson & Lindh, 1993). Most of the important cities of the world, such as Alexandria, Lagos, London, Rotterdam, Shanghai, Tokyo and Venice, are located within the coastal environment, while two thirds of the world's cities having a population of over 2.5 million are within the coastal zone (Borrego, 1994). The coastal environment is very rich in both living and non-living resources. For example, a lot of crude oil and gas exploration and exploitation take place with the coast.

Wetlands are known to be a very productive ecosystem. Most of these wetlands are located in the coastal areas. They are the sanctuaries to many global endangered species and also can assist in dampening the effect of flooding from normal sea flooding, storm surges and sea level rise. Fishes that are caught in the upwelling zone of the Canary Island coast are hatched within the mangrove ecosystem of the Niger Delta and later migrate to the upwelling area. Similar relationships are found in most of the world's major fishing waters.

The coast is therefore a very important zone. Having discussed the importance of the coastal areas, it is now necessary to define the 'coastal zone.' Bird (1967; 1985 & 1993) defines the coast as a zone of varying width including the shore and extending the crest of cliff, the head of a tidal estuary, or the solid ground that lies behind the coastal lagoon, dunes and swamps. Komar (1976) on the other hand defines the coastal zone to include the littoral zone and extending further inland to include the sea cliffs, any marine terraces, dune fields and so on; the seaward limit is limitless. For most studies the coastal zone refers to that zone that is affected by what happens on the sea and on land. The coast is therefore very important for the existence of human life.

14.1.2 Integrated Coastal Area Management

Integrated Coastal Areas Management is defined as a dynamic process in which a coordinated strategy is developed and implemented for the allocation of environmental, socio-cultural and institutional resources to achieve the conservation and sustainable use of the coastal area (Coastal Area Management and Planning Network, 1989; Nwilo, 1995). Planning for sustainable resource management is based on weighing priorities, translating these priorities into policies and finally defining goals, identifying responsibilities for each step and establishing a time frame for action and review (Nwilo, 1995). There is no one

'right' way to manage coastal areas. However the design of a coastal management programme or policy for a nation or a region should take into consideration the legal instrument for the implementation of the program as well as the instrumental frame work for policy implementation (Emovon, 1991).

In order to practice effective coastal management, planners need to understand the way the natural environment and human activities are interconnected to form a system. Key aspects of the system include the following information themes:

i. Biological: This includes type and extent of ecosystem, primary productivity, specie diversity and abundance, nursery grounds and life cycles;
ii. Physical: This includes topography, geology, temperature, salinity, nutrients, tides, sea level and current, meteorology, sediment types and distribution, flooding and erosion/ accretion;
iii. Socio-economic: This includes human population distribution and growth, economic activities and land use;
iv. Legal and Institutional: Land tenure system, resource use rights, relevant laws and regulations, responsible agencies and availability of financial and human resources (Borrego, 1994).

Each of these activities is greatly influenced by activities within and beyond the coastal zone. It is for this reason that the resolution of conflicts in the use of coastal resources requires a broad perspective on the environmental process and interaction among human activities.

14.2 THE GUINEA CURRENT LARGE MARINE ECOSYSTEM PROJECT

14.2.1 The Concept of Large Marine Ecosystem Project

Large Marine Ecosystems are regions of the ocean space encompassing coastal areas from river basins and estuaries to the seaward boundaries of the continental shelves, and the outer margins of the world's current system. These marine regions are considered in terms of their ecological unity based on their distributive bathymetry, hydrographic, productivity, and trophic linkages (Sherman *et al.*, 1993; UNIDO, 2002). The world's 64 LMEs are the most productive ecosystems, and together produce 95% of marine fishery biomass yields. It is also in the LMEs that most of the global ocean pollution, fisheries over-exploitation and coastal habitat alteration take place.

The LME ocean management approach focuses on the sustainable development of the ocean resources and requires a paradigm shift from a small spatial scale to a larger one and from a short-term to a long-term perspective. It requires countries bordering the LME to set priorities on how to tackle their common transboundary issues. Since the early 1990s, the developing countries have approached the Global Environment Facility (GEF), the United Nations Industrial Development Organisation (UNIDO) and other United Nation implementing agencies for technical and scientific assistance in restoring and

protecting their coastal and marine ecosystem. GEF agreed to provide guidance and funding in addressing these issues within the framework of sustainable development. It recommended the use of the Large Marine Ecosystem (LME) concept and their contributing freshwater basins as the geographic focus for addressing the issues (UNIDO, 2002).

14.2.2 The Guinea Current Large Marine Ecosystem Project Implementation

The Guinea Current Large Marine Ecosystem Project is funded by the Global Environment Facility (GEF) and managed by the United Nations Industrial Development Organisation (UNIDO). The phase I of this project was started in 1995 and ended in 1999 with the countries of Cameroon, Nigeria, Benin Republic, Togo, Ghana and Côte d'Ivoire participating. Apart from GEF and UNIDO, some form of scientific and technical support came from the United Nations Education and Scientific Cultural Organisation (UNESCO), other UN agencies, and the US National Oceanic and Atmospheric Administration (NOAA). The participating countries provided in country support in the form of logistics such as provision of offices and transportation vehicles. The execution of the project was in form of modules. The modules that were covered in the project included Integrated Coastal Areas Management (ICAM), Geographic Information System (GIS), Mangroves, Industrial Pollution, Policy Issues, Fisheries, Coastal Erosion, Plankton and other pollution. The structure made provision for a National Project Director in each of the participating countries and a National Expert for each of the modules. All the national experts were reporting to an International Expert who co-ordinated each of the modules. The project had a Project Coordinator who was based in Abidjan, Côte d'Ivoire. The office of the Project Coordinator also served as the Secretariat for the project. In each of the participating countries, there was a Focal Point Agency and Focal Point Institution.

In Nigeria, the now-defunct Federal Environmental Protection Agency was the focal point agency, while the Nigerian Institute for Oceanography and Marine Research was the focal point institution. There were other participating institutions such as the University of Lagos. In the other participating countries, the focal point agency was the Ministry of Environment. Efforts were made in the project to collaborate with relevant institutions.

The second phase of the project is bringing in an additional 10 countries. These include Guinea Bissau, Guinea, Sierra Leone, Liberia, Congo Brazzaville, Democratic Republic of Congo and Angola. These countries, in addition to the original six, are in partnership activities for sustainable development of the Guinea Current Large Marine Ecosystem (GCLME). The addition of these to the original six countries meant that the full extent of the Gulf of Guinea Current Large Marine Ecosystem is covered. This stage of the project will commence in January 2004 (UNIDO, 2002).

All participating countries are making contributions to a Transboundary Diagnosis Programme (TAD) and a Strategic Action Programme (SAP) for the project (UNIDO, 2002).

14.2.3 The ICAM Module

The essence of the Guinea Current Large Marine Ecosystem project is the sustainable management of the living resources of the Gulf of Guinea region. The region was experiencing a serious environmental stress due to urbanisation, pollution from industries and domestic wastes, population explosion, oil spillage, deforestation, erosion, and over-fishing. The fish stocks were depleting at a fast rate and the socio-economic lives of the inhabitants are adversely affected. The lagoons that dot the coast from Côte d'Ivoire to Nigeria had become heavily polluted. Most of the problems highlighted above are transboundary in nature. There was therefore a need to reverse the situation and address these problems from a regional perspective rather than from a national perspective.

Under the module, an experienced ICAM professional prepared guidelines for implementation of ICAM in the countries. The National Experts prepared a country profile for each of the six participating countries in the first phase. The country profile is a baseline of the situation in each of the participating country's coastal area. The information used in preparing the country profile was obtained from existing literature and from relevant institutions. This was followed by a three-day workshop where stakeholders discussed the profile and made recommendations where necessary. A final copy of the country profile was made after effecting the necessary corrections from stakeholders.

An outcome of the workshop was the setting of the National Integrated Coastal Area Committee for each of the participating countries. Another success of the workshop and activities of the Guinea Current LME phase 1 is the creation of awareness on the importance of Integrated Coastal Area Management: prior to the Guinea Current LME project, there was no National ICAM Committee in any of the six participating countries.

As part of the efforts to assess the health of the Guinea Current LME, a fish trawl survey was carried out from Côte d'Ivoire to Cameroon. Results from the survey confirmed the fear that the fish stock, together with the plankton, was being depleted.

Figure 14.1 shows the Gulf of Guinea Region while Figure 14.2 shows the countries that took part in the first phase of the project

Figure 14.1 The Guinea Current Region

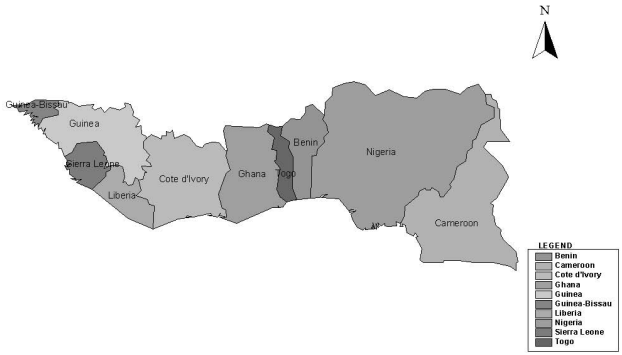

Figure 14.2 Countries that participated in the GCLME Project, Phase I

14.2.4 Application of GIS to The Project

As was the case in the Integrated Coastal Area Management Module, there was a National Expert for the GIS Module in each of the participating countries in phase I of the project. The author served in this position for Nigeria. The project started in 1995 but the National experts were engaged in 1997 for a two-year period. The contract was on part time basis.

The major goal of the GIS application in the project was to use GIS as an information and decision support system. Decision-makers are not always in a position to read all the volumes of materials that are passed to them. The graphic displays that are provided by GIS will invariably reduce the time that would have been spent in reading several volumes of materials, and assist in taking decisions that affect a project quickly. For example, it is easy to visualise the way a mangrove ecosystem of a region is changing over time through graphical displays.

14.2.5 Capacity Building for the GIS Module

The project provided for National Experts to attend Training workshops and conferences. A Project Expert Committee Workshop was organised by the Project Coordinator's office in Abidjan in April 1997 for all the National GIS Experts. This workshop touched on GIS application in the project and in particular the issue of metadata. Since the project is regional in nature the issue of harmonisation of different mapping datums in the region was discussed extensively. The National Experts provided information on institutions using GIS in the different participating countries. It was also a forum for experts to get to know each other. Another GIS Expert meeting took place in Abidjan between 29-30 September 1998 to deliberate on issues affecting the project.

14.2.6 SIMM Coast Workshop

SIMM is an acronym for sustainable integrated management and so SIMM Coast stands for sustainable integrated management of Coast. This workshop was organised by Prof. McGlade, formerly of the Centre for Marine Research, University of Plymouth, United Kingdom. It was essentially on the application of artificial intelligence in integrated coastal management. All the GIS National Experts were sponsored by UNIDO to participate in the workshop. This workshop took place at the Food and Agricultural Organisation office in Accra, Ghana between July 30th and 31st, 1998.

14.2.7 The Accra Declaration

The first meeting of the Ministerial Committee of the Gulf of Guinea Large Marine Ecosystem (GOG-LME) Project took place in Accra, Ghana, on 9th and 10th of July, 1998. Five Ministers with responsibility for the Environment respectively in Benin, Cameroon, Côte d'Ivoire, Ghana and Togo and the Director General/Chief Executive of the Federal Environmental Protection Agency of Nigeria attended the meeting.

After the deliberations of the ministers, which were based on extensive and substantive preparations, the Committee of Ministers adopted the Accra Declaration on Environmentally Sustainable Development of the Large Marine Ecosystem of the Gulf of Guinea. Part of the decision reached was that efforts shall be made to initiate, encourage and work synergistically with current and/or programmed national and international programmes on integrated coastal zone management in the region. The national concerns of flooding, and pollution caused by hydrocarbons, toxic chemical products, fisheries productivity and over-exploitation and, above all, coastal erosion, call for the special attention of donors. Also, data and information networking between the GOG-LME countries should be improved. National and Regional databases on the coastal and marine environment should be established using the Geographical Information System (GIS) to support decision-making, to be available to all users.

14.2.8 Results from the Phase I of the GCLME Project

As part of the success story of the GCLME project, guidelines for integrated coastal areas management and planning have been developed for Benin, Cameroon, Côte d'Ivoire, Ghana, Nigeria and Togo. Country coastal profiles were similarly developed and major issues and options for national and regional actions were identified.

The Gulf of Guinea Large Marine Ecosystem (GOG/LME) project has organised and facilitated a series of activities that have enabled each country to take the appropriate steps toward the adoption of Integrated Coastal Areas Management Plans, including strengthening legal and policy frameworks. In addition, these plans and policies are available for incorporation into National Environmental Action Plans. ICAM has proven to be the most effective way to involve the grassroots stakeholders in a meaningful way and could be the cornerstone for the GOG/LME potential Phase II Project.

Indications that member countries will embrace and make this effort sustainable are beginning to appear. First, National Steering Committees have been established by legal instruments. Second, the individuals who are participating in the programme range from top Ministry officials to citizens in NGOs and CBOs, indicating the existence of multilevel support.

An important parallel development with the effort to put National ICAM Plans in place has been the process of establishment of information management and decision-making systems such as Geographic Information Systems (GIS) at both the national and regional levels. ArcView 3.1 GIS software was chosen as the GIS platform for the project. It is hoped that in the second phase of the project, ArcGIS 8.3 will be the platform.

Some of the maps, which were developed from existing information in Nigeria during the execution of the project, are shown in Figures 14.3 and 14.4.

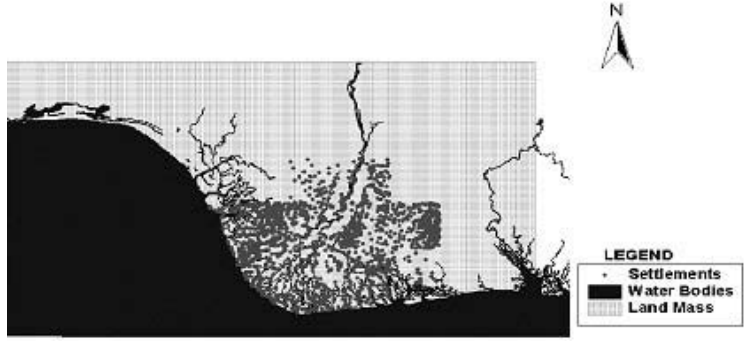

Figure 14.3 Settlements in the Niger Delta

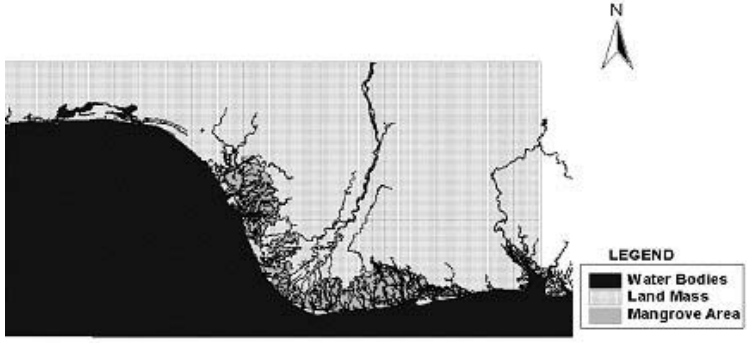

Figure 14.4 Mangrove Ecosystem in the Niger Delta

14.3 OTHER COASTAL AREAS PROJECTS IN AFRICA

14.3.1 Niger Delta Environmental Survey

The Niger Delta is an environmentally sensitive and fragile region owing to its peculiar natural physical setting and its distinctive ecological features and functions which over the years have drawn the attention of conservationists especially on the need for sustainable development and the protection of its biodiversity (NDES, 1997). Considerable changes are occurring in the ecological environment and in the socio-economic setting of the Niger Delta as a result of both natural and another anthropogenic transformations that include: upstream dam construction, coastal zone modification, urbanisation, deforestation, agriculture, fishing, industrial development, population pressure, and crude oil exploration and exploitation. The Niger Delta is therefore under increasing pressure from rapidly deteriorating ecological and economic conditions, social dislocation and tension in communities, problems that are not being addressed by current policy and behaviour patterns.

It is for this reason that the Niger Delta Environmental Survey (NDES) was set up. The NDES, in concert with communities and other stakeholders, undertook a comprehensive survey of the Niger Delta. It established the causes of ecological and socio-economic changes over time and induced corrective actions by encouraging relevant stakeholders to address specific environmental and related economic problems aimed at improving the quality of life or the people and achieving sustainable development in the region. Part of the objectives of the survey was to generate data and information on the Niger Delta including the establishment of a Geographic Information System (GIS). The data and information can be used in formulating strategies and plans for effective natural resource management towards the sustainable use of resources, in order to protect the environment and the livelihood of peoples of the region (NDES, 1997).

Analogue maps of the Niger Delta at scale of 1/25,000 were digitised and updated with remotely sensed images. The map information is now in a GIS environment, and is used in decision-making for the planning and management of the Niger Delta.

14.3.2 Secretariat for Eastern African Coastal Area Management (SEACAM) Project

SEACAM means secretariat for Eastern African Coastal Areas Management. It was set up in August, 1997 in Maputo, Mozambique, with the purpose of accelerating the implementation of integrated coastal zone management in the region as put forth in the Arusha Resolution of 1993 and Seychelles statement of 1996 on ICZM. The Secretariat is hosted by the Ministry of Environmental Affairs for Mozambique.

The objective was to assist Eastern African Countries to implement ICZM following up the Arusha resolution and the Seychelles statement on capacity building and information dissemination. It was supported by the Government of Finland, Danish International Development Assistance (DANCED), the World Bank and UNESCO. A number of other donors provide important support to select activities that match their programme areas.

In 1996, the Western Indian Ocean Marine Science Association organised an expert and practitioners workshop in Taga, Tanzania on integrated coastal area management, which provided an input into the second ministerial policy conference on integrated coastal and zone management in Eastern Africa and Island States held in Seychelles, October, 1996. It is not certain whether GIS was used in this project.

14.3.3 Lake Victoria Environmental Management Project

For decades, East African scientists, policy makers, stakeholders and others around the world noted the escalating environmental degradation of Lake Victoria, which is an international water body. It was observed that increased population is a major contributing factor. The total population of the riparian communities currently stands at 30 million.

As a result of the degradation the riparian countries to Lake Victoria, which are Kenya, Tanzania and Uganda, initiated discussions immediately after the United Nations Conference on Environment and Development (UNCED) to broaden regional cooperation in environmental and social issues affecting Lake Victoria Basin. This led to the signing of a triplicate agreement in 1994. The project attracted financial support from the International Development Association (IDA) and Global Environmental Trust Fund (GEF) to the tune of US $70.00 million. The participating countries agreed to contribute $7.2M as counterpart funds. Apart from other achievements of the project, mapping of the present land use/land cover and soil erosion hazard in the Lake basin is almost completed. Data on pollution loading are being collected from selected micro-catchments and provide useful information on soil nutrients and water losses. Human capacity is

being developed. An important component of the project is community participation in the preparation and implementation of the project. It is not clear whether GIS was used as an information management tool but it is obvious that there was mapping which could, if still in analogue format, be converted to digital format and managed in a GIS environment.

14.3.4 Information Technology for Coastal Zone Management of the Nile Delta

This is an initiative for development and implementation of an integrated coastal analysis and monitoring system. A workshop was organised between 7 – 10 April 2003 aimed at addressing issues such as coastal erosion, pollution, monitoring and fisheries management. It will serve as a model for information system implementation in the developing world context, where the need for operational coastal management is often great but for which information infrastructure and knowledge base are frequently lacking.

14.3.5 Eastern African Coastal Resource Maps Project

The Eastern African Coastal and Marine Environment Resources Database and the Atlas was founded within the framework of the 1985 UNEP brokered Eastern African Action Plan for the protection, management and development of the Marine Environment of the Eastern African Region (EAF). The countries of Comoros, La Réunion, Kenya, Madagascar, Mauritius, Mozambique, Seychelles, Somalia and Tanzania participated in the project.

The project was initiated in 1993 by the Ocean and Coastal Area Programme Activity Centre (OCA/PAC) in co-operation with the Global Activity Centre (GRID/PAC-Nairobi). The project was scheduled to run for five years. The first phase of the project only focused on Kenya while Phase II and III (1995-1996) concentrated on Comoros, Mozambique, Seychelles and Tanzania. Phase III and IV (1996-1997) concentrated on Madagascar, Mauritius, La Réunion and Somalia. Phase V is intended to round up all activities at the National Level.

The production of the digital database led to wiser use of resources and helped reduce wastage of non-renewable resources. The main objective of the project is to collect existing information on coastal resources of the region and to summarise the same in country map sheets managed in a GIS environment (Okemwa, 1995).

Scientists from the participating countries took part in the collaboration of the information and the development of the database. Information in the database covers parameters including but not limited to climate, hydrology, oceanography, coastal types, geomorphology, geology, tourist infrastructure, important ecosystems such as mangroves systems, wetlands, estuaries, rangelands and mineral resources.

The maps will be useful in studying the vulnerability of the coastline and indeed as a versatile tool in making strategic intervention in cases of oil spills.

14.4 CONCLUSIONS

Various coastal management projects in Africa have been discussed above. It is observed that most of these projects were conceptualised and executed by the developed countries, mainly European countries, while the African scientists only played supportive roles. Two projects in the opinion of the author stand out as clear exceptions to this situation. These are the Guinea Current Large Marine Ecosystem project and the Niger Delta Environmental Survey.

As earlier stated, the Guinea Current Large Marine Ecosystem project is funded by the Global Environment Facility and managed by the United Nations Industrial Development Organisation. Initially, the project was conceptualised by the governments of Nigeria, Ghana, Togo, Cameroon, Benin and Côté d'Ivoire. It was later realised that there was a need to include all the countries bordering the Guinea Current and this increased the number of participating countries to sixteen.

The other project, the Niger Delta Environmental Survey, was conceptualised by the oil prospecting companies in Nigeria. Its mission statement is: "In concert with communities and other stakeholders to undertake a comprehensive environmental survey of the Niger Delta, establish the causes of ecological and socio-economic changes over time and induce corrective action by encouraging relevant stakeholders to environmental and related socio-economic problems identified in the survey to improve the quality of life of the people and achieve sustainable development in the region" (Niger Delta Environmental Survey, 1996). Incidentally, these two projects are in Nigeria.

There is therefore a need to involve the African scientists and researchers from the conceptualisation stage of projects on the Continent. This is believed to be more beneficial to these countries and their scientists, particularly in the area of capacity building.

CHAPTER FIFTEEN

High-Resolution Elevation and Image Data Within the Bay of Fundy Coastal Zone, Nova Scotia, Canada

Tim Webster, Montfield Christian, Charles Sangster, and Dennis Kingston

15.1 INTRODUCTION

The Applied Geomatics Research Group (AGRG) is a component of the Centre of Geographic Sciences (COGS) located in the Annapolis Valley, Nova Scotia. Its mandate is the application of geomatics technology for environmental research within Maritime Canada. In the fall of 1999 and summer of 2000 a large data acquisition campaign was initiated to collect high-resolution elevation and other remotely sensed image datasets along the Bay of Fundy coastal zone (Figure 15.1 and colour insert following page 164). The purpose of the research was to evaluate their effectiveness in obtaining critical information about the coastal zone, particularly data to be used to assess flood-risk potential associated with storm surge events. Global mean sea level has been increasing between 0.1 and 0.2 meters per century. With increasing greenhouse gases, sea level rise is expected to accelerate and the Intergovernmental Panel on Climate Change predicts that global average sea level may increase by 0.09 to 0.88 meters by 2100, placing the lives and property of an estimated 46 million people at risk (Houghton et al., 2001). The Bay of Fundy is no exception: relative sea-level is rising in this region by an estimated rate of 2.5 cm per century and many coastal areas are becoming more susceptible to flooding from storm events (Stea, Forbes, and Mott, 1992). In addition to sea level rise, storm surge and ocean waves are also factors at the coastline and are carried to higher levels on rising mean sea level. Storm surge in general is defined as the algebraic difference between the observed water level and the predicted astronomical level as one would find in tide tables. With possible increased storminess associated with climate change, the next 100 years will probably see more frequent flooding of coastal zones, and an increase in erosion of coastal features. With the recent increase in the spatial resolution of geomatics data available, both multispectral imagery (Ikonos, Quickbird, CASI) and high accuracy elevation data, landuse planners and policy makers now have access to the information required to manage the coastal zone.

LIDAR (Light Detection and Ranging) technology has been employed for a number of years in atmospheric studies (e.g. Post et al., 1996; Mayor & Eloranta, 2001) and as an airborne technique for shallow bathymetric charting (e.g. Guenther et al., 2000), although cost was initially an impediment to widespread acceptance for the latter purpose. The technology can also be used to image the land and water surface (Hwang et al., 2000), as was done in the present study. Terrestrial LIDAR applications have been demonstrated in forestry (Maclean & Krabill, 1986), sea-ice studies (Wadhams et al., 1992), and glacier mass balance investigations (Krabill et al., 1995, 2000; Abdalati & Krabill, 1999). A general overview of airborne laser scanning technology and principles is provided by Wehr and Lohr (1999). Applications to coastal process studies in the USA have been reported by Sallenger et al. (1999), Krabill et al. (1999), and Stockdon et al. (2002), among others. Preliminary trials in Atlantic Canada were reported by O'Reilly (2000) and subsequent experience was described by Webster et al. (2001, 2002, 2003) and McCullough et al. (2002). Most of the coast of the conterminous USA has now been mapped using this technology (Brock et al., 2002). A comprehensive review of the theory and applications of Digital Elevation Models (DEM) covers both terrestrial and marine LIDAR as well as other technologies

used for DEM construction such as IFSAR – interferometric airborne synthetic aperture radar – is given by Maune et al. (2001).

Two different data providers were contracted to acquire LIDAR for the region. This chapter will discuss the details of the LIDAR systems, mission planning, data validation, and processing. The LIDAR DEM was then used in generating flood-risk maps associated with storm surge events along the coastal zone. This information has been passed to the local planning commissions to aid in management of the coastal zone. Another outcome of the project is that one of the data providers has significantly improved their acquisition system and approach to quality assurance when collecting LIDAR data.

15.2 DATA ACQUISITION AND PLANNING

Data that were acquired during the fall of 1999 were airborne polarimetric synthetic aperture radar (PSAR) data from the Convair 580 aircraft operated by Environment Canada, and satellite imagery from Radarsat-1, and Landsat-7. The polarimetric SAR was a simulation of Radarsat-2, Canada's second earth observation satellite planned for launch in 2005. Data acquired in the summer of 2000 campaign included high-resolution airborne data from the Compact Airborne Spectrographic Imager (CASI), and LIDAR systems, and more satellite imagery from Ikonos, Radarsat-1, and Landsat-7 (Table 15.1).

Table 15.1 Types of data collected during 1999, 2000 summers.

Data Type/Sensor	Resolution (m)	Attribute
PSAR	6	Polarimetric SAR signal, C-Band 5.6 cm, HH, VV, HV polarizations
Radarsat	12 (variable)	C-Band 5.6 cm, HH polarization, variable incidence angle
Landsat	15 pan, 30 mss	Visible, near and mid-infrared imagery
Ikonos	1 pan, 4 mss	Visible and near infrared imagery
CASI	2 (variable)	Visible and near infrared imagery
LIDAR	2 (variable)	Elevation (ground and non-ground)

Polarizations: HH – horizontal transmit, horizontal receive, VV – vertical transmit, vertical receive, HV – horizontal transmit, vertical receive.

The study area consists of the Annapolis Valley region of Nova Scotia, located on the southeast shore of the Bay of Fundy (Figure 15.1). LIDAR and CASI coverage consisted of the entire length of the valley and coastal zone. The satellite coverage was concentrated in the Annapolis and Minas Basins (Figure 15.2, see colour insert).

15.2.1 Acquisition Planning Issues

The Bay of Fundy is famous for its great tidal range, up to 13 m in this area. For such a large study area the timing of the tides vary by approximately 1 hour between Digby, within the Annapolis Basin, and the Minas Basin. Because of the variability of tide times within the study area, three locations were used to predict tide times and sites: Digby, Margaretsville, and the Minas Basin/Cape Blomidon. Acquisition of remotely sensed data at low tide has several applications including: 1. validation of tidal models; 2. determination of inter-tidal slope from derived elevations from the "waterline method" i.e. knowing the water depth at the time of image acquisition allows the land/water line to be used as a topographic isoline; 3. morphological and biological classification of the inter-tidal zone. Tide predictions were acquired for each port via the Internet (http://tbone.biol.sc.edu/tide/sitesel.html).

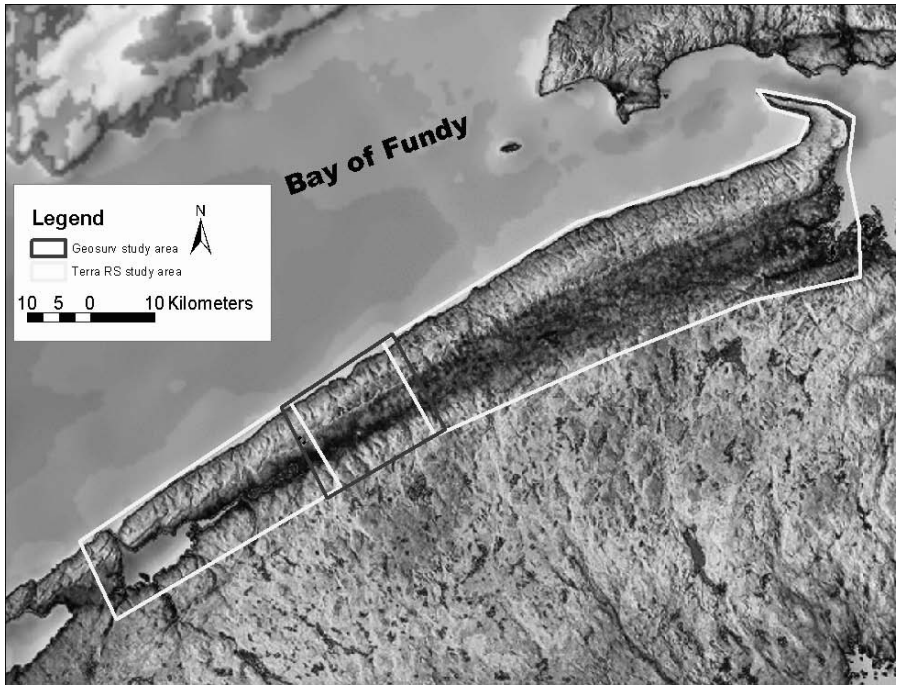

Figure 15.2 Location map of Annapolis and Minas Basin showing LIDAR, and airborne CASI coverage. Minas Basin is located in the upper right of the study area, and Annapolis Basin is located in the lower left of the study area. Radarsat data © 1996, Canadian Space Agency.

Radarsat-1 standard mode 2 scenes and a Landsat 7 scene were acquired near low tide conditions. The Ikonos satellite, which is owned and operated by Space Imaging, is capable of acquiring 1 m panchromatic and 4 m multispectral (3 visible and 1 near infrared band) imagery. Ikonos imagery were acquired near low tide by determining the date of low tide near 11:30 am local time (sun synchronous orbit

pass time) and requesting image acquisition from 2 days prior to the low tide's date to 2 days after the low tide's date. This allowed for variable weather conditions (clouds or overcast) and the fact that tide times advance approximately 45 minutes each day. Ikonos orders were sent through a local distributor. In addition to the satellite coverage, the coastal areas were imaged twice with the CASI sensor, once at high tide (3 m resolution) and once at low tide (1 m resolution) (Figure 15.3). The LIDAR survey area was divided into three regions, two flown by Vendor A, and one by Vendor B (Figure 15.2). The coverage for each company overlapped to allow a comparative analysis of the data from each company. All coastal areas were flown near low tide in order to acquire detailed inter-tidal topography. The in-land vegetation state in mid-July is at maximum leaf cover. Both LIDAR providers assured the AGRG that canopy penetration was still possible and that a significant number of laser hits would make it through the canopy to the ground. The data accuracy and data specifications for the LIDAR can be found in Appendix 15.1. The accuracy specifications are discussed in more detail in section 15.4. Details on each LIDAR system are presented in sections 15.3.1 and 15.3.2.

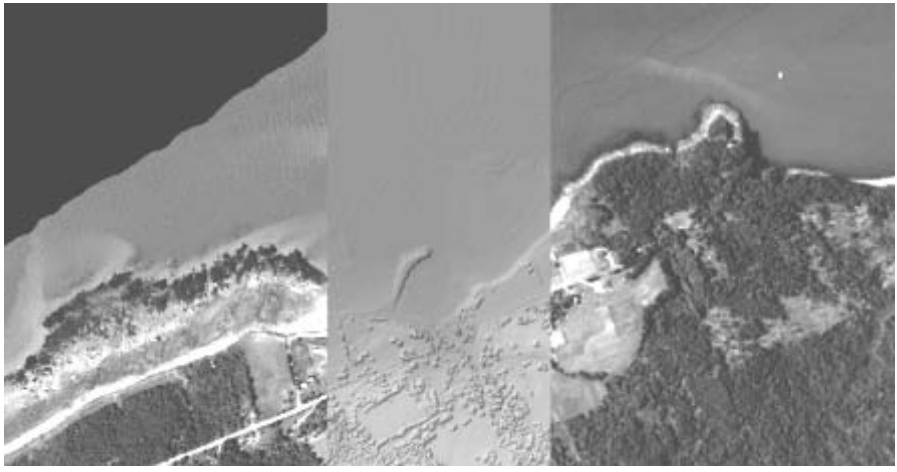

Figure 15.3 Mosaic of 1 m CASI at low tide (left image), 2 m LIDAR DSM at low tide (centre image), and 3 m CASI at high tide (right image) for Port Lorne along the Bay of Fundy. Overall image is approximately 4 km across.

15.2.2 Data Acquisition Issues

LIDAR is an active system providing its own pulse of near-infrared laser radiation and recording the reflected signal; thus it is not dependent on cloud free weather conditions as is the case for traditional aerial photography. However, rain or fog would cause the LIDAR survey to be delayed because the radiation cannot penetrate dense cloud or fog and therefore could not hit the ground. As a safety measure to ensure the laser is at a significant distance from the target, thus the power levels of the laser are not harmful to human eyes, the system will

automatically shut down if a laser return is detected to be at too close a range. For example, if the laser were to reflect off of an underlying cloud, high fog, or rain the system would automatically shut down. The LIDAR systems used in this project typically flew at a relatively low altitude, ranging from 300 m to 800 m, thus were often below any clouds. The ground activities for the LIDAR survey consisted of two tasks: 1. provide the aircraft with precise carrier phase GPS base station observations, and 2. collect precise elevation profiles to assist in data validation. Vendor B LIDAR area was estimated at 3 collection days and the Vendor A LIDAR area was estimated between 5 and 7 days.

15.3 LIDAR TECHNOLOGY

The terrestrial LIDAR system consists of an aircraft equipped with a GPS, attitude sensor and active near-infrared laser source and sensor. As the plane advances along the flight path the laser is fired, the pulse is directed toward the ground by an oscillating mirror and the reflected signal from the ground is recorded. By measuring the time it takes for the laser to reach the ground target and return, the range to the target can be accurately determined. The Time Interval Meter (TIM) records the time the pulse is transmitted and when the pulse is returned as well as the angle of the scanning mirror. This information, in combination with differential precise-code GPS and attitude measurements (e.g. pitch, yaw, and roll correction), is used to determine the height of the terrain relative to the ellipsoid. The LIDAR sensors available for this survey could record first or last returns only, while new generation sensors record multiple returns and the intensity of the signal. The Vendor B Optech ALTM 1020 system could record either the first or last laser return. The last return was specified since there is more chance of obtaining ground returns in this mode and a ground DEM was most desirable for our study. The resultant data from a LIDAR survey consists of a series of point location (laser hits) with associated heights above the ellipsoid. Since the ellipsoid based on the World Geodetic System of 1984 (WGS84) is a smooth mathematical surface which approximates the earth, a transformation is used to convert the heights relative to the geoid which is an equipotential surface based on the earth's potential gravity field. For this region, the transformation is based on a Geoid/Ellipsoid separation model known as HT1_01 that allows the data to be referenced to the Canadian Geodetic Vertical Datum of 1928 (CGVD28) defined by the Geodetic Survey of Canada of Natural Resources Canada. With heights now related to the geoid, termed orthometric height, they relate to approximate mean sea level. Since the geoid model is continually being refined, we requested the LIDAR data to contain both ellipsoid heights and orthometric heights (CGVD28). Therefore when new geoid models are released in the future, one can easily recompute the orthometric heights from the ellipsoid heights using the latest separation model.

15.3.1 Vendor B LIDAR Survey

Vendor B used two base stations for aircraft GPS control, the COGS permanent base station and a mobile station set up in the center of the study area to be surveyed. The distance of the survey aircraft from the base station should not exceed 40 km generally, because the GPS error increases with distance from the base station. The location of this central point was calculated based on observations between there and the COGS base station located at the eastern edge of the block (Figure 15.2). In addition to the LIDAR operator, Vendor B had two people on the ground collecting precise elevation values to be used to validate their LIDAR results. In addition to Vendor B, COGS also collected Real Time Kinematic (RTK) GPS elevation values within a limited radius of COGS in Lawrencetown due to the required line of sight radio link between the roving GPS unit and the COGS broadcasting base station. Vendor B collected both fast static point observations and kinematic locations from their vehicle, which required post processing.

Vendor B used a twin engine Piper Navajo airplane that they based out of the Digby airport. Trimble technology similar to that of COGS was used for their GPS collection, thus making data sharing very easy. The attitude information of the aircraft was collected using an Applanix POS Inertial Measurement Unit (IMU). The laser unit from Optech was housed in the camera mount within the aircraft. An Optech ALTM1020 sensor was used in the survey operating at a 5000 Hz laser repetition rate and a 15 Hz scan rate for the mirror. The area was flown at an altitude of 800 m above ground level (AGL) with a scan angle of 18 degrees, producing a swath width of approximately 520 m with raw laser point spacing every 3 m. At this altitude the laser beam had a footprint diameter of 25 cm. This sensor can capture first or last laser returns. For this survey it was set to collect the last return information, thus increasing the probability to hitting the ground in vegetated terrain. In addition to the LIDAR, a digital video camera also collected nadir looking video to be used later to assist in interpreting the laser returns and separating them into ground and non-ground hits.

Vendor B started their survey on July 6 and ended on July 13. They were delayed by some bad weather days, many due to rain and air turbulence. The study area consisted of approximately 64 flight lines, oriented parallel to the coast with two lines running transverse to the coast to be used to cross check the data. After processing the LIDAR data back in Ottawa they detected a problem with some elevation data that could not be resolved. As a result they re-flew several lines on September 1.

15.3.2 Vendor A LIDAR Survey

The Vendor A crew consisted of two people, one on the ground and the LIDAR operator. They used a Bell Ranger helicopter on the belly of which they mounted a pod containing the laser and video camera. Vendor A used Ashtech technology for their GPS collection thus requiring the COGS Trimble GPS data to be translated into an intermediate RINEX file format. The attitude information of the aircraft was collected using a Litton Inertial Reference System (IRS). An IRS is similar to an IMU in function, also known as an Inertial Navigation System (INS). Vendor

A's area of coverage was significantly larger than that of Vendor B and they used the Waterville airport as their base for the eastern block and the Digby airport for the western block. GPS control for Vendor A's local base stations, located at the two airports, was brought in from the COGS base. Vendor A's quality control strategy consisted of firing laser pulses at the base station antenna and comparing the LIDAR-determined height with that derived from GPS observations. They used the permanent COGS base station as a back up for the western extent of the eastern block. For the western block they established another mobile base station location over a provincial High Precision Network (HPN) point. This point is part of the geodetic GPS control network and is located near the Digby runway. Vendor A used a commercial first return laser unit operating at 1047 nm wavelength with a laser pulse repetition of 10,000 Hz and a 10-15 Hz scan rate for the mirror. The area was to be flown at an altitude of 600 m with a scan angle of 50 degrees, producing a swath of approximately 600 m with raw laser point spacing every 3 m. At this altitude the laser beam had a footprint diameter of 1.8 m.

Vendor A started their survey on July 11 and ended it on August 31 for the Nova Scotia study. During the data collection in the eastern block they experienced a power loss problem with the laser. The source of the problem could not be determined and it resulted in less penetration through the vegetation canopy. To remedy the situation they changed the flying altitude from 600 m to 300 m. This also affected the line spacing, since a lower altitude results in a smaller swath of coverage. With this system the relationship is roughly one to one i.e. at 600 m altitude a 600 m swath can be imaged. This caused much less area to be covered than the original estimated time, which in turn led to another problem of pilot fatigue causing more delays in addition to bad weather delays. The loss of power issue was eventually partially resolved by increasing the gain setting on the laser, thus allowing the aircraft to fly at the original altitude of 600 m.

15.4 GIS LIDAR PROCESSING AND VALIDATION

Raw LIDAR data may contain many erroneous hits. Collectively, these are known as 'noise.' Noise is usually filtered out by the vendor prior to delivery of the data using an algorithm. The data set will also contain hits from any number of surfaces (trees, buildings, roads, water, etc.). The vendor will also filter and classify the LIDAR point cloud into ground and non-ground hits (e.g. vegetation, buildings) prior to distribution. Thus two separate files may exist for a single 'tile' of LIDAR data. One file will contain only the ground hits, and one will contain points for all surfaces but the ground. It is important when working with LIDAR data to be aware of the composition of data sets being used. It is also prudent to use some sort of visualization software or technique to check for erroneous points that have escaped the noise filtering process or the ground/non-ground separation process. The LIDAR data was delivered on CD separated into 4 km by 4 km tiles. For both vendors tens of erroneous points per tile were identified by using a threshold of expected height values between –20 and 300 m. These erroneous points were probably a result of laser hits reflecting off of suspended aerosols. Each tile contained approximately 3 million LIDAR points and was in ASCII format. The survey specifications required an average point spacing, or "hit,"

every 3 metres. The ASCII files were imported into ARC/Info GIS and converted into point coverages. Triangular Irregular Network (TIN) files were built from point coverages of the ground hits. The large study area was processed using multiple tiles in overlapping sections to construct the TINs. The TIN files using ground only points were then gridded to produce a DEM at 2 m resolution using both a 5^{th} order polynomial fitting and a linear interpolation method. In the case of anthropogenic waterfront structures such as wharfs and breakwaters, the linear interpolation method is more suitable, while in rural areas, the quintic approach is more suitable to smooth the data. A Digital Surface Model (DSM) was generated from all of the LIDAR data, ground and non-ground points combined, using a linear interpolation method. A DSM differs from a DEM because it takes into account the height of the vegetation and buildings, while a DEM represents the "bald earth." The overlapping grids were then used to construct a seamless mosaic of the LIDAR surfaces, both a DEM and DSM.

The validation of the LIDAR involved both a comparison of benchmark GPS points to proximal LIDAR points and to the DEM. Two areas of the quality assurance testing involved the investigation of the spatial distribution of the LIDAR points and vegetation penetration, and the vertical accuracy of the LIDAR data utilizing GPS points. The horizontal accuracy of the data was assessed visually by comparing LIDAR map products to the 1:10,000 Nova Scotia Topographic Database.

15.4.1 Vendor B LIDAR Validation

Validation of the vertical accuracy of the Vendor B LIDAR was accomplished by measuring the differences between high precision GPS points and corresponding LIDAR points and by comparing GPS with the interpolated cells of the raster surface constructed from the LIDAR points. This was accomplished through differencing and linear regression of both the GPS elevation values and the LIDAR elevation data.

The first step in the validation process was to obtain quality benchmark data from GPS surveys. To compare the GPS points with the LIDAR surface, GPS accuracy needed to be equal to or better than that of the LIDAR points. This meant that only carrier-phase GPS could be used. This is the most accurate and expensive type of GPS. In the more common differential code GPS it is the code component of the GPS signal that is used to determine the position of the receiver. This code signal has a cycle width that is equivalent to a length of roughly three hundred meters. It is modulated onto a carrier wave that is approximately 20 cm in length. It is this carrier wave that is used to determine the position of the receiver during carrier phase GPS. The shorter carrier wavelengths provide a much finer degree of positioning than the 300 m cycle width of the code signal. This allows a positioning accuracy of within a decimeter using real-time and fast static techniques, or within less than a few centimeters with standard static techniques. Differential code GPS could only provide 1.5 – 0.5 m accuracies that would be insufficient for LIDAR validation. The GPS data used for this validation were collected using the real-time, static and fast static methodologies.

The validation points were compared to the LIDAR surface by a point-in-raster overlay. The validation points were intersected with the LIDAR interpolated

ground surface (DEM). The elevation values from the selected LIDAR surface cells were then joined to the validation point's attribute table. At this point the difference between the height values of the validation points and the corresponding LIDAR surface was calculated. In both cases the elevations used were orthometric heights derived from the CGVD28 geoid model. The results of a linear regression between the ground LIDAR surface and the validation points shows a very high correlation coefficient of 99.999%, with a standard error of 0.1869, indicating a very strong agreement between the elevation values from the two data sets.

Table 15.2 contains statistics on the elevation difference values between the LIDAR and the validation points. The vertical specifications in the contract were defined in the following terms: "[t]he vertical accuracy will be within an average of 15 cm of the measured GPS points, and 95% of the data points will not exceed 30 cm in vertical accuracy." As can be seen in the summary table of statistics, all specifications were met. One must be aware of issues that arise from the classification process that separate ground from non-ground points. For example, highway overpasses and bridges may be classified as non-ground points. Therefore any GPS points on and approaching such structures should not be used to compare with the DEM surface. The research group has acquired a Leica System 500 RTK GPS unit in 2003 and has since augmented the GPS checkpoints for this area. An analysis of these new data confirms that the vertical specifications were met.

Table 15.2 Summary of vertical validation of Vendor B LIDAR ground DEM.

Statistics	**Elevation Difference Values (m)**
Mean (specification 1)	0.13
Standard deviation	0.10
Minimum	0.00
Maximum	0.40
Median	0.10
Mode	0.10
Count	934
No. points <= 0.30 meters	915
Percentage points equal to or less than 0.30 meters (specification 2)	97.96%
Are specifications met?	Yes

15.4.2 Vendor A LIDAR Validation

A similar procedure was used to validate the Vendor A data, although it covered a much larger area. After an examination of the LIDAR point files, a distinct pattern was visible where there were no points, and thus no LIDAR returns, for the buildings or roads. This is because the roads and building rooftops are asphalt and low reflectivity to the near-IR laser. This lack of LIDAR return relates back to the

power loss experienced in the LIDAR unit during the survey. The lack of returns on the road made it difficult to check the precise relationship to the Nova Scotia Topographic Database but did allow us to determine that the road network generally corresponds to the lack of LIDAR returns along the road.

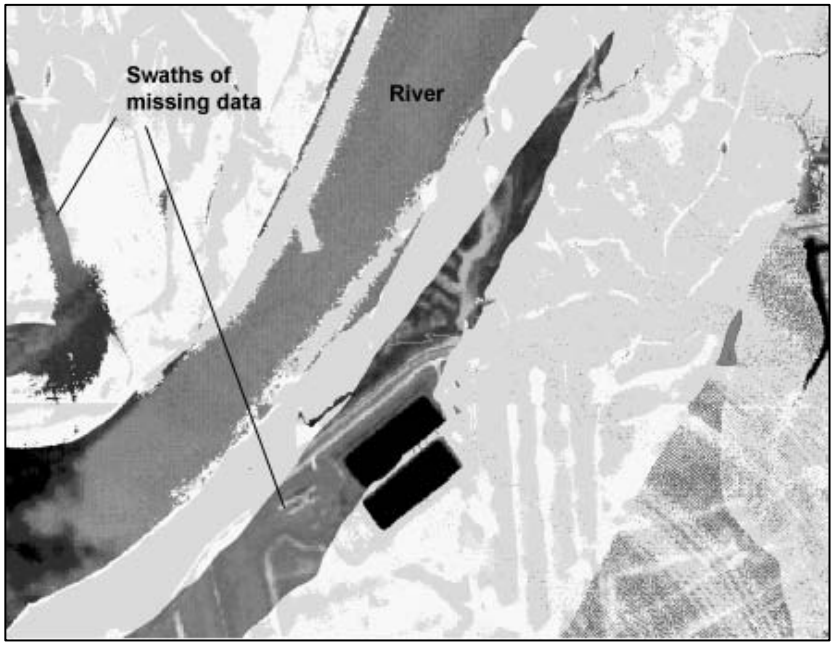

Figure 15.4 Vendor A LIDAR points (darker grey = ground, lighter grey = non-ground) over an Ikonos image for the Grand Pre dyke lands. Notice the missing swaths of data through the centre of the image and to the west. As a result of this missing data the dyke is not represented. Also the classification of ground and non-ground is not correct for the dyke area. Includes material copyright Space Imaging, LCC.

The other problem encountered with the point distribution along the coastal zone involved gaps in the LIDAR coverage. This was probably caused by the adjustment in flying altitude as a result of the power loss issue mentioned earlier. An example of this situation is shown in the area of Grand Pré near the Cornwallis River in the Minas Basin (Figure 15.4). The LIDAR hits for ground and non-ground are overlayed on the orthorectified Ikonos image acquired at low tide. Two areas of missing data swaths are evident, one in the central part of the image that includes the dyke land surrounding the river and the other in the western extent of the image. As a result of this area not being imaged during the LIDAR survey there is a lack of points; thus the ground and non-ground surfaces interpolated from the points do not accurately represent the presence of the dyke area, a critical barrier to coastal flooding. This results in a surface that is not accurate for flood risk modeling. In this case, the LIDAR data were supplemented by adding points manually in order to construct a valid surface model for this area. The Ikonos image was used as a guide for placing artificial points at the top and bottom of

both sides of the dyke feature in the areas of missing LIDAR data. Elevation values for the artificial points were based on values obtained from the LIDAR for the top and bottom of the dyke. Also, LIDAR points along the dyke misclassified as non-ground were selected as ground. This is an example of the type of visual quality inspection that should be done in such a project prior to using any derived data for decision-making.

Similarly to the Vendor B data the vertical accuracy of the LIDAR was examined in two ways: 1. comparing LIDAR point values close to the validation points, and 2. comparing the gridded LIDAR ground surface to validation points. There were not as many GPS validation points initially available for the Vendor A data set as for the Vendor B data set. However, three HPN points were compared to the LIDAR ground returns and statistics measured. LIDAR points within 10 m of the HPN points were selected for the comparative analysis. In general the differences between the average orthometric height of the nearest LIDAR hits and the HPN points were between 1 m and 3 m (Figure 15.5). The variance of the LIDAR hits associated with each HPN point were small and could not account for the differences between heights measured with LIDAR and the HPN network. It should be noted most HPN locations are near roads and the lack of LIDAR hits on and near roads does not facilitate a perfect correspondence of LIDAR hits to HPN points. Concurrent to this study, Vendor A also surveyed an area in Prince Edward Island for a Climate Change Action Fund project to derive flood risk maps. An offset of 0.9 m between GPS points and the LIDAR data was detected in that study (Webster et al., in press).

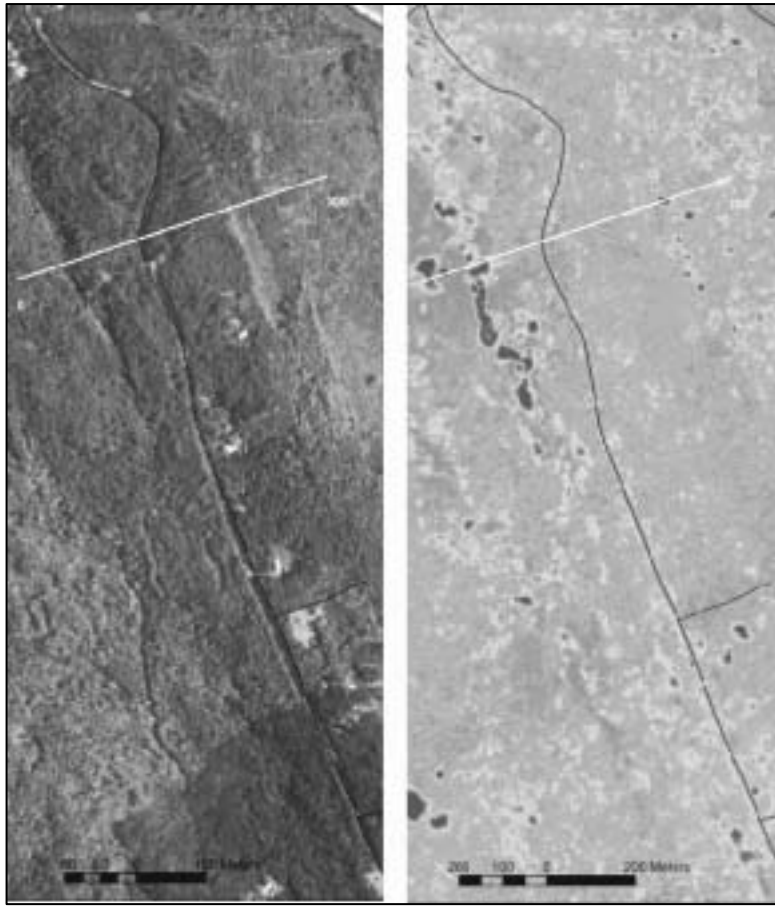

Figure 15.5 Comparison between Vendor B (2000) and Vendor A (2003). Left image is a digital true colour composite (converted to grey for this volume) CASI image; next is the difference map between the Vendor B and Vendor A 2003 DEMs. The main differences occur in the densely vegetated stream valley, and the small mounds (bumps) in the forest region.

As a result of this vertical bias in the LIDAR data, a follow-up GPS campaign was completed in the summer of 2001 by AGRG in the Annapolis Valley and shared with Vendor A in order to understand the nature of the problem. In this case GPS points were collected uniformly across the entire LIDAR swath in open flat areas. This was done to determine if the vertical bias was related to the scan angle of the system. It was finally deduced that the error resulted from the calibration of the system. An important aspect of a LIDAR calibration is the determination of any errors in the raw laser ranges. To properly calculate this value, multiple passes of varying altitudes must be made over known points. Since this aspect of the LIDAR calibration was not properly undertaken in the 2000 survey, an error of approximately 0.9 metres was introduced into the survey

(Webster et al., in press). Since calibration passes were made at an altitude of approximately 300 metres difference from the actual survey, the elevations matched at the calibration sites but did not match over the survey area. Comprehensive tests following the survey showed the need for a laser range bias and a laser range scale factor correction. Several lines of the LIDAR data in the survey area have since been re-processed by Vendor A to confirm these parameters.

15.4.3 Vendor A Re-fly of the LIDAR

As a result of the vertical offset and the limited vegetation penetration issues, Vendor A agreed to re-fly the area in the spring of 2003 at no additional costs. Since the 2000 survey there have been several improvements to their system and deployment strategy as a result of this experience (Shreenan, R. personal communications, 2003). A crucial step to any successful LIDAR survey is to conduct daily calibration passes over objects with known coordinates. Objects with long, straight elevated edges such as bridges and buildings are particularly favoured since they provide a check for both horizontal and vertical alignment. As mentioned earlier, calibration passes for this particular LIDAR survey entailed daily passes over the GPS base station. Although calibration parameters were adequately defined from this information the introduction of elevated man-made features allows a refinement of the calibration computation. This process has a direct impact on the overall accuracy of the survey and Vendor A has since adopted this practice.

The accuracy of a LIDAR system is only as good as the weakest component of the system. Since the 2000 survey, Vendor A has integrated a new Aplannix IMU into their system, which significantly improves the measurement of the roll, pitch and heading components of the aircraft over the previous sensor. The introduction of the new IMU improves the resolution of the aircraft attitude by a factor of five times for the roll and pitch and ten times for the heading (in comparing manufacturer specifications). Equally as important, the components of the IMU have been combined with the navigation sensors (GPS) for the purpose of regulating the IMU errors to those of the navigation sensors. This is commonly referred to as GPS Aided Inertial Navigation Systems and has greatly increased the overall accuracy of the system.

A final step to ensuring that an accurate product has been captured is to compare the processed LIDAR data to points that have been captured at a higher accuracy than the LIDAR. This practice has been adopted by Vendor A and uses the U.S. Federal Geographic Data Committee (FGDC) Geospatial Accuracy Standards (Parts 1-3) (www.fgdc.gov/standards/status/textstats.html) as a guideline for determining overall accuracy of all LIDAR surveys.

Another important step to any successful LIDAR survey is the accurate extraction of features from the LIDAR point cloud. The ability to perform this task accurately and reliably has a direct bearing on the overall accuracy of the survey. As a result of this survey, Vendor A embarked on developing and purchasing new software to reliably handle these tasks. The proprietary software used to process the collected dataset presented in this paper was extremely effective for single line corridor mapping but lacked the algorithms for processing multiple lines of

LIDAR. Also, the software lacked the visualization tools required to adequately detect outliers. The software now employed handles all of these issues as well as provides a host of other processing options including: 1. the removal of large outliers, thus improving the ground extraction algorithm's ability to accurately define ground hits; 2. the LIDAR data is processed according to neighbouring hits rather than the sequence of capture; 3. new hardware which enables tens of millions of points to be processed simultaneously rather than just millions of points; 4. several new visualization techniques have been implemented to help review the processed data and detect anomalies in the ground surface; and 5. video and digital mosaics are now used extensively to help review classified data.

Other improvements in the system include the introduction of a collimator attached to the end of the laser head. This device decreases the divergence of the laser beam to better than 0.3 mrad. This enables weaker reflective signals such as black top pavement and roofs to be captured because of the increased concentrated signal coming from the laser. Additionally, more penetration through the treetops is accomplished with the less divergent beam and therefore more ground hits captured. The foot print diameter in 2000 was 1.8 m, compared to 0.18 m in 2003. This was especially critical to reach the ground with a first return system.

In additional to improvements in the equipment, new field procedures have been implemented to include better field quality control to ensure no gaps exist between LIDAR flight lines. Gaps in the laser data can easily be identified on a daily basis, which can then be re-flown. Also, the laser data storage device has been reconFigured and repackaged which helps to eliminate data loss caused by the vibration of the airframe.

In the spring of 2003 prior to leaf-on conditions, Vendor A re-flew the eastern block at no additional costs and plans are in place to re-fly the western block (Figure 15.2) with a first and last multiple return LIDAR system in the fall of 2003. The preliminary data collected in the spring of 2003 has met the vertical specifications of 30 cm and is a significant improvement in terms of point density, returns from low reflectors (asphalt), and ground penetration in vegetated areas.

15.4.4 Comparison of LIDAR surfaces

When the original LIDAR areas were selected for each data provider, an area of overlap between the regions was maintained in order to compare the quality of the resultant DEMs between the two providers. For each data provider a ground DEM was constructed from the LIDAR points. This included Vendor B (2000), and Vendor A (2000 and most recently 2003 data). The ground surface was based on the construction of a TIN and quintic interpolation to a 2 m DEM grid.

The area of overlap is south of Lawrencetown and consists of a mixture of dense forest within a stream valley to cleared areas on the hilltop. The resulting DEMs are contrasted in Colour Plate 15.1 (following page 164). The problem with the original DEM derived from Vendor A is apparent by the triangular facets. This is a result of few LIDAR shots making it to the ground; therefore the DEM surface is not an accurate representation of the terrain. However, the DEM from the 2003 data that Vendor A re-flew is very similar to that of Vendor B. In fact, many of the small "bumps" on the landscape present in the Vendor B DEM have been removed in the Vendor A 2003 data. Although not verified in the field yet, these bumps are

interpreted to probably represent dense brush or other vegetation, based on their size, and do not truly represent the ground elevation. This highlights the improvements of the ground/non-ground classification algorithms from 2000 to 2003, thus enabling the production of a more accurate DEM.

15.5 COASTAL APPLICATIONS OF TERRESTRIAL LIDAR

Although much of this paper has been concerned with operational acquisition and validation of the LIDAR, end applications have been developed for the coastal zone concentrating on flood simulation modelling, inter-tidal slope calculations and merging the terrestrial LIDAR with bathymetry. For the flood-risk mapping, a similar methodology as in the studies by Webster et al. (2001, 2003, in press) have been employed.

Floodplain boundaries are important to emergency management personnel, insurance agents, and developers, as well as ordinary citizens. Flat floodplains are also attractions for further developments. Existing floodplain maps mainly derived from coarse elevation data do not depict actual floodplain boundaries. Major uses of LIDAR data include developing hydrological and floodplain models, telecommunications planning and analysis, transportation assessment, urban planning and natural resource and forest management.

For this study, the Minas Basin area was used because of the increased population and infrastructure that could be vulnerable to coastal flooding. The derived maps were passed to the municipal and town planning authorities to be used to assist in land development policies. In the absence of current land use vector data, Ikonos satellite imagery for the study area was classified to derive land cover types. The imagery was orthorectified using 1:10,000 road vectors and 5 m DEM from 1:10,000 contours. The land cover types derived through a maximum likelihood supervised classification were intersected with the flood levels derived from the LIDAR DEM to determine the percentage of affected areas.

The LIDAR ground points were used to construct the DEM surface. While delineating inundation areas on the derived DEM, some problems were discovered that related to the dykes not being properly represented. As mentioned earlier, some points along the dyke had been removed from the ground file. To depict the actual ground surface, it was necessary to construct a DEM with dykes. The dykes were extracted from the non-ground file by using the coded topographic base map vector database in combination with the Ikonos imagery. These points were in turn used to construct a new surface. As described earlier, where the LIDAR swath was absent points for the dyke and ground area were manually inserted. The heights were obtained by enquiring the LIDAR points adjacent to the missing areas.

Storm surges are the major cause of flooding in coastal areas. Storm surge is an abnormal rise in sea level accompanying a hurricane or other intense storms, and whose height is the difference between the observed level of the sea surface and the level that would have occurred in the absence of the storm. A storm surge at a low tide might go unnoticed but the storm surge at the highest tide might cause heavy coastal destruction. Therefore, the following calculations are performed for surges associated with high tides only.

Table 15.3 Height in meters above Chart Datum at Hantsport, Minas Basin. Source: Canadian Hydrographic Service Chart, HW – high water, LW – low water.

Large Tides		**Average Tides**		**Mean Sea Level (MSL)**
Higher HW	*Lower LW*	*Higher HW*	*Lower LW*	
14.8	-0.1	13	1.2	7.1

Tide levels and land elevation must be referenced to common datum in order to compute coastal flooding inundation areas. Because the LIDAR data and derived DEM are referenced to the geoid (CGVD28-MSL), and the tide levels are referenced to chart datum, which is typically the lowest elevation the largest tide will reach, the tide levels must be converted to reference a mean sea level datum (CGVD28). Thus the chart datum elevation of 7.1 m is subtracted from all the tidal water levels in order to relate them to MSL. Table 15.3 provides the original tidal information derived from the local chart, and table 15.4 shows the computed tidal levels in reference to mean sea level.

Table 15.4 Height in meters relative to Mean Sea Level (MSL) Datum, Hantsport, Minas Basin.

Large Tides		**Average Tides**		**Mean Sea Level**
Higher HW	*Lower LW*	*Higher HW*	*Lower LW*	
7.7	-7.2	5.9	-5.9	0

As can be observed in the above table, the highest tide in Minas Basin is 7.7 m above MSL. The average storm surge measured from all recording stations in the Bay of Fundy is 0.6 m for a one-in-twenty year event and 1.2 m for a one-in-one hundred year event. Surge levels were computed based upon these predictions. Table 15.5 provides the water levels predicted by combining tidal levels and storm surge levels referenced to MSL.

Table 15.5 Storm surge values. Probable return times of storms, one-in-20 year event, one-in-one hundred year event. Source : CHS Chart

Return Period	**Highest tide (m)**	**Storm Surge (m)**	**Resultant water level above MSL (m)**
Twenty-year flood	7.7	0.6	8.3
Hundred-year flood	7.7	1.2	8.9

Dykes have been constructed to protect low-lying coastal agricultural areas from tidal waters. The average dyke height ranges around 8.5 m. This means that the low-lying areas beyond the dykes would be flooded only if the tide level was

greater than 8.5 m. It could be deduced that low-lying coastal farmlands are well protected by dykes for floods with a storm return period of twenty years. The dykes are insufficient to stop flooding in a one-hundred-year storm event occurring at the largest tide of 8.9 m water level. These water levels do not take into account relative sea-level rise, which in this region is estimated at 25 cm per century (Stea, Forbes, and Mott, 1992). Therefore, for this project, a 9 m flood level was selected as the extreme limit to derive flood risk maps. The town of Kentville, located near the coast of the Minas Basin, has also used this level for their Municipal Planning Strategy maps.

Flood risk maps were generated using off-the-shelf GIS software tools rather than using flood models such as Mike11. The DEM used in the project has orthometric height values (MSL). The procedure of extracting inundation areas for various flood levels consists of selecting all the cells whose elevation (cell value) is less than or equal to that particular flood level. In order to determine the spatial extent of the flooding associated with a storm surge event, 10 flood levels at 0.5 meter increments were selected with the intention of building an animation. These were 4.5, 5, 5.5, 6, 6.5, 7, 7.5, 8, 8.5, and 9 m above MSL. An Arc Macro Language (AML) script was written for generating flood level grids where cells with values below the flood level are selected resulting in a binary map of flooded areas. In order to check for continuity between the flooded areas and the source of the water, in this case the bay or estuary, the grids were converted to polygons to permit selection of contiguous areas. For an area to be flooded, it must satisfy two conditions; the area must have elevation less than or equal to a surge level, and it must be connected to the water source, for example the Cornwallis River (Figure 15.6).

The process does not consider the effects of culverts and bridges due to lack of data of such infrastructure. However, it is known that many of the culverts and control gates of the smaller estuaries have one-way values to allow water to drain to the bay and control water flowing upstream. The flood levels of a storm return period of twenty (0.6 m, 8.3 m above MSL) and one hundred years (1.2 m, 8.9 m above MSL), with no consideration of sea-level rise, were overlaid on the Ikonos imagery to visualize the areas possibly affected. The calculated surge level is 8.3 m above mean sea level for a storm return period of twenty years and 8.9 m for a storm return period of hundred years. The flood levels generated in this study have been used for GIS overlay analysis to produce reports on the land cover and properties that could potentially be affected by a flood (see example, Colour Plate 15.2). The flood levels have been used to generate a series of visualizations including perspective views and flood animations. A report on the methodology, data processing, and results of the overlay analysis was given to the Kings County Planning Commission to be used for future recommendations.

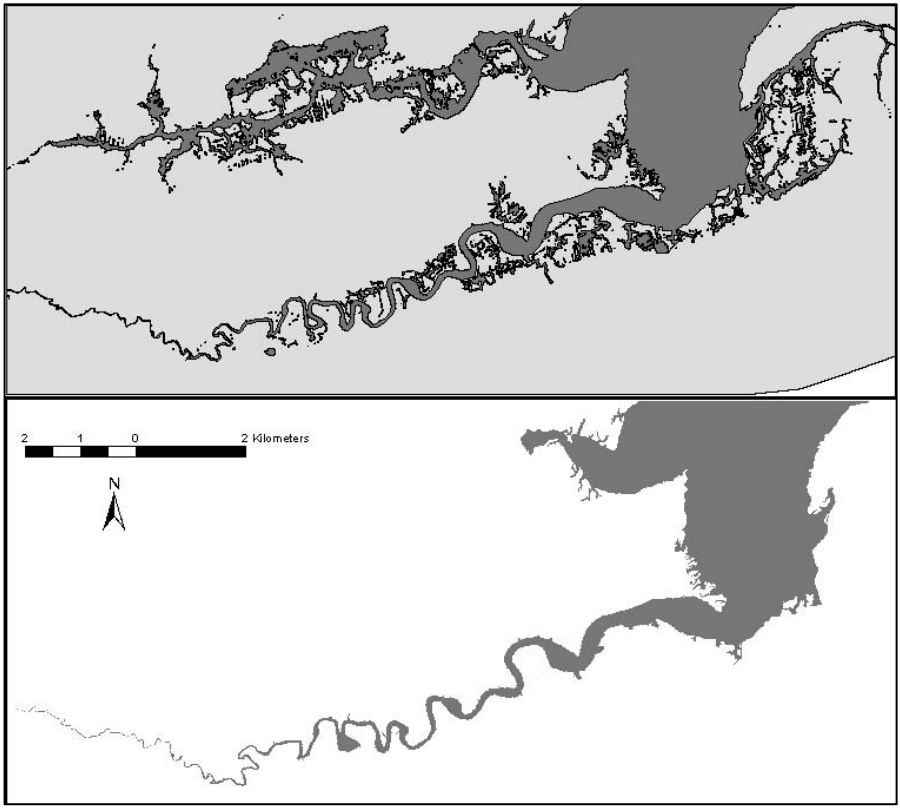

Figure 15.6 Example of how the flood-risk polygons are generated. Top image is the result of coding all cells less than or equal to 4 m. Bottom image shows only the areas that have connection with the bay or estuary. Flood level is 4 m above MSL; average high tide is 5.9 m above MSL.

15.6 CONCLUSIONS

The integration of high-resolution imagery and DEMs derived from LIDAR has several applications within the coastal zone. Here we have discussed the application of these technologies for developing flood-risk maps associated with possible storm surge events. LIDAR is a relatively new technology capable of providing dense elevation points of high precision and accuracy. It is important, however, for users of the data to be sure the data has met the accuracy specifications and independent validation data should be collected for this analysis. The validation of the LIDAR data indicated that the information from Vendor B met the specifications, while that from Vendor A did not for the 2000 survey. However, we worked with Vendor A to determine the cause of the problem and they have re-flown the area at no additional costs in 2003. The preliminary results of the new Vendor A data meet vertical specification of within 30 cm of measured GPS locations. In the case of both data providers, the separation algorithms removed features that the end user may want in the ground datasets, for example

highway overpasses and dykes. The end user must carefully inspect the LIDAR point data both for erroneous points, missing swaths of data, and for areas where the points have been misclassified into the ground or non-ground categories prior to using a gridded surface for decision-making. However, these problems often quickly reveal themselves after a surface has been constructed and a colour shaded relief has been made for visual inspection. The Bay of Fundy is unique because of the large tidal range, thus allowing the inter-tidal zone to be imaged with the LIDAR system. Wet smooth mud surfaces act as a spectacular reflector and often a low percentage of LIDAR hits return to the sensor, especially near the edges of the swath as one move away from nadir angles. Thus the overlap between flight lines should be increased to ensure laser returns in such environments.

The LIDAR data has been demonstrated to be applicable to determine areas at risk for coastal flooding associated with storm surge events. Once flood inundation boundaries have been calculated they were overlaid with the other infrastructure and property maps that exist for the municipality to calculate possible economic impacts of such events. High-resolution satellite imagery has been used to update the current land cover maps that were used in the overlay analysis with flood inundation areas. These types of data and information products are critical for land use planners and policy makers in order to manage the coastal zone effectively. This management could include restricting development in areas of high flood risk or mediation to try to minimize the impacts of such events. Other applications of these data for the coastal zone that have not been discussed in this paper but have been examined by the research group include generating slope maps of the inter-tidal zone, validating local tide models for the Minas Basin, and the generation of a seamless terrain model merging the land elevations and bathymetry for the area.

15.7 ACKNOWLEDGEMENTS

The processing of this data and validation examination has been a team effort at the AGRG. Team members include: Steve Dickie, Montfield Christian, Frances MacKinnon, Jamie Spinney, Charles Sangster, Michael Palmer and Trevor Milne. We would like to thank all of them and the other AGRG graduate students who have contributed for their dedication, hard work, and diligence. Also thanks to Dr. Robert Maher and David Colville, research scientists at the AGRG, for review of the manuscript and helpful discussions. We would like to thank Andy Sherin, Darius Bartlett and especially Jennifer Smith for the invitation to include this work in the book and assistance in preparing the manuscript. We are grateful to the staff and field crews from both Geosuv (now Mosaic Mapping) and Vendor A, especially Roger Shreenan of Vendor A, along with all of the other data providers including Hyperspectral Data International, GeoNet, and Radarsat International. We are grateful to the Nova Scotia Geomatics Center and the Municipality of Kings County for providing the base and property information for the study. Funding for the data collection was supported by a research grant from the Canadian Foundation for Innovation of Industry Canada.

APPENDIX 15.1

Terrestrial LIDAR Data Specifications for both vendors.

The LIDAR data will be supplied to the Applied Geomatics Research Group of COGS. The data will be in ASCII format, one row per elevation data point, organized in five columns as follows:

UTM Easting (WGS84)
UTM Northing (WGS84)
Height above Ellipsoid (WGS84)
Orthometric Height above Geoid (HT1_01)
GPS time

Three files will be delivered in this format on CDROM, containing

all data points,
ground points,
non-ground points.

The raw data files and airborne down-looking video will also be provided to the clients in care of COGS in formats they are capable of reading. Appropriate quality control information such as aircraft attitude and speed, quality of GPS positioning, and post-processing error data will be appended to each data point in one or all of the data files.

GPS control points will be occupied within a suitable range of the survey areas to achieve this accuracy and precision. Data will not be collected during increased ionisphereic activity which could degrade the GPS signal. Data will be collected under suitable conditions for video collection, under adequate light with no obscuring cloud beneath the aircraft. Data for coastal inter-tidal areas will be collected within 1 hour of lowest daily daylight tide levels in the survey area of Nova Scotia and within 2 hours of lowest daily tide in the Charlottetown, and North Rustico PEI survey areas.

All laser height, video, GPS, aircraft attitude and speed, and other quality control data will be delivered to the clients in care of COGS.

Full ownership of the data and information including working papers and reports will reside with COGS for data collected in Nova Scotia and the HM The Queen in Right of Canada (as represented by the Minister of Natural Resources) for data collected in PEI.

CHAPTER SIXTEEN

Mapping and Analysing Historical Shoreline Changes Using GIS

Courtney A. Schupp, E. Robert Thieler and James F. O'Connell

16.1 INTRODUCTION

Understanding coastal change has become increasingly important to the 78 coastal communities in Massachusetts. About half of Massachusetts' 6.2 million residents now live in the coastal zone, and the coastal population is growing rapidly. Erosion threatens beachfront houses and development along much of the state's 2400 km of shoreline, creating a critical need for the government and the public to have accurate, up-to-date information on shoreline change. Prior to this shoreline change update, however, Massachusetts' existing historical shoreline change database had not been updated since 1978. New maps and data displaying long-term and more recent trends of shoreline behaviour increase the capability for sound decision-making and enhance public awareness of coastal change in Massachusetts.

To produce the necessary maps and data, we compiled historical shoreline positions in ArcInfo from a variety of map and aerial photograph sources. We generated 1:10,000 scale maps of the Massachusetts coast that display historical shorelines, rates of change, locations of rate-of-change measurements (transects), and orthophotographs. We also enhanced a Microsoft Access database created by Van Dusen (1996) that contains transects, dates, and rates of change; it can be used to perform spatial queries and to compile regional statistics and trends. The Massachusetts Office of Coastal Zone Management (MCZM) will distribute these maps, along with the data tables and a manual describing how to use the information, to regional government offices and coastal communities. These products will also be made available to the public through the Internet.

16.2 METHODS

16.2.1 Data Sources

Previous projects digitised and assembled historical shoreline data for the Massachusetts coast from 1842 to 1978 into ArcView GIS format (Benoit, 1989; O'Connell, 1997). Those projects obtained shorelines from six different data sources: 1) National Ocean Service (NOS) topographic maps (T-sheets), 2) NOS hydrographic maps (H-sheets), 3) Federal Emergency Management Agency (FEMA) Flood Insurance Study topographic maps, 4) printed orthophotographs, 5) aerial photographs, and 6) digital orthophotographs. The early shorelines (1842 to 1950) were digitised exclusively from NOS T- and H-sheets. Shorelines from the 1970s were compiled by digitising FEMA topographic maps, printed orthophotographs, and aerial photographs. These early data sets were digitised and placed into a GIS-compatible format using the Metric Mapping System (Clow and Leatherman, 1984; Benoit, 1989).

The aerial photography used to generate the 1994 orthophotographs has a nominal scale of 1:48,000 and was taken by the National Ocean Service in September and October of 1994. MCZM provided full-colour digital mosaicked orthophotographs that have a resolution of one meter per pixel. We used these geographically registered orthophotographs to digitise the 1994 shoreline directly within ArcView GIS software.

There are several possibilities for identifying a high-water shoreline. In most locations, we delineated the shoreline using the high-tide wrack line. However, due to the range in geomorphology along the Massachusetts coast, other delineations were sometimes more appropriate, such as the wet/dry interface, algal lines along rocky shores, vegetation changes in salt marshes, and the interface between seawalls and open water. Photographs of some areas, such as bleached-out sandy beaches, were difficult to interpret visually. In these cases, field checks and historical shorelines aided interpretation of the orthophotographs.

To verify the accuracy of orthophotograph rectification, we selected control points along the Massachusetts shore at easily recognizable sites, such as building corners and street intersections. We located these sites in the field and recorded the DGPS coordinates, which we then compared to orthophotograph coordinates. Results show that the orthophotographs comply with National Map Accuracy Standards (U.S. Bureau of the Budget, 1947).

Due to the variety of aerial photograph data sources and analytical techniques used to compile the shoreline positions described here, there are a number of potential sources of error that affect the accuracy of the shoreline positions shown on the shoreline change maps. Since much of the historical database had not been checked previously for geographic accuracy, the historical database was subjected to quality control review. The relatively high geographic accuracy and photographic detail of the 1994 orthophotographs, as evidenced by the accurate display of roads, buildings, and shoreline structures, allowed the identification of errors in the pre-1994 shorelines. Although the pre-existing data set was represented to comply with National Map Accuracy Standards, there are inevitably errors in any large spatial data set that more accurate data bring to light.

Our analysis resulted in the removal of approximately 43 kilometres of poor-quality data that could have contributed to erroneous interpretations of shoreline change.

Analysis of the various sources of error suggests that the individual shoreline positions in our completed data set are generally accurate to within +/- 8.5 meters. Rates of shoreline change derived from these shorelines have a resolution of +/- 0.12 meters/year (Thieler et al., 2001).

16.2.2 Generating the 1994 Shoreline

We used the line tool in ArcView 3.2 to delineate shoreline segments for each orthophotograph at a scale of >= 1:2,000. After saving shapefiles of the 1994 shoreline segments for each orthophotograph, we used the ArcView Geoprocessing Wizard extension to merge all segments into a single shapefile containing the 1994 shoreline. We added the attributes "length" and "year" to the attribute table before using the Geoprocessing Wizard again to merge the 1994 shoreline with the shapefile of historical shorelines.

Some areas had highly migratory shorelines, such as barrier islands where the landward migration over the past 150 years exceeded the width of the island. To ensure that seaward shorelines would only be compared to other seaward shorelines, and not to any landward shorelines, it was necessary to create two edited versions of the shoreline coverages. One coverage included only the seaward edge of migrating areas (for example, only the open-ocean side of a barrier island); the complementary coverage included only landward coasts (for example, only the bay side of a barrier island). This method enabled us to examine barrier island migration in addition to shoreline change.

16.2.3 Preparing the Workspaces

We used a suite of Arc Macro Language (AML) programs and a modified version of programs in the Digital Shoreline Analysis System (DSAS; Danforth and Thieler, 1992; Thieler and Danforth, 1994; Van Dusen, 1996) to pinpoint shoreline positions, cast orthogonal transects along the shoreline, compute a linear regression of the rate of shoreline change at each transect location, collect all of the rates and statistics into an INFO database, and create 1:10,000 scale maps. To achieve this it was necessary to establish a shore-parallel baseline and to create sequentially numbered workspaces containing data for each coastal area.

To establish a point of reference for shoreline change measurement, we used the *buffer* command to draw baseline segments 50 meters landward of and parallel to the general trend of the shorelines. We used a combination of the ArcEdit commands *unsplit, grain*, and *spline* to modify the baseline, placing vertices at 20 meter intervals. Van Dusen (1996) described a similar approach using the *spline, generalize*, and *densify* commands.

We saved each baseline segment, typically about 7 kilometres long, in its own workspace along with a coverage containing the corresponding shorelines. Using polygon coverages, we clipped the larger shoreline coverages, thereby creating smaller coverages to reduce AML processing time.

Once all of the completed shoreline and baseline coverages were saved in the appropriate workspaces, we ran an AML to format the data for the transect-casting and rate calculation software. In each workspace, the AML created a frequency file listing of all of the shoreline years in that area. The AML then used this file with the *reselect* command to select arcs by their year attribute before using the *build* and *ungenerate* commands on the coverage. It also used the frequency file to create a file containing the date for each shoreline. It created formatted text files for the baseline and all shorelines using the generate files.

16.2.4 Digital Shoreline Analysis System

As described by Van Dusen (1996), the basic software used to determine shoreline rates-of-change was a modified version of the DSAS, developed by the U.S. Geological Survey (Danforth and Thieler, 1992). This software is comprised of two C programs. Using the formatted text files, the first program applied a baseline-vertex approach to cast orthogonal transects from each vertex on the baseline to the most seaward shoreline (Figure 16.1 and colour insert following page 169). The program also created a file that contained both the coordinates of points at which the transects crossed each shoreline, and the dates associated with each of those shoreline points. A second C program used this file to compute the rates of change between shorelines at each transect location and to collect all of the rates and statistics into an INFO database. The resulting output file includes four statistical measurements for each transect: the end point rate, average of rates, linear regression rate, and jackknife rate.

These rates of shoreline change (Dolan et al., 1991) were calculated by measuring the differences between shoreline positions through time along a given transect. The end point rate was calculated by dividing the distance of shoreline movement by the time elapsed between the oldest and the most recent shoreline. The average of rates method (Foster and Savage, 1989) involved calculating separate end point rates for all combinations of shorelines and then taking the average of all end point rates. A linear regression rate-of-change statistic was determined by fitting a least squares regression line to all shoreline points for a particular transect; the rate is the slope of the line. The jackknife rate was implemented as an iterative linear regression which calculates a linear regression fit to shoreline data points with all possible combinations of shoreline points, leaving out one point in each iteration. The slopes of the linear regression lines were averaged to yield the jackknife rate.

16.2.5 Compiling the Data

A suite of four AMLs formatted the output files from the two C programs for the maps and database. The first AML created a coverage of the transect lines with associated shoreline change rates. To do this, it built the transect coverage as lines with the *build* command and added formatting symbols and values for the baseline and transect numbers to the attribute table for use in labelling transects on the maps. In order to determine angle and direction of the lines, it then built line and node topology and added coordinates of the transect nodes to the coverage's node

attribute table. Next, it imported the data from files created by the rate-calculation program into the ArcInfo tables and established a relate in the workspace for the next step. After joining the area files to the transect attribute table for that area, the AML brought the related information and arcs to a new appended coverage.

At this point, all of the necessary map coordinates and rate-of-change statistics were calculated. A second AML made a database for export to Microsoft Access. This AML employed the *append* command to create a new coverage containing the transects for the area workspaces. It then used the *tics* option with the *append* command to renumber transects in the appended coverage with unique, sequential ID values. After building the line coverage, the AML added a new item to the attribute table to allow reselection of every other transect. It then deleted alternate transects, creating a 40 meter interval for display on the printed maps, and renumbered the transects for labelling in the database and on maps. It also utilized the *additem* and *join* commands to add the town names from a separate coverage to the transect coverage. The final routine sorted the transect coverage by baseline and transect numbers.

We used ArcMap to remove manually the poorly located transects that crossed inlets and jetties. After the manual edits, a third AML added items to the attribute table of the transect coverage and selected the attribute table in ArcTables. It used the ArcEdit command *unsplit* to combine the identification arcs in the transect coverage and then built the transect line coverage. The AML then sorted the transects by transect number in ArcTables. After using the *copyinfo* command on the transect attribute table to create a data file, the AML used *dropitem* to delete attributes such as TNODE that are unnecessary for a user database. It then sorted this data file by transect number and used the *infodbase* command to create a database file. A final AML created the last files needed for the database by indexing the transects according to which map would display them. Using the *infofile* command, it created a DAT file for each map containing the transect number, town name, and town identification number. Finally, it used the *infodbase* command to copy this information into DBASE III+ files.

We imported the INFO database into Microsoft Access and converted it to a standalone application to improve users' ability to perform spatial queries and to compile regional statistics and trends. The database forms, reports, and macros were set up for an interactive display; only the tables needed to be replaced with the new database files and the transect coverage database. We used a macro to update the database with the new statistics and to calculate mean rates and bounding shoreline dates for each transect.

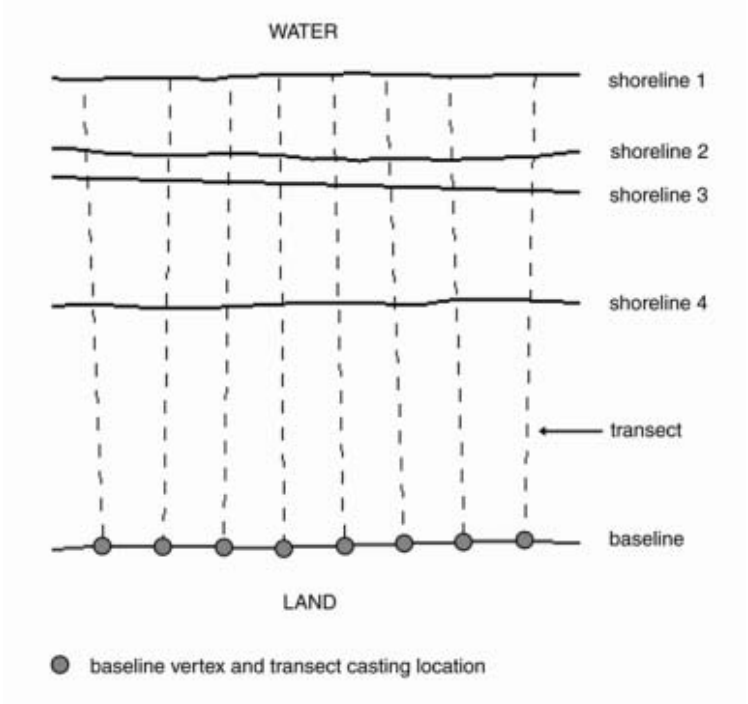

Figure 16.1 The transect casting scheme used to determine locations for the measurement of shoreline rates of change.

16.2.6 Map Production

The final project goal was to generate maps displaying shoreline change. We used an AML to format the maps with a legend and other explanatory information. This AML used the *reselect* command to draw shorelines with a different colour for each era. It also used the command *relate add* to correlate the files created by the rate-calculation program to the existing relate environment, which was saved as an INFO file. The *readselect* command selected every other transect in the writefile of selected transects, and the ArcPlot commands *arcendtext* and *leadertolerance* allowed the transects to be labelled with the associated identification number and linear regression rate of change.

16.3 RESULTS

The series of programs described above produced an Access database that can be searched by map number, community name, or transect number. Transect statistics can be listed in a table or graphed in histograms. The tables and histograms can either be printed or viewed on screen (Figure 16.2 and Figure 16.3).

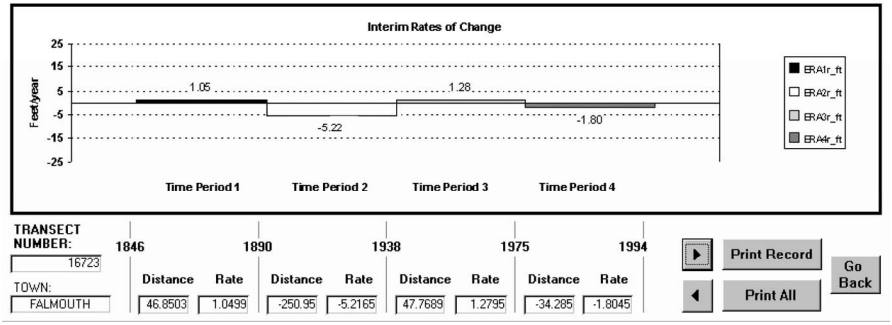

Figure 16.2 Sample histogram depicting interim rates of change.

MASSACHUSETTS HISTORIC SHORELINE CHANGE PROJECT — Transect Statistics for FALMOUTH

Statistics for each interim time period show the distance difference and the derived rate of change. Summary statistics show the overall derived Long Term Annual Shoreline Change Rate.

* units in feet, ** units in feet/year, ~ determined using linear regression.

Go Back | Print

Figure 16.3 Sample transect listing produced by the Access database.

The programs also produced 91 ArcPlot files. The area maps of the Massachusetts coast are at a scale of 1:10,000 and display historical shorelines, transect locations, and long-term rates of change overlaid on the 1994 orthophotographs (shown in Colour Plate 16.1, following page 164).

The resulting database and maps include a total of 30,354 transects spaced at 40 meters along the coast of Massachusetts. Linear regression rates indicate erosion at 68% of the transects, accretion at 30% of the transects, and no net change at 2% of the transect locations.

Both the highest and lowest linear regression rates, 15.2 meters per year of accretion and 12.9 meters per year of erosion, occur on Nauset Beach in Chatham, where the barrier island shoreline faces the open Atlantic Ocean.

Several coastal areas have nearly the same number of accreting areas as eroding areas, such as Hingham (47% eroding, 48% accreting) and Hull (50% eroding, 46% accreting). Both of these areas are located within 40 kilometres of Boston, are highly populated, and have a number of seawalls holding the shoreline in place.

Eroding transect locations predominate in Plum Island (74% eroding, 24% accreting), Truro (83% eroding, 15% accreting), Wellfleet (81% eroding, 18% accreting), and Barnstable (73% eroding, 25% accreting). All of these areas have exposed sandy beaches.

The number of accreting transect locations exceeds the number of eroding transect locations in Harwich (36% eroding, 63% accreting), which is shielded by Monomoy Island to the southeast, and Manchester (40% eroding, 53% accreting), which is characterized by rocky cliffs interspersed with stretches of sandy beaches. The maps and database serve many purposes and interests. For example, state and local government agencies use the historical rate-of-change data to manage and regulate coastal development. Developers and potential homebuyers can examine the maps to determine the stability of beachfront property. Residents can view post-storm erosion in the context of long-term shoreline variability. This information can also aid in evaluating past management efforts, such as the emplacement of seawalls, jetties, and groins that have influenced shoreline change.

MCZM distributes these maps, along with the database and a manual describing how to use the information, to regional government offices and coastal communities. These products will also be made available to the public on the Internet.

16.4 SUMMARY

This project addresses the increasing need to measure and document coastal change by combining established shoreline evaluation techniques with improved GIS applications. The resulting maps and database comprise a current and accessible source of information on coastal change in Massachusetts, including historical shorelines and shoreline change statistics. Coastal managers in Massachusetts can continue to benefit from the database by updating the database with new shorelines and rerunning the suite of AMLs and C programs that calculate change and produce maps.

Academics, consultants, citizen groups, developers, and government agencies can use the map and data products described in this paper for a variety of purposes and interests. The database and maps have the potential to improve decisions concerning coastal management, residential and commercial development, and coastal research by making shoreline data comprehensible and available to a wide audience. The maps displaying shorelines and rates of change are visually appealing and quickly understood, particularly when overlaid on orthophotographs. More detailed information is readily available in an interactive database. If further modifications are desired, new modules can be incorporated into the current program and database structure. These methods and products are an excellent resource for anyone interested in coastal change, and they serve as a solid foundation for future applications.

16.5 ACKNOWLEDGEMENTS

The Massachusetts Shoreline Change Project was funded by the Massachusetts Office of Coastal Zone Management pursuant to a grant from the National Oceanic

and Atmospheric Administration, Award NA970Z0165. Susan Snow-Cotter, Steve Mague, Diane Carle, and Rebecca Haney of CZM offered many valuable suggestions for the development of the maps and users guide. Bill Danforth of the USGS provided computer support. Technical reviews by Laura Moore and Larry Poppe improved the clarity and content of the paper.

CHAPTER SEVENTEEN

GIS for Assessing Land-Based Activities that Pollute Coastal Environments

J.I. Euán-Avila, M.A. Liceaga-Correa, and H. Rodríguez-Sánchez

17.1 INTRODUCTION

According to Heathcote (1998), the development of workable management options (structural and non-structural actions) in a watershed requires the identification of all point and non-point sources of pollution. Discharge of effluents from industrial, urban and sewage treatment plants where a pipe or diffuser outfalls into a water body are called "point sources" of contamination. Another type of source, called a "non-point source" (NPS), is described as the diffuse drainage of rainwater from urban, industrial and agricultural lands that can introduce nutrients, pesticides, and metals to water bodies. Non-point sources are some of the more serious forms of pollution and the effects are often less obvious than those of point sources (Abel, 1998). Clapman *et al*. (1998) indicated that agricultural impacts on ground and surface water quality are more significant than other land use impacts because of their large aerial extent compared to other human land uses. Lack of information related to agricultural practices may lead to overuse of fertilizers and herbicides, and deforestation with serious impacts on soil erosion and water quality.

The Yucatan Peninsula is blessed with large freshwater reserves, bays and coastal lagoons and an exclusive economic zone of 200,000 km^2. However, the maintenance of the water quality seems to be an enormous challenge for the State and other interested groups considering the unfulfilled basic needs of a large part of the population, rates of population growth, immigration, and lack of an integrated approach to the management of the resources and coastal areas. In June 1996 a massive kill of 20,000 fish of the species *Arius felis* was reported in the Bay of Chetumal, State of Quintana Roo (SEMARNAP, 1996). Studies reported harm to their organs and accumulation of PCBs, organochlorine insecticides and polyaromatic hydrocarbon (Noreña-Barroso, 1998). Concerns exist that increasing loss of water quality may have adverse effects on mangroves and coral reefs in an area where the second most important barrier reef, the Mesoamerican reef, and the sanctuary of the manatee *Trichechus manatus* are drawing international attention.

Agricultural activities introduce diffuse pollution to watercourses, aquifers, lagoons and estuaries in the form of sediments, nutrients, pesticides, viruses, salt and other toxins which affect aquatic organisms. Pollution cause-and-effect relationships are complex and the need to find practical tools to generate useful information for decision-making may be addressed with models that introduce expert knowledge. Within this framework, this exercise attempts to rank the agricultural lands according to several factors that may contribute to water contamination on the Mexican side of the Rio Hondo watershed near the Othon P. Blanco municipality border with Belize.

17.2 GEOGRAPHICAL SETTING

17.2.1 The Yucatan Peninsula

The Yucatan Peninsula in México has mainly sub-surficial water dynamics driven by its geological and topographic nature: there are few rivers or lakes in the area. Exceptions are the Candelaria and Champotón rivers in the zone of the Términos Lagoon in Campeche, and the Hondo River in the State of Quintana Roo near the border with Belize. Yucatán has no rivers; however underground discharge in the coastal zone has been estimated at 9.7 million m^3 per year (CNA, 1998). The main features of the coastal areas are bays and lagoons, which are distributed throughout the three states: Términos Lagoon in Campeche; Celestún, Dzilam and Rio Lagartos in Yucatán; and Chetumal, Ascensión and Spiritu Santo bays in Quintana Roo. Surrounding these water bodies, other wetlands cover an area of approximately 8000 km^2, thus forming an important part of the coastal ecosystem (CNA-UNU/RIAMAS, 2000).

Due to its geographical location between the Caribbean Sea and the Gulf of Mexico, the region is influenced by severe hydrometeorological phenomena. The climate of the region is semi-arid in the coastal zone of the north part of the Peninsula and warm with variation of dry to humid in the rest of the peninsula. The mean annual temperature is 26ºC. There are two main seasons in the regional climate: the “rainy season,” including extreme phenomena such as hurricanes and tropical storms from May to October; and the "winds of the north” season, from November to April. The region receives abundant but uneven rainfall with mean annual precipitation ranging from 1600 mm in the southeast to 500 mm in the north. Mean annual evaporation is around 1.78 mm (CNA-NU/RIAMAS, 2000).

Human activities in the Yucatán Peninsula are related to agriculture, livestock production, tourism, fishing, oil production, and transportation, and recently to a large number of *maquiladoras*. Fertilizers, pesticides and metal residues have been found in coastal waters and the aquifer. These negative effects on the environment have been reported in several locations (Pacheco and Cabrera, 1996, Benitez and Bárcenas, 1996, Ortiz and Sáenz, 1997, Noreña-Barroso *et al*., 1998, CAN, 1998, Herrera-Silveira *et al*., 1998). Coastal resources in the Yucatan Peninsula provide increasing opportunities for economic development in a large number of traditional fishing communities. Lack of awareness of the deleterious effects of land-based activities on water quality may lead to a reduction in

biodiversity and esthetical quality of the landscape, thus putting at risk the continuity of fishing, tourism, and recreational activities.

17.2.2 The Municipality of Othon P. Blanco

Othon P. Blanco is a municipality located in the State of Quintana Roo in the southeast part of the Yucatan Peninsula (Figure 17.1). It has an area of 619,799 hectares, 161,226 (26%) of which are occupied by agricultural use, 129,396 (20.9%) by natural and cultivated grass, 325,155 (52.5%) by forest and 4,021 (0.6%) by other uses.

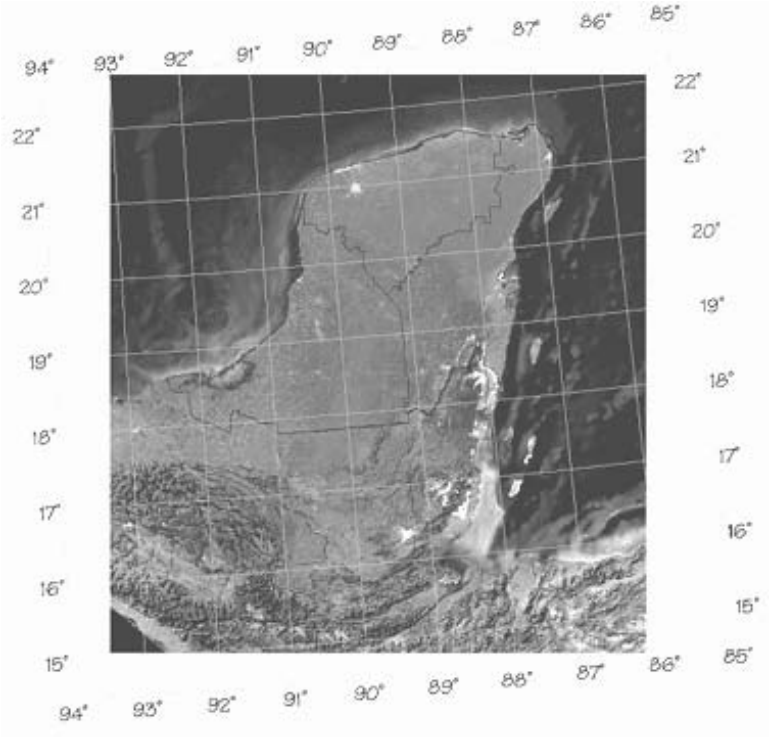

Figure 17.1 Study area in the Yucatan peninsula, Mexico. Municipality of Othon P. Blanco in the state of Quintana Roo. Main hydrological features are the Hondo River and the Bay of Chetumal.

The population in 1990 was 172,563 with 53.5% less than 19 years of age. The municipality has 437 rural and urban centers with 45% of the population living in 436 towns with less than 5,000 inhabitants. Close to 50% of the population are immigrants. Of the population 15 years or older, 17.4% completed elementary school (INEGI, 1991a). Main crops by cultivated area include: corn (19,196 hectares), sugar cane (16,000), chili (5,151), and beans (1, 391) (INEGI, 1993). Production in 1991 was estimated at 12,000 tonnes for corn, 785,000 for sugar

cane, 26,000 for chili, and 84 for beans. Other crops cultivated in the area are orange, coconut, and banana (INEGI, 1994).

Some of these agricultural lands can be found in the watershed of Chetumal Bay. The Bay is 67 km in length and 20 km wide, and receives freshwater from the Hondo River and Guerrero Lagoon, causing it to exhibit estuarine characteristics. Man-made channels and other tributaries close to agricultural lands are linked to the Hondo River. The most dominant soil types, Rendzinas and Litosoles, cover 70% of the Peninsula and 85% the study area (INEGI, 1985).

17.3 MODEL AND DATA LAYERS

17.3.1 Model

The selected model attempts to rank agricultural lands according to the potential menace they represent to water quality. The model is a multi-criteria evaluation method provided by the IDRISI software, which combines several layers as the criteria to form an index of evaluation (Eastman, 1999). Relevant factors in the process of NPS pollution assessment (being those for which an estimate was available) were: amount of agrochemical inputs, slope, proximity to surface water, and distance to aquifer. Given the natural continuity in factors, ratio layers and a weighted linear combination of them can provide an index for ranking. Their mathematical representation is as follows:

$$S = (\Sigma\, w_i * x_i) * \Pi\, c_j \qquad (17.1)$$

where s= NPS index, w_i= weighting factor i, x_i= factor i, c_j= constraint j

Factors must be normalized according to the accuracy of our knowledge of their respective ranges of impact, as well as the ways in which they behave at different scales. The procedure used, which is based on fuzzy sets, is also provided by the IDRISI program. Finally, the model allows a weight to be assigned for the relative contribution of each factor. Criteria called Analytical Hierarchy Process (AHP), based on a pair-wise comparison of factors along a continuous rating scale, can derive weighs by calculating the principal eigenvector of the created matrix (Eastman, 1999).

17.3.2 Data layers

17.3.2.1 Geographic location of agricultural lands

A good estimation of the location of agricultural land is a basic prerequisite for assessing NPS pollution. A two-band WIFS image with 180 x 180 m spatial resolution acquired in 1999 was used to estimate the location and extent of the

agricultural lands in the Othon P. Blanco municipality (Figure 17.2a). A supervised classification was conducted to estimate the total cultivated land in the area. Census data from the AGROS system elaborated by the INEGI provided crop information for areas called Basic Geo-statistical Area (AGEB in Spanish) (INEGI, 1996). Each AGEB is a well defined polygonal (vector) area with a link to a data base (Figure 17.2b). These two layers were used to estimate the location of cultivated areas by AGEB.

17.3.2.2 Agrochemical practices

The quantification of chemicals used per unit area and frequency of use was another factor in the analysis. A survey was conducted in September 1999 for the purpose of estimating the quantities of fertilizer and pesticides used per crop each year. A total of 97 farmers were interviewed in five agricultural towns: 1) Nicolás Bravo, 2) Palmar, 3) Pucté, 4) Sergio Butron, and 5) Morocoy. The questionnaire was divided into three sections to learn about fertilizer, insecticide, and herbicide practices per crop. Each section focuses on names, dosage, and frequency of applications of agrochemicals by crop per hectare per year. Substances were normalized according to thresholds determined through consultation with experts in the field.

17.3.2.3 Digital elevation model and slope

Slope is a well known factor that favours the movement of the substances on the terrain surface. Slope and aspect are the main factors that determine velocity and direction of the overland flow during storms. In areas with long slopes, the capacity of vegetation to reduce erosion is diminished. Slope was computed from a DEM of the area using the TNT software (Figure 17.2c). The DEM was produced by INEGI in a scale of 1: 250,000. Two archives, E1604 and E1607, were mosaiced to cover the studied area.

17.3.2.4 Proximity to surface water

Distance from agricultural activities to water bodies is also a factor that may facilitate contaminants reaching water courses, ponds, or estuaries. Proximity maps were constructed based on water features identified on band 2 of the WIFS image as well as those features found on topographic maps E16-4-7 at a scale of 1:250,000 produced by INEGI. These two layers were combined to generate a reference object for computing proximity to surface water (Figure 17.2d).

17.3.2.5 Proximity to groundwater

In karst formations (carbonated rocks) such as the Yucatan Peninsula in Mexico, precipitation tends to infiltrate rapidly because of the high number of fractures and solution cavities in the massif. Depth to the aquifer was estimated from a regression model using 15 well depths provided by the Regional Office of the *Comision Nacional del Agua* (CNA) and their corresponding elevation in the DEM (Figure 17.2e).

17.4 RESULTS

17.4.1 Agricultural lands

Agricultural areas detected from the satellite image were defined based upon the 1991 census. These areas were mainly devoted to growing sugar cane, corn, beans and *jalapeño* chili. The statistical data from AGEBS was proportionally assigned to current agricultural lands for a better spatial location of the cultivated areas (Figure 17.2b). As an example, Figure 17.2b shows, by AGEBS, the percentage of the total cultivated surface with sugar cane in 1991. The percentage for corn, beans and *jalapeño* chili was related to the area in a similar fashion.

17.4.2 Agricultural practices

Data from the five sampled regions indicated that farmers are working those lands for 11 years on the average (the interval is from 1 to 30 years with a standard deviation of 7 years, out of 93 valid cases). The mean value of the farmers' age was 42 (the interval was from 18 to 74, and the standard deviation was 12). The number of years each farmer had spent at school had a mean value of 4 (from 0 and 14, with a standard deviation of 3). These farmers reported applying agrochemicals to their primary crops (sugar cane, corn, *jalapeño* chili, and beans) during cultivation. Sugar cane is one of the main crops in the area and it received a large number of agrochemicals (more than 25 commercial products were identified). Given the large number of products, only those with a high frequency of use in each category (fertilizers, insecticides and herbicides) were selected for analysis. From these selected products, active substances were estimated giving the total applied quantity per hectare per year (an example is provided in table 17.1 for sugar cane). A layer with total phosphorous used in one year in kg/ha was calculated from four top selected crops with values of 70.25 kg/ha for sugar cane, 18.8 kg/ha corn, 40.19 kg/ha *jalapeño* chili, and 15.21 kg/ha beans each year. Similar computations were used to estimate nitrogen in the fertilizer category. In the case of herbicides substances such as 2,4D, paraquat, and ametryne were estimated. Finally, estimated substances in the insecticides category were metamidophos, chloropiriphos, and monocrotophos.

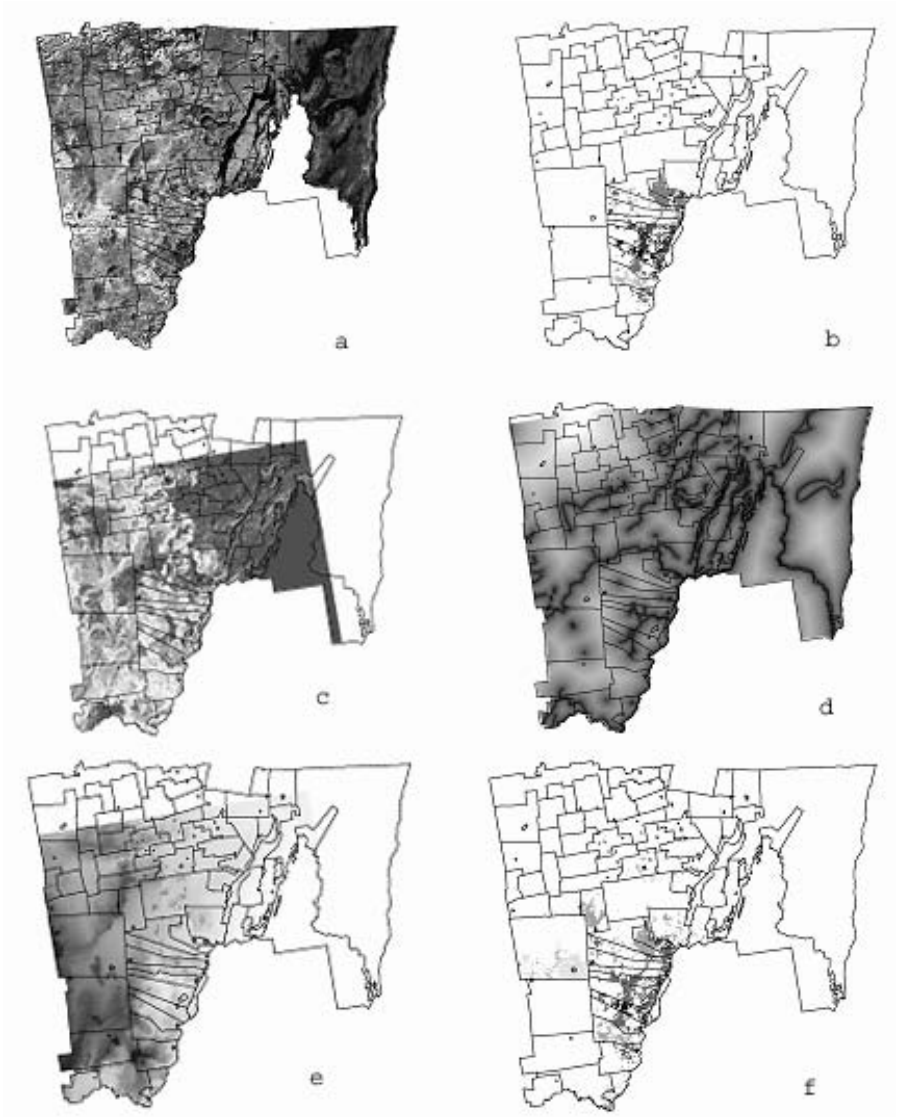

Figure 17.2 (a) WIFS image band 2, (b) cultivated areas for sugar cane and AGEBs, (c) slope from DEM, (d) proximity to surface water, (e) distance to aquifer, and (f) rank of nutrients (P and N).

17.4.3 Slope

Figure 17.2c shows the magnitude in percentage of slopes calculated from the DEM. Slopes in the area range from 0% to 48% with a mean value of 1.3% and a standard deviation of 2.5%. Elevation in the area ranges from 0 to 300 m. Slopes

on agricultural lands had a mean value of 1.84% and a standard deviation of 2.98%. These data were standardized from 2 to 10% increasing.

Table 17.1 Agrochemical substances used in sugar cane cultivation.

Substance	% of users	Mean annual number of applications and std. dev.	Mean quantity and std. dev. per application	Unit	Total amount of active substance
PK al 17%	44/60	1.40 - 0.92	317 - 089	Kg/ha	55.25
PK al 15%	14/60	1.30 - 0.61	332 - 130	Kg/ha	15.00
					70.25
N al 17 %	44/60	1.40 - 0.92	317 - 089	Kg/ha	55.25
N al 15 %	14/60	1.30 - 0.61	332 - 130	Kg/ha	15.00
N al 46 %	34/60	1.20 - 0.6	153 - 071	Kg/ha	47.84
					118.1
Ametryne 39.2%	14/60	1.10 - 0.28	2.8 - 0.86	l/ha	0.29
Ametryne 25%	24/60	1.50 - 0.77	3.9 - 1.2	l/ha	0.387 0.677
2,4-D 49.4%	31/60	1.20 - 0.66	2.3 - 1.1	l/ha	0.73
Monocrotophos 44.24%	17/60	1.90 - 1.00	1.9 - 2.6	l/ha	0.45

17.4.4 Proximity to surface and ground water

Proximity to surface water is shown in Figure 17.2d. Features included in the surface water category were rivers, ponds and channels. Results indicated a mean distance of 3.6 km, standard deviation of 3.2 km and mode of 0.9 km. The largest distance was 17 km. These data were standardized from .5 to 5 km decreasing. Finally, the result of the regression model for distance to the aquifer is shown in Figure 17.2e. Regressed elevation and depth measurements resulted in the following equation: aquifer depth = $0.0029h^2 + 0.2891h + 3.8161$ (h = elevation in the DEM), $r^2 = 0.97$ for n = 15. Depths ranged from 3.8 m to 211 m with a mean value of 42.5 m, standard deviation of 37.9 m and mode 3 m. Data was standardized from 1 to 15 decreasing.

17.4.5 Model results

Distribution of the S index for fertilizers, herbicides, and insecticides was calculated as a potential threat to water quality. An example, based upon nutrient load, is illustrated in Figure 17.2f. Parameters to compute the S index for standardized factors were selected from the observed data range of factors in the area. Equal weights were assigned to factors. With these parameters, the NPS index for fertilizers (phosphorous and nitrogen) had values from 1 to 204, a mean

value of 82 and a standard deviation of 44. Higher values of the index were found in the areas of Pucté and Palmar where sugar cane is the main crop. In the vicinity of Morocoy and Sergio Butron medium values were recorded, and the smallest values could be found in the area of Nicolas Bravo. The NPS index for herbicides (2-4D, paraquat, and ametrine) had values from 1 to 155, with a mean of 50 and a standard deviation of 32. Large tracts of Pucté and Palmar displayed higher values, while Sergio Butron displayed medium values and Morocoy and Nicolas Bravo the smallest. Finally, for insecticides (monocrotofos, chloropyrifos, and metamidofos) the NPS index ranged from 1 to 124, with a mean value of 40 and a standard deviation of 23. In this case, large areas of Pucté and Palmar displayed higher values, Sergio Butron and Morocoy displayed medium values, and Nicolas Bravo showed the smallest. The analysis suggest that Pucte and Palmar are major potential areas of threat to water quality as a result of nutrient, herbicide and insecticide inputs, while the importance of Morocoy, Sergio Butron and Nicolas Bravo in this respect changes according to the type of agrochemical under analysis.

17.5 CONCLUSIONS

An exercise in the use of GIS tools was conducted to characterize agricultural NPS pollution in the Yucatan Peninsula. Standard GIS processes and digital data from satellite, maps, and other digital products available in Mexico allowed ranking of agricultural lands in the Hondo river watershed according to the threat posed to water quality by the use of agrochemicals on these lands. Standard procedures available in the TNTmaps and IDRISI software packages were used to feed and run a multi-criteria model for decision-making. Three indices suggested that two out of the five agricultural study areas, where sugar cane is the main crop, have a large potential and non-homogeneous threat to water quality as indicated by the NPS index. The potential contribution of the other agricultural areas varies when examined by category (nutrients, herbicides, and insecticides). Increasing water contamination and limited resources in developing countries can be better allocated when knowledge of the co-occurrence of practices and terrain features is integrated into models for the assessment of the potential effects of human activities on water resources. As new knowledge is integrated these scenarios can be fine-tuned with more precise data and expert knowledge, providing improved spatial information to assist decision makers in the selection of appropriated management actions in the arena of NPS pollution.

17.6 ACKNOWLEDGMENTS

We thank the following people for their many contributions: J. Acosta, H. Hernández, G. Mexicano, Ricardo Rodríguez, Dr. Jorge Alvarado, P. I. Caballero, and students from the Centro de Estudios Tecnológicos del Mar (CETMAR). This research has been supported in part by Secretaría del Medio Ambiente Recursos Naturales y Pesca (SEMARNAP).

CHAPTER EIGHTEEN

Applying the Geospatial Technologies to Estuary Environments

David R. Green and Stephen D. King

18.1 INTRODUCTION

Around the World the value and vulnerability of estuaries has long been recognised. The National Estuary Study of 1969 in the U.S. is just one such example (http://www.inforain.org/mapsatwork/oregonestuary/Oregonestuary_page 4.htm). In the UK, initiatives by English Nature (EN) and Scottish Natural Heritage (SNH) to develop new approaches to estuary management in England and Wales, and Scotland respectively, led to Estuary Management Plans (English Nature, 1993). In Australia there have also been many similar initiatives to develop sustainable management of estuarine environments increasingly coming under pressure from tourism and industry (NLWRA, 2002) and, more recently, in the UK, from the impact of offshore windfarms e.g. Robin Rigg in the Solway Firth (Anonymous, 2003).

Green (1994; 1995) proposed the idea of GIS-based estuary information systems in the UK as a means by which it would be possible to collect, store, analyse and display spatial data and information to aid in estuary management. At the time, GIS was just beginning to develop into a practical tool for environmental applications in coastal zone management. In the intervening years, a great deal of interest has been shown in the development of GIS and the related geospatial technologies to aid in environmental monitoring, mapping, modelling, and management. Rapid developments in information technology (IT), including the Internet and the related technologies, have also led to the more widespread use of geospatial data and information for environmental applications by coastal managers and practitioners. Such developments have been responsible for providing the basis for access to data and information for management and public participation exercises. Increasingly, decision support systems (DSS) and information systems are also being used to support data and information requirements for coastal management.

With the continuing evolution of Information Technology (IT), the collection of, and access to, both data and information have rapidly been extended to the use of mobile technologies. These include Personal Digital Assistants (PDAs), Wireless Application Protocol (WAP)-enabled mobile phones, Global Positioning Systems (GPS), digital still and video cameras, and mobile GIS products such as ESRI's ArcPad, PocketGIS (http://www.posres.com), HandyGIS

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

(http://www.handgis.com) and FastMap (http://www.surveysupplies.com). Field data collection and access to information, via remote uploading and downloading, sending email attachments (e.g. photographs taken with a digital still camera or camera accessory for a mobile phone), and accessing the Internet using wireless technology are now all providing new opportunities to collect, work and interact with spatial data 'on-the-fly' (e.g. Vivoni and Camilli, 2003).

Alongside the hardware and software developments there have also been a number of new and important airborne and satellite-borne sensors. These have provided new sources of finer spectral and spatial resolution data to assist in the monitoring of coastal and estuarine environments e.g. CASI (Compact Airborne Spectrographic Imager), whilst LiDAR (Light Detection and Ranging) data provides unique high-resolution height data. The launch of ENVISAT in 2002 by the European Space Agency (ESA) for dedicated environmental monitoring, and European projects such as COASTWATCH (http://www.coastwatch.info) are also increasing awareness of the role of EO data for coastal monitoring in the context of GMES (Global Monitoring of Environment and Security).

This chapter presents an overview of some of the recent developments in the application of the geospatial technologies to estuary environments as the basis to support growing requirements for data and information in the context of environmental monitoring, mapping, and management. The role of some of the different geospatial technologies for environmental data collection, processing and access to information is examined. To conclude, some future developments are discussed. The chapter is illustrated using a number of examples drawn from Europe (including the UK), North America, and Australia.

18. 2 THE ESTUARY ENVIRONMENT

Estuaries are very well studied features of our coastal environment. A great deal of research has been undertaken into the physical processes operating in an estuary including sediment movement, water circulation, pollution and erosion (e.g. Stapleton and Pethick, 1996; Stove, 1978; Townend, 2002). The use of modelling techniques has been widely applied in an attempt to increase our knowledge and understanding about the processes that are active (e.g. Hinwood and McLean, 2002). Ecological studies of estuarine environments have included investigations into coastal habitat, macro-algal weedmats, and bird population distribution (e.g. Jernakoff *et al.*, 1996; Young *et al.*, 2000; Lewis and Kelly, 2001; Ripley *et al.*, 2002).

Estuaries are complex and highly productive ecosystems (among the most productive on Earth) supporting a wide range of habitats and species, extending from the river's upper tidal limit to the sea, and provide a constantly changing environment where sea and fresh water mix. They provide:

- Habitat (live and feed)
- Nursery Areas (reproduce and spawning)
- Productivity (abundance and biodiversity)
- Water Filtration (fresh and salt marshes)
- Flood Control (buffer to flood waters, dissipate storm surges)

- Erosion Prevention and Stabilisation (grasses and plants)
- Cultural Benefits (recreation, scientific knowledge, education, aesthetic value)
- Economic Benefits (natural resources used for recreation, industry, fishing, tourism)

(http://inlet.geol.sc.edu/nerrsintro/nerrsintro.html and http://www.epa.gov/owow/estuaries/about1.htm)

Many different habitat types, for example, are found in and around estuaries (http://www.epa.gov/owow/estuaries/about1.htm) including:

- Shallow open water
- Freshwater and salt marsh
- Sandy beaches
- Mud and sand flats
- Rocky shores
- Oyster reefs
- Mangrove forests
- River deltas
- Tidal pools
- Sea grass and kelp beds
- Wooded swamps

These are home to an abundance and diversity of wildlife including:

- Shore birds
- Fish
- Crabs and lobsters
- Marine mammals
- Clams
- Shellfish
- Marine worms
- Sea birds

(http://www.epa.gov/owow/estuaries/about1.htm)

Estuaries are also multi-value resources to society (NWLRA, 2002). They provide a whole suite of human resources, benefits and services (http://www.epa.gov/owow/estuaries/about1.htm). Such environments support commercial, traditional, and recreational fisheries, tourism, and wilderness experiences. They have also long been a source of inspiration for the human mind through aesthetics, art, and poetry. Since early times estuaries have been places for human settlement, providing sheltered harbours, transport and trade routes and natural resources for industry (http://www.iwight.com). Some are still relatively sparsely developed whilst others have become densely populated areas.

Not surprisingly the wide range of potential uses results in many conflicts, and therefore necessitates a management strategy. Each estuary has its own distinct characteristics, susceptibility to impacts, and management requirements. An

increasing number of national and international designations, policy and bylaws also make management of an estuary environment potentially very complicated. Worldwide there is now a wide range of organisations with statutory responsibilities on land, sea, and across the intertidal zone. In addition, there are many coastal and estuary management plans (http://www.iow.gov.uk) designed to provide a more holistic approach to sustainable management of coastal areas.

As local, national and international interest in estuaries has grown, so too have the sources of information available to managers and the public. Besides documents such as estuary management plans, there are now many local community groups who seek to involve and inform the public about estuaries. In the UK, for example, there are a number of organisations who look after the interests of the local estuary communities; for example, the Thames Estuary Partnership, the Solway Firth Partnership, the Moray Firth Partnership, and the Forth Estuary Forum to mention but a few. Besides providing documentation in the form of management plans, papers and publicity, these groups are also increasingly actively involved with local communities through the development of websites, online mapping and various local activities e.g. litter monitoring, habitat surveys, field visits and seminars.

In other parts of the world, for example the US and Australia, there are similar approaches to estuary management. For example, in Australia: the site http://www.dlwc.nsw.gov.au/care/water/estuaries/Inventory/Index_Geogr.html, and in the USA the sites http://www.spn.usace.army.mil/bmvc/baylink.html and http://www.estuaries.gov/about/programs.html provide lists of national programs and organisations involved in estuaries and resources. A number of recent projects have also focused on the status of Australian estuaries. For example, Australia's Near Pristine Estuaries: Assets Worth Protecting (NLWRA, 2002) has made a preliminary classification of all of Australia's estuaries based on their 'condition.'

18.3 ESTUARY MANAGEMENT

Estuaries are clearly very complex, interesting, and dynamic components of coastal zones around the World. They provide an interface between freshwater and saltwater environments, one that is constantly changing. They are also fragile environments and easily affected by human activities whether it be settlement, industry or tourism. Changes, however small, can be very harmful to the survival of an estuary (http://estuaries.gov/about/aboutestuaries.html).

With growing numbers of people settling and utilising estuaries, there are many activities that are now considered to endanger the survival of estuaries; such as dredging, the infill of flats and marshes, pollution, reconstruction of shorelines for housing, transportation, and agricultural needs. Also, marinas and tidal barrages can lead to dramatic changes in water circulation, erosion, and sediment movement. The effects of changes that have taken place have been unsafe drinking water, closure of beaches and shellfish beds, the development of harmful algal blooms, unproductive fisheries, loss of habitat and wildlife, and fish kills, as well as a host of other human health and natural resource problems (http://www.epa.gov/owow/ estuaries/about1.htm). Addressing such problems involves the use of planning, protection measures, and the implementation of

management strategies. The protection of estuaries from detrimental change is considered vital in order to preserve natural 'beauty and bounty,' as well as to sustain livelihoods that depend upon fishing and tourism. The designation of protective zones, use of patrols and enforcement can be used, whilst management, for example, can help to restore estuaries (http://www.estuaries.org).

But estuaries are often difficult areas to manage successfully because of all the conflicting interests that exist. Whilst local partnerships between communities, industry and government can be, and have been, very helpful in addressing some of the problems facing estuarine environments (for example, the Scottish Firths initiative e.g. the Forth Estuary Forum) the many competing interests are often very difficult to accommodate satisfactorily. Ideally for management to be successful requires the identification of a lead organisation at a higher level. National policy in Australia, for example, is still deemed essential despite the local and regional initiatives. But, the piecemeal approach to coastal management that seems to have developed around the World has also led to many problems. As noted by Brown (1995), "the current coastal management system is the cause of the failure to redress the problem of the coastline. This management system is characterised by fragmentation of responsibility between spheres of governments, among different professional areas of expertise, and across different social, economic and environmental interests. It is indeed difficult for the existing systems of coastal management to become part of the solution to coastal degradation while it remains part of the problem."

18.4 GEOGRAPHY AND THE GEOSPATIAL TECHNOLOGIES

Geospatial technology has the potential to assist in the future management of estuarine environments in a number of ways. Brown (personal communication, 2003) considers GIS, for example, to have multiple roles including record keeping, monitoring change, advising scientists, and most crucially (and currently the least developed) for demonstrating relationships between biophysical systems and socio-political options. The rationale for using geospatial technologies in a coastal environment is also clearly highlighted by Fabbri (1998) in the following quote:

"Given the complexities of coastal systems and the multidisciplinarity required for sustainable coastal development, computerized systems are necessary for the integration and distribution of vast amounts data and expert knowledge. They are also vital for performing analyses to aid decision makers in their difficult task of proving optimal and compromise coastal management solutions"

In this chapter, 'geospatial technologies' are considered to include remote sensing (aerial photography, airborne and satellite data and imagery), Geographical Information Systems (GIS), Global Positioning Systems (GPS), mobile computing e.g. portable computers and Personal Digital Assistants (PDAs), WAP-enabled mobile telephones, digital still and video cameras, portable data storage and compression, and the Internet. Together these technologies are all rapidly becoming increasingly useful tools for a wide range of environmental projects that have a requirement for data collection and access to digital spatial data and

information. These technologies, comprising both computer and other hardware and software, enable us to undertake:

- Data collection
- Data processing
- Data analysis
- Modelling and simulation
- Visualisation
- Communication and networking
- Provision of distributed data services
- Remote data access

Remote sensing (airborne and satellite sensors), for example, offers data collection and monitoring capabilities for estuarine environments at a number of different spatial, spectral, and temporal resolutions. This ranges from simple low-cost data acquisition platforms such as kites and balloons, model aircraft, and helicopters (Green *et al.*, 1998), and microlights for small-scale project work using 35mm cameras, digital cameras, and video, to the use of CASI and LIDAR, and satellite-based sensors on platforms such as IKONOS, ERS (European Remote Sensing Satellite), ENVISAT (Environment Satellite) and RADARSAT. Taken together these offer a powerful source of environmental data and information about estuary environments providing opportunities to derive up-to-date information on, for example, habitat type, algal weedmats and algal blooms, water depth, and sediment movement.

Rapidly decreasing costs of both hardware and software, together with improved usability and functionality, now offer end-users a wide range of tools that, when integrated, provide a practical framework for both acquiring and accessing data, storage, processing, analysis, modelling, and visual display. Recent developments in user-interfaces to both hardware and software have also made the geospatial technologies much easier to use than in the past. Likewise, developments in infrared (IR) and Bluetooth technologies have revolutionised communication links, facilitating the movement of large datasets from one location to another e.g. local to remote and vice versa. All of these developments now provide significant opportunities to interact with geospatial data in a laboratory and a field environment, the latter providing a means by which it is possible to access data and information 'on the fly.'

As these technologies have become cheaper and more usable, so they have become more accessible to a wider and more diverse end-user community including: academics who want to collect data in the field as part of a research project; commercial users working on contracts; ecologists, botanists, and biogeographers who need to gather data at a field study site; students collecting data as part of a dissertation; and schoolteachers and pupils wishing to undertake practical fieldwork as part of a curriculum requirement, class, or to aid in the development and creation of a virtual field course. All of these different categories of people are potential contributors to the well-being of an estuary, the very basis of the UK estuary fora.

Geospatial technology is rapidly becoming all-pervasive and there is growing interest in the potential that it can offer in terms of mobile access to data and

information. Already there is much 'geospatial' data and information available over the Internet, and together with developments in interface technology and the capability for greater end-user interactivity, the Internet is now providing access to powerful new tools that allow the delivery of online maps, animation, and virtual reality, not only on the desktop but now also in the field. For example, a combination of a PDA and a mobile phone will allow remote access to the Internet. Map data collected in the field using a GPS can be captured on a PDA and processed using software such as PocketGIS. Maps can be downloaded locally to a PDA, updated in the field and, with the aid of a mobile phone, uploaded into a remote database for storage, querying, retrieval, analysis, and display.

18.5 EXAMPLE GIS APPLICATIONS IN ESTUARY MANAGEMENT

The following are some examples of the different ways in which the geospatial technologies can and are currently being used in relation to an estuary environment:

18.5.1 Artificial Reef Siting

Artificial reefs have become increasingly popular as the means to attract fish populations for a variety of purposes, one of which is commercial fishing sport. These usually take the form of large metal structures, e.g. old boat hulls or drilling rigs, that are sunk thereby forming an 'artificial reef,' an ideal fish habitat. Where such structures are to be sited in shallow waters, close to the coast, and in areas in which there are many other potential users of the coastal area or zone, care must be taken in the siting process. The process of siting can be undertaken manually using relevant geographical information and siting criteria. An alternative approach is to use GIS to achieve the same task, with the added benefit of being able to undertake the process more quickly and efficiently, using more geospatial information, and the bonus of being able to generate a number of different siting scenarios. This type of siting exercise is a relatively simple example of using GIS in an analytical capacity. It involves the creation of an environmental database, comprising a number of raster and vector datasets, the selection of suitable environmental datasets according to certain criteria, the use of GIS functionality e.g. buffering, and the use of multi-criteria overlay analysis to create a composite in which only those areas that fulfil all the siting criteria are shown, those where artificial reefs might be located. An example of using this approach is a study in Moray Firth in the northeast of Scotland (Green and Ray, 2002; Wright *et al.*, 1998).

18.5.2 Habitat Management

The Nature-GIS (http://www.gisig.it/nature-gis/) project began in 2002 to examine the different ways in which geographic data and information are currently being used for protected areas management. Protected Areas Management includes Marine Protected Areas (http://www.ukmarinesac.org.uk) within estuaries.

Involving a total of nineteen European partners, the project also has as one of its aims the development of a protected areas geospatial data model (Green *et al.*, 2003). The data model aims to help standardise the way in which protected areas data is collected and stored for display and analysis with geographic data-handling tools, and subsequently used in protected areas management.

18.5.3 Erosion

Coastal erosion is of growing concern around the World. A European project, EUROSION (http://www.eurosion.org), has recently begun to provide documentation and information about coastal erosion along the coastlines of Europe. One particular area of concern is erosion in estuarine environments. Typically estuaries are sheltered areas of the coast protected from the force of the sea. However, the process of erosion is still active within such an environment. Consideration is being given to coastal erosion management, including some cases of estuaries in the Netherlands and Portugal. (Further details can be found at http://www.eurosion.org/project/reports.html.)

18.5.4 The Siting and Management of Yacht Marinas

In the UK, yacht and boat marinas have become increasingly popular coastal developments to cater for the growing leisure and tourism industry (Sidaway, 1991). Many of the estuaries around the UK coast are now home to both small- and large-scale marina developments. GIS can be used in a similar way to the artificial reef-siting example discussed above, to assist in the siting of a new marina. The GIS utilises a number of geospatial datasets and marina siting criteria to undertake an environmental impact assessment (EIA) and subsequently to isolate the ideal or optimum geographical location(s) for a marina. GIS can also be used as an effective data management tool for the marina and its assets. Already there are a number of commercial marina management tools available e.g. The Marina Program (http://www.ccmarina.com/index.htm). Although many largely are extended mapping toolboxes, the addition of a database in which to store the attributes describing the marina infrastructure and the location and characteristics of the boats in the marina provides an example of the functionality of the GIS toolbox. Mobile GIS hardware (e.g. Compaq iPAQ) and software (e.g. PocketGIS) and Global Positioning Systems (GPS) also provide considerable potential to enhance a marina database with information about the features that are not available from traditional data sources such as maps e.g. boat locations. Online GIS and mapping tools can provide the means to develop interactive retrieval and display systems for marina users, even extending to public information systems.

18.5.5 Weedmat Mapping

The problem of weedmats is common to many estuarine environments throughout the World. In estuary catchments that are predominantly agricultural, and where

there are areas of shelter, nutrient enrichment, and the growth of macro-algal weedmats may be common threats. There are also many other factors besides pollution that can affect the location and spatial distribution of weedmats, including sediment type and distribution as well as water flow. Macroalgae such as *Enteromorpha*, *Ulva* and *Chaetomorpha* typically form vast 'mats' that lie on the surface of estuarine mud- and sand-flats. These mats can either be very fine coverings (thin) or several centimetres deep (thick).

Remote sensing, most often aerial photography (panchromatic, colour, and colour infrared (CIR)) because of its spatial and temporal resolution, and more recently hyperspectral data (because of its finer spectral resolution), has been used to monitor and map weedmats with varying degrees of success. An example of this is the recent work undertaken on the Ythan Estuary in the north east of Scotland to establish a practical methodology for deriving weedmat area over time (Green and King, 2002; Orr, 2003).GIS can be used to undertake simple temporal differencing using overlay techniques to estimate change in weedmat area and distribution over time, as well as to establish area estimates for weedmat coverage using additional functionality contained in ArcView extensions such as Xtools (http://www.odf.state.or.us/DIVISIONS/management/state-forest/XTools.asp). In the longer term, the data may form the basis of an Ythan Estuary GIS (desktop and online using ArcIMS), which seeks to establish an environmental database comprising remotely sensed imagery, Ordnance Survey (OS) digital map data, digital hydrographic bathymetry from the United Kingdom Hydrographic Office (UKHO) and other digital datasets e.g. bottom sediment distribution, bird count data and distribution, and water quality data.

18.5.6 Search and Rescue (SAR)

In coastal search and rescue operations access to geographical data and information is vital. As well as occurring along the coast and out to sea SAR operations also occur in estuarine environments.

Information may be required during both the search and the rescue stages. Whilst some relevant data and information may be available e.g. in the form of maps and charts, much of the baseline data and information is currently not available at a scale that is useful to a SAR operation. Increasingly it has been recognised that such information should ideally (a) be available in a digital format, (b) take advantage of the digital communications networks, (c) embrace the Internet and online Geographical Information Systems (GIS) technology and (d) comprise sources of information at many different scales, the most important of which is local knowledge (Figure 18.1).

The acquisition of local knowledge and information can be greatly enhanced through the use of the mobile geospatial technologies that are now available, integration of which can be developed into a decision support system framework for coastal and marine search and rescue operations. For example, a wide range of mobile technologies can be brought together to provide a basis for gathering, processing, displaying, and communicating geospatial data and information in real-time. Hardware in the overall IT equation might include a PDA with PocketGIS for detailed mapping of an access footpath to a beach; a mobile phone to upload

the datafile to an online GIS e.g. ArcIMS; an on-shipboard PC with a wireless access to the Internet, accessing the ArcIMS-based online decision support system; a digital camera that sends by email on a mobile phone a picture of the coast from the seaward side to the local Coastguard either onboard a ship or to a rescue team on the cliff top; sonar information that can be uploaded to an ArcIMS system and combined with e.g. an Ordnance Survey digital coastline; a video clip or panoramic photograph of a section of the cliffline that can be zipped and sent as an attachment by email. Additional components of the system may also include digital or paper fax machines, which could, for example, be used to communicate an annotated sketch map or photograph to someone on land, on a lifeboat or inflatable, or at an RNLI (Royal National Lifeboat Institution UK) or Coastguard station.

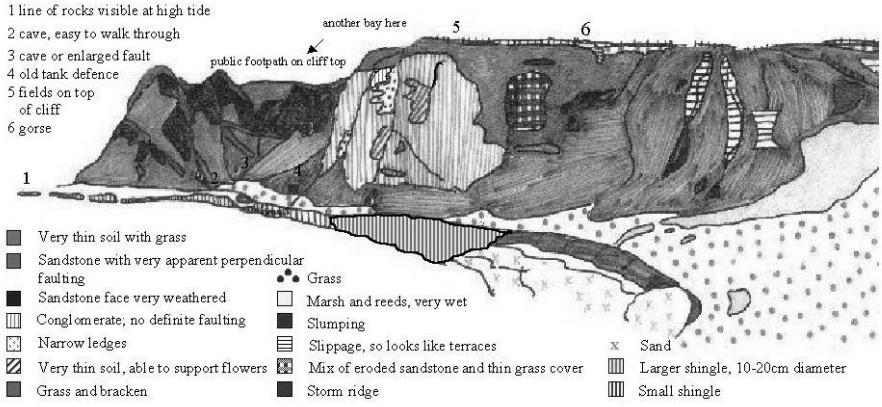

Figure 18.1 A field sketch of a section of coastline (courtesy of Joanna McDonald, MRI)

18.5.7 Participatory Planning

One outcome of the work reported earlier in this chapter about weedmat monitoring and mapping was to input the resulting information into a GIS, as a means to deliver information to a wider audience in the context of environmental awareness and participatory planning. Whilst geographic datasets can be viewed in a desktop GIS environment, not everyone has access to GIS software. An alternative is to place the datasets on CD to disseminate the information to the end-user. A more effective approach is to distribute the datasets with a GIS viewer such as ESRI UK's MapExplorer (http://www.esriuk.com). MapExplorer is freeware that allows the user to access GIS datasets for viewing and output, as well as providing limited GIS functionality such as zoom, pan, overlay, and measurement tools. MapExplorer is a 'cut down' GIS package with navigational functionality allowing an end-user to open and explore the information. GIS tools have also been developed for the Internet. The Internet is an ideal medium in which to deliver maps and images because it is a familiar interface to many people. ERSI's ArcExplorer (http://www.esri.com/arcexplorer), for example, can be used

to connect to an Internet webserver. Online mapping and GIS software provides an ideal mechanism to involve the public in the environmental planning process through simple interactive interfaces to visualise geospatial data and information in the form of maps and imagery.

18.5.8 Modelling

Developing an improved knowledge and understanding of the complexity of an estuary can often be aided through the use of modelling techniques and tools. Whilst often abstract, such models nevertheless help to provide insight into the physical and biological processes active in such an environment. One such model is the Forth Estuary Modelling System (FEMS). FEMS was developed as part of a Forth Estuary Forum (FEF) Flagship project. The aim was to take an ecological model and present this to the wider community in a form that would help to educate people of all ages about ecological processes active in the Forth Estuary. It comprised a Pelagic Submodel; Benthic Submodel; Fish Submodel; Sea Birds/Mammals Submodel; and a Human Influences Submodel. The model was written using an interactive modelling toolbox, STELLA. Initially distributed on a CD-ROM complete with HTML documents, FEMS was designed to be accessed as an educational tool from the Forth Estuary Forum website, facilitating updates as the model evolved (Green and King, 1999).

18.5.9 Education and Training

One application of GIS technology, either as a desktop or web-based system, is to provide the basis for helping to aid in education and training programmes about estuaries and estuary management. Access to data and information stored in a GIS using standard information retrieval and query tools is a simple way for people to retrieve, display, and communicate geographical information, most often in the form of an interactive map. Simple querying of a spatial database and visualisation in the form of a chart or a map can often help to raise awareness and educate people. Additionally, provision of simple end-user interfaces to the information e.g. using ArcView or ArcIMS on the Internet increases the power of the 'map' to communicate spatial information. Toggling map layers on or off can help to communicate spatial patterns and reveal spatial relationships. GIS mapping can also provide a simple data exploration tool.

GIS can also be used as an effective training environment to learn about estuarine environments. The GIS toolbox provides the means to integrate geographical datasets, to examine patterns, explore data, establish relationships, as well as to visualise data and information in a variety of different ways e.g. 2D, and 3D. Much of the output resulting from simple database queries, statistical summaries, analysis, and visualisation exercises provides a very effective form of communication that can be used as input to documents, reports, slide shows and presentations.

Many of the estuary websites now becoming available are primarily designed to provide access to both data and information. They usually comprise webpages,

downloadable documents, datasets, software and sometimes even models. These help to maximise access to information for a wider community. In some cases, these websites are taking advantage of many of the software tools that accompany the Internet including, for example, online mapping and GIS. Although most online mapping systems currently have relatively limited GIS functionality, they nevertheless provide significant potential to allow end-users to view information in the form of text and images. Some also include access to remotely sensed imagery (airborne and satellite) that can be viewed as 'quicklooks' or in some cases takes advantage of image compression software such as Lizardtech's MrSID, or ERMapper's ECW format, to deliver high-resolution images rapidly across the Internet.

18.6 INTERNET-BASED INFORMATION SYSTEMS

18.6.1 GDSPDS - Solway Firth

In 1999, a research project began at the University of Aberdeen to develop an Internet-based coastal information system. The aim of the project is to prove the concept of the need for and the capability to deliver geospatial information (digital images, documents, maps and remotely sensed imagery) to the coastal manager via the Internet, using the Solway Firth as a case study area. The Geo-information Decision Support Processing and Dissemination System (GDSPDS) is capable of serving GIS data, digital photography and video as well as remotely sensed imagery via the Internet.

The Solway Firth GDSPDS is built around Windows NT Server 4.0 using Internet Information Server 4.0 as the web server. In addition, ESRI ArcIMS 4.0 is used to deliver online mapping capabilities, and ER Mapper's Image Web Server (IWS) version 1.7 and LizardTech's Content Server are used to deliver remotely sensed imagery. The imagery is compressed using either ER Mapper's Enhanced Compressed Wavelet (ECW) technology or LizardTech's MrSID Geospatial Encoder (v1.4). Both of these compression technologies allow remotely sensed imagery to be both stored more easily (for example, a colour air photo mosaic of 178.7Mb can be compressed to 3.2Mb in ECW (30:1) and 3.11Mb in MrSID format (30:1)), and also served rapidly across the Internet to any PC with a web browser. In the case of ECW files, a relatively small plug-in must be installed to view the imagery. MrSID imagery can be delivered either via a plugin viewer or as a series of JPEG images. The imagery is stored in an MS Access database which is searchable using a web-based form. A number of basic search queries have been developed to try and help guide the user to the correct imagery for their specific management problem or application.

As well as being accessible on a desktop computer, the GDSPDS can also be accessed via a PDA connected to the Internet using a mobile phone. Remotely sensed images can be viewed in the web browser on the PDA, while ESRI's ArcPad software can be used to access and retrieve maps from the ArcIMS map service. This enables a coastal manager to go into the field and access geospatial

information to use for navigation and for carrying out temporal comparisons as well as completing updating tasks.

The GDSPDS is a means of more easily disseminating geospatial information to a wider audience without the need for each user to have expensive GIS software on their own computers. It provides support for data collection and updating, decision-making and report writing as well as greater interaction between coastal managers and users (Figure 18.2).

18.6.2 Interactive Mapping using the Oregon Estuary Plan Book

Inforain has developed the Oregon Estuary Plan Book (http://www.inforain.org/interactivemapping/). Interactive maps from the Oregon Estuary Plan Book have been designed to help planners and decision makers in the evaluation of estuaries. The maps comprise several data layers allowing users to explore specific management units and habitat types. There is a base map layer together with other layers comprising information on dredge material disposal sites, estuary habitat, mitigation and special mitigation sites, estuary management units, shoreline management units, and areas of significant habitat (http://www.inforain.org/dlcd.asp). Datasets for download are stored in a compressed format. Provision of an image record is especially useful for

interpretation and communication to the layperson, either in a raw or processed format.

18.6.3 FREMP GIS: An Estuary Management Tool

FREMP (Fraser River Estuary Management Program) uses a GIS as a tool to promote integrated decision-making in the estuary (North and Beckmann, 1999). It uses orthophotos as a base layer and a number of thematic data layers including habitat inventory to assist in environmental recommendations. Initially FREMP did not use GIS software, but instead utilised aerial photographs and digital databases. Adoption of GIS, however, improved spatial data organisation and integration and provided wide access to data and information. It also provided a communication tool. Datasets comprised habitat inventory and shoreline classification maps, digital photographs, development projects, basemaps from FREMP and other external sources. In addition, metadata was provided. The interface to FREMP is an extension of the standard ArcView software but designed to be more user-friendly and including added functionality.

18.6.4 Virtual Estuary

This is a comprehensive online system for retrieving, analysing and integrating data and information related specifically to the Hudson Estuary in the USA. It has been targeted at a wide range of end-users from the scientist, to the decision-makers, and the general public. A joint project of Columbia University, COAST (Clean Ocean and Shore Trust) and a range of other institutions and agencies with a direct interest in the estuary. An online mapping system (using ESRI's ArcIMS) is also part of the Virtual Estuary project and is designed allow the creation of 'on-the-fly' maps from the estuary databases (http://www.nynjcoast.org/ Hudson_Estuary/hudson_estuary_.html).

18.6.5 OZEstuaries

OZEstuaries (http://www.ozestuaries.org) is an Australia-wide database that enables managers and stakeholders to develop a greater understanding of their own estuary, and where it fits into the national picture. It facilitates comparison, provides information on estuarine form and function, identifies potential threats, provides information on environmental indicators, delivers the National Land and Water Resources Audit (NLWRA Estuary Assessment, 2000) condition assessment, and provides a single point of entry for information on Australia's estuaries. This will be enhanced over time with the help of scientists, managers and stakeholders, with the provision of additional data, the addition of a GIS front end, estuary models and feedback from end-users.

18.6.6 PIVOT

In the USA, the National Estuary Program of the Environmental Protection Agency links community to agencies. PIVOT (Performance Indicators Visualization and Outreach Tool) provides an interactive graphics and maps toolbox to help users better understand the issues and visually track the National Estuary Program's progress toward achieving its habitat restoration goals. Provision of a map that combines spatial relationships of factors to priority issues and the management actions designed to address those issues is deemed to be a powerful tool as it helps to raise questions about the effectiveness of management actions (http://www.epa.gov/owow/estuaries/pivot/overview/intro.htm).

18.6.7 DEMIS

DEMIS (Dynamic Estuary Management Information System) is part of the Oregon Coastal Management Program and is designed to provide a useful information depot for both traditional and digital information for the estuaries of Oregon (http://www.lcd.state.or.us/coast/demis/demisfaq.htm). It provides access to data, GIS layers, metadata, estuary plan book information, as well as a CD. DEMIS has arisen in response to the problems associated with the current fragmentation of information. It has been designed to help improve access to information; establish a GIS (aggregate, standardise, distribute digital data); accumulate and analyse data for estuary restoration; incorporate new data into an information management system; and to maintain timely and efficient updates.

18.7 SUMMARY AND CONCLUSIONS

Powerful information technology tools now support the development, operation and use of estuary information systems of various different types, providing considerable potential to aid in estuary management. Information technology has greatly enhanced the data-into-information pathway, providing the means and the tools to collect more data, to process it more rapidly, and to communicate the results of analyses more effectively to a wider community. In recent years, rapid developments in the geospatial technologies have greatly enhanced the collection of spatial data, information processing, modelling, and visualisation of information in new, interesting, and informative ways. The capability to gather higher resolution data from remote sensing, to process, integrate and visualise environmental data within a GIS, and the use of GIS as a data handling tool for spatial analysis and modelling has provided the basis for studying the environmental processes operating in an estuary. Online GIS and decision support tools are also empowering the policy and decision-maker, as well as the coastal manager and practitioner.

In the future the practical application of the geospatial technologies will grow considerably providing tools that will aid the coastal manager and practitioner in the workplace. Some of the important issues that will govern the greater use of this technology in the future, however, will be end-usability of the hardware and

software, integration, and functionality. Moreover, data availability, data standards, data costs and copyright will also largely determine how much of the potential of geospatial technology can be practically implemented and realised in the workplace.

CHAPTER NINETEEN

A Territorial Information System (TIS) for the Management of the Seine Estuary – Environmental and Management Applications

Jean-Côme Bourcier

19.1 INTRODUCTION

Located at the geographic, sociological, economic, and environmental convergence of multiple interest groups, the estuary of the Seine (Normandy, France – Figure 19.1) presents itself as a coastal zone subject to divergent, if not contradictory, anthropogenic pressures. In fact, its position vis-à-vis its ecosystems gives it rare and specific functions and its location within geographic space confers strategic advantage. The urbanisation and level of primary industry of the region must develop in directions that respect an ecological heritage, and an exceptional landscape, that is subject to the attention of local communities as well as local, state and European levels of administration. Furthermore, the existence of various pollutants, risks from technological hazards, the exploitation of natural resources, an upstream/downstream divide, a disparity between left and right banks, and multiple activities, etc., are just some of the key issues in this unique space.

In this context, geographical information systems (GIS) present a wealth of applications as tools capable of collecting, harmonising and analysing data about the estuary coastline in order to monitor the health of the region and provide summary information as an aid to decision-making. Harnessing these technological, methodological, and operational tools enables coastal management problems to be defined and resolved in an holistic and consensual manner. They could also lead to a new approach to management and a remediation, by providing a better understanding of coastal processes, functioning and change; an approach more attuned to the natural and human complexities of a geographic space that encompasses all levels of organisation, and which has set sustainable development as primary goal.

These distinguishing features justify the establishment and use of a GIS specific to the Seine estuary within the CIRTAI laboratory at the University of

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

Le Havre (UMR 6063 CNRS – Research's group CIRTAI). More specifically, it consists of a territorial information system (TIS) tied to a multidisciplinary and multi-thematic, geographically referenced database designed to improve understanding of the processes and functioning of the estuary in order to support operational and participatory management practices. Within the range of spatially referenced information systems, (Prélaz-Droux, 1995), this territorial information system sits mid-way between the two end-points of land information system and geographical information system as defined by the author: it exceeds the institutional limits of a land information system, and applies the potential of a GIS in its ability to support development of land and environment in a complex geographic space that requires management at multiple scales and involving multiple actors.

The aim of this article is to demonstrate a particular application of the TIS, as an observatory of the natural heritage of the Seine estuary. Within this application, different levels of information have been integrated and analysed in order to provide qualitative and quantitative assessments of this heritage by means of territorial diagnostics.

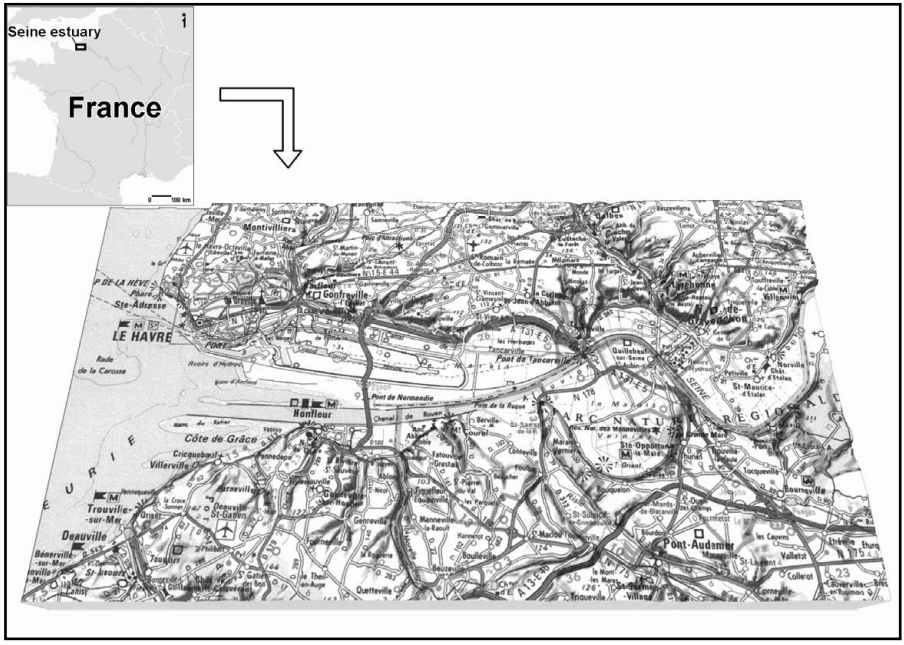

Figure 19.1 The Seine estuary (Normandy, France).

19.2 ON THE NEED FOR AN OBSERVATORY OF THE NATURAL HERITAGE IN THE SEINE ESTUARY

As a meeting point for terrestrial, fluvial and marine environments, the Seine estuary integrates a number of biologically productive and varied ecosystems. It is

an integral element in the routeway for many species of migrating birds and provides shelter and nutrients for fisheries and shellfish farming as well as for certain invasive species.

The estuary basin is characterised by the juxtaposition of alluvial plains and calcareous plateaux, giving rise to an extraordinarily diverse range of humid-zone landscape types that act as sponges and filter-cleaners for the environment.

Nowadays, the natural heritage of this estuary is subject to the impacts of numerous activities and processes at the local scale (industrialisation, urbanisation, agriculture, resource exploitation) as well as nationally (it is the outlet of a drainage basin within whose borders is found 30% of the French population and 40% of the national economic activity). This convergence of interests, and the conflicts that arise, raises the problem of how to conserve natural spaces whose resources are limited and whose equilibrium is fragile.

Management of this territory must therefore ensure balanced development, taking into account both scientific data and socio-economic factors (Chappuis, 1993), at a scale that is essentially local but which also has national and international elements (Bailly, 1995). Every stage in the process involves nature and the landscape, and it is often necessary to draw on a complete inventory of the natural and landscape heritage in order to steer decision-making in appropriate directions whenever choices present themselves.

In order to address these requirements, the Seine Estuary TIS acts as an observatory of natural heritage, and an intelligent tool for providing territorial and environmental indicators needed to manage this unique coastal system. GIS offers technologies with potential for better planning, management and analysis of our environment (Bryant, 1993); for tackling the integrated, holistic and rational management of space; for pooling necessary information; and for overcoming institutional limitations, to allow all levels of environmental organisation (hydrological systems, landscape systems, drainage basins, etc.) to be taken equally into account.

The objective is to make available to environmental managers and decision-makers a suite of key indicators that will allow better understanding of disparities between left and right banks of the river, conditions of flood and low water, competition and compatibilities of estuarine biota, etc., and ultimately allow the delimitation of zones of strong environmental vulnerability. This will also help bridge the gaps between scientific research and real-world practice and, more precisely, between those scientists, technicians, professionals, and politicians who are involved in strategic and political decision-making.

The territorial information system for the Seine estuary aims to bring the many facets of the same geographic reality into a common framework. Thus organised and structured, all available data for a given location may be integrated as part of a single analysis, in order to better define environmental objectives, and to provide support for decisions relating to territorial planning and management within the estuary.

19.3 FROM DATA COLLECTION TO DEVELOPMENT OF ENVIRONMENTAL DIAGNOSTICS

This TIS for the Seine estuary exploits a multi-source and multi-thematic geographically referenced database, presently consisting of more than 80 layers of data in vector format, standardised on the Lambert conformal conic projection and georeferenced on the Lambert zone 1 coordinate system (the local system for the north of France). Data in raster format are used to provide rapid enrichment and updating of the database, according to immediate needs. These data layers are all subject to a number of quality-control parameters (Laurini and Milleret-Raffort, 1993) including accuracy, precision, and timeliness (Rouet, 1991), and each layer is the subject of a file of metadata (Bourcier *et al.*, 1998) to ensure that it is used appropriately and optimally. A dynamic link has been developed, so that the metadata may be consulted directly via the user interface of the GIS software.

The operational use of the TIS requires, *inter alia*, data to be updated regularly, since they describe a territory that is subject to strong spatio-temporal evolution.

Data relating to the natural heritage of the Seine Estuary are collected on a regular basis by various groups: the regional Ministry of Environment for Upper and Lower Normandy, the Department of Hunting, an organisation for the conservation of wetlands, the Regional Nature Park of Brittany, Nature Park, etc. This demands an effective partnership, in order to respond to the specified quality criteria. Initially, exchange of these data was via hard-copy paper media (maps, cadastral plans, etc.), which implied heavy, time-consuming digitisation overheads. More recently, all the data-providing partners have opted for the advantages of digital technologies (GIS platforms, CAD, computer-assisted cartography), which has enabled much more efficient implementation of the system.

An environmental geodatabase is by definition multidisciplinary and multi-territorial; its quality and relevance depend on, among other factors, the abilities of the GIS team to manage interdisciplinary conflict, institutional compartmentalisation and protectionism, hierarchical management "pyramids" and cultures of regulation, etc.; and especially possessive attitudes and the equation of information with power, leading to a reluctance among some players to share information with others.

19.3.1 Environmental heritage diagnostics in the Seine Estuary

As has been discussed above, all management practices have environmental implications, and therefore require access to a complete inventory of the natural heritage. This essential knowledge of the natural resources of a region needs no further justification.

The natural heritage value of the Seine estuary is recognised through the implementation of a number of statutory instruments of national or European origin: the Ecological Fauna and Flora Inventory ("ZNIEFF"), Nature Reserve, Special Areas of Conservation (SACs), Biotope conservation, etc. To these are added other protective measures, such as the purchase of land.

It seems evident that this accumulation of regulations makes the direction of management projects even more difficult, especially since many of these provisions lack clarity, are obsolete, are contradictory and of uncertain relevance, or are imprecise and subject to multiple, subjective interpretations.

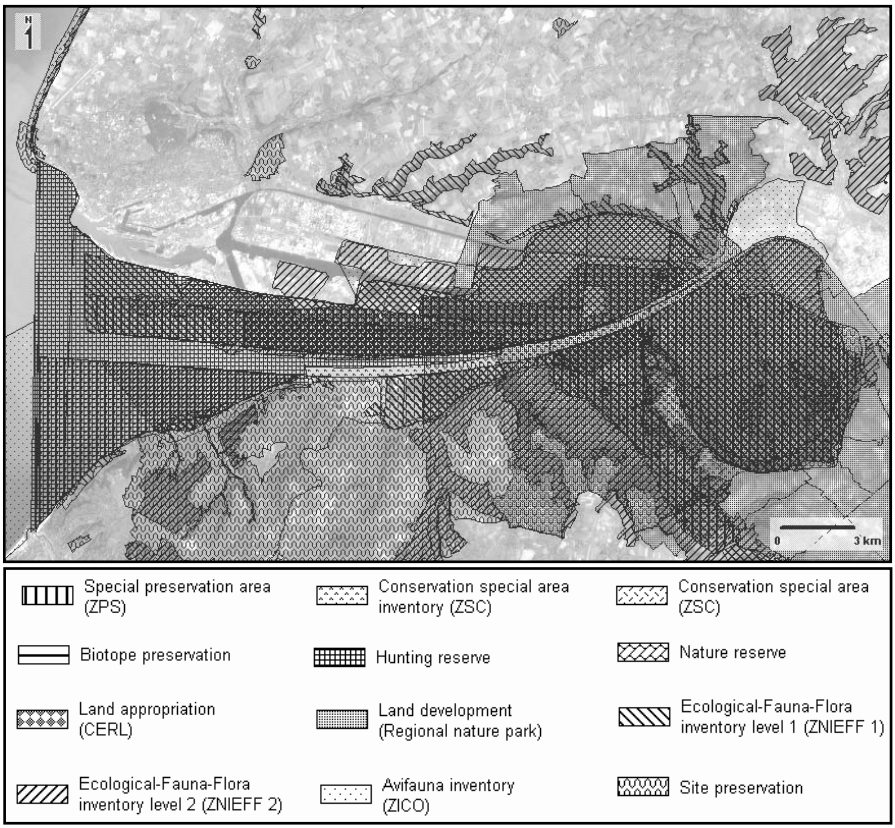

Figure 19.2 Spatial concentration of environmental conservation in the Seine estuary.

Superimposition of all these layers demonstrates visibly the multiplicity of initiatives and regulatory measures that currently apply to this territory. We may also note several important geographical overlaps between these various measures, rendering their representation in cartographic form particularly difficult.

Overall, such a representation implicitly demonstrates the high heritage value of this estuary, but the resulting legislative overload demonstrates clearly the need for harmonization of French Environmental law. French estuaries present a major challenge for the law, which must find ways to address their hybrid character and their multifunctional nature. Analysis of the legal treatment accorded these spaces demonstrates the weak acknowledgement in national law of their distinctive nature and, indeed, a strong tendency to promote their development, despite the accumulated knowledge of their ecological interest and their vulnerability (Auger and Verrel, 1998).

In terms of spatial analysis, it is necessary to go beyond simple superimposition of data layers, to examine the spatial distribution of particular entities and to synthesise the information they present. The aim is to create a new layer of information that compares, aggregates and analyses various perspectives on the region, so as to present alternative views of reality, for better environmental comprehension, decision-making and management. The complexity of the real world is thus rendered easier to read and communicate.

Thanks to the topological functionality of GIS, an expansion of the various layers of information relating to this natural heritage has enabled a "quantitative synopsis of protection measures" to be drawn up. This spatial analysis facilitates easy identification and classification of zones according to the sum of the protective measures that apply to them (Figure 19.3).

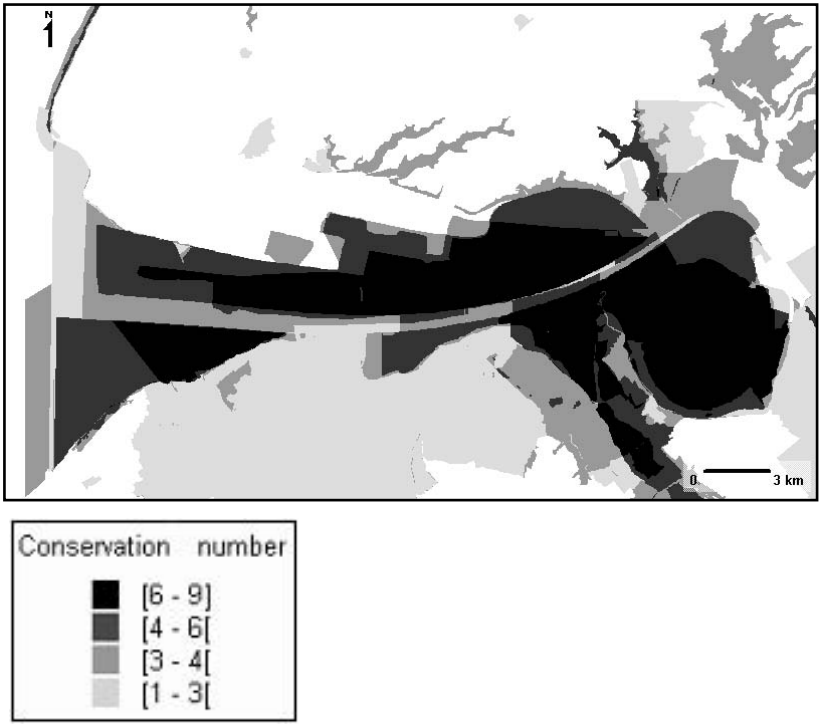

Figure 19.3 Quantitative synopsis of nature conservation in the Seine estuary.

While a diagnostic utility of this type is visibly effective at demonstrating the multiple protective measures, it also underscores the relevance of the known natural heritage of the Seine estuary, and explicitly reveals the conservation importance of the intertidal areas and of the flood plains. These latter are wetlands of acknowledged ecological importance, according to the National Programme of Research on Wetlands (Bourcier *et al.*, 1999). The TIS allows real-time spatial and thematic analyses, such as calculating the type, number and surface area of

biotopes for each of the identified sectors, thereby allowing optimal planning and management for these environments.

Still within the perspective of generating useful indicators for stakeholders and decision-makers, the foregoing increase in topological data is further enriched by the addition of information relating to the level of legal protection accorded to these zones. This leads to a "qualitative synopsis of the degree of protection of the natural environment", which identifies and classifies different zones according to a cumulative index of conservation (Figure 19.4).

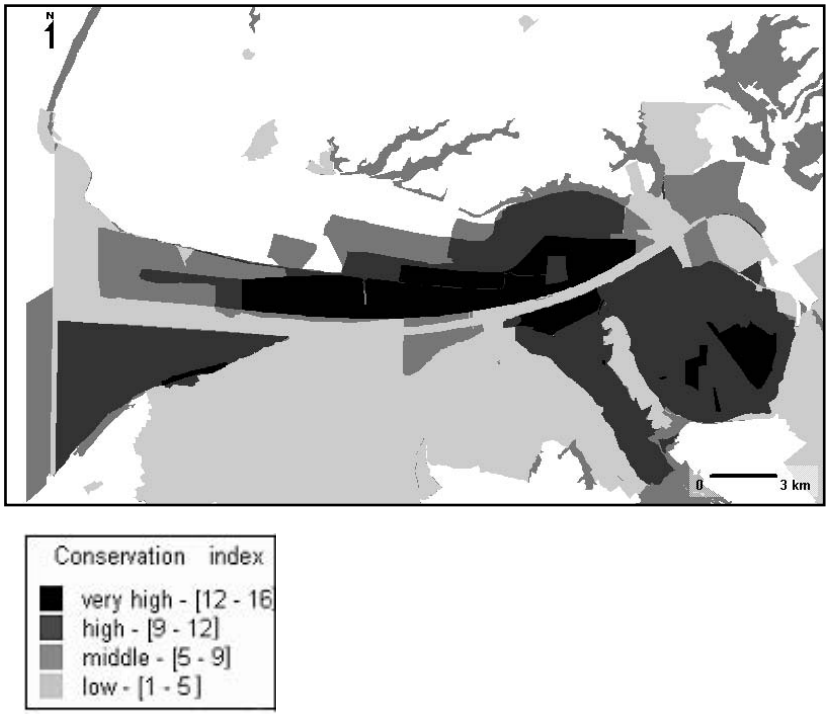

Figure 19.4 Qualitative synopsis of nature conservation in the Seine estuary.

The most protected zones (very high value) are located mainly in the alluvial plains, which underscores the ecological importance of these habitats.

This territorial index usefully complements the preceding map, by conveniently summarising the environmental constraints of the estuarine lands, providing indispensable information when territorial management projects or planning exercises are undertaken.

Achieving an optimal management of the natural heritage, at all levels of organisation, will probably require a greater harmonisation of the many superimposed levels (local to international) of environmental protection, in legal as much as in economic terms.

Additionally, this harmonisation offers the advantage of representing environmental constraints as homogenous zones that transcend administrative

boundaries, and which are thereby more appropriate to holistic understanding of the environment from the global to the estuarine scale.

From the perspective of optimal management of the natural environment, would it not be useful to avoid the heavy imposition of all these different protected zone boundaries and, perhaps, rely on European and international commitments (e.g. the Natura 2000 network)? These levels of administration could provide powerful tools for protection through regulatory and financial instruments.

19.3.2 An environmental impact of coastal management in the Seine Estuary

The usefulness of the spatial analytical functions of the TIS may equally be demonstrated in the assessment of the impacts of traffic noise on the bird life of the estuary: by combining different of layers of information which, at first sight, have no apparent link between them, we can demonstrate the complexity of the real world and, more particularly, the influence of human activities on the natural environment (Figure 19.5).

The alluvial plain north of the Seine estuary is also subject to conflicts between natural environment and economic development, the resolution of which calls for sustainable development strategies to be drawn up. In this context, spatial analysis allows vehicular traffic levels to be correlated with the natural habitat of the Spoonbill (*Platalea leucorodia*, a migratory bird, see Figure 19.6), in order to measure the potential impact of noise pollution on the distribution of this bird. The routeways thus identified are of particular interest when they lie adjacent to the Natural Reserve of the Seine Estuary, liable to be directly linked to Port 2000, the future expansion strategy for the current commercial port.

Statistics on the movements of vehicles (light and heavy freight) were obtained from the authorities of the three departments concerned, and were used to calibrate the “road traffic” data layer.

A noise level envelope was calculated, based on traffic levels of 5000 vehicles per day (all vehicles, travelling in both directions), which corresponds to a noise level of 70 dB SPL. The TIS then allows a buffer polygon to be created around selected entities, and this can be intersected with the Spoonbill habitats to create an output layer that precisely identifies those areas where noise disturbance could be a potential problem. By simple querying, it is easy to obtain the location of each area, as well as their spatial attributes (length, width, perimeter, area, etc.).

Figure 19.5 ***Platalea leucorodia*** (Spoonbill: a migratory bird).
(© Cybernat - Le Havre University).

Figure 19.6 Effect of road traffic noise on *Platalea leucorodia* area.

This type of spatial analysis can also be applied to other domains (pollution of air or soil, etc.), by developing specialised algorithms for use in modelling impact analysis or simple diagnosis and visualisation. In the final analysis, the GIS tools have demonstrable relevance to aiding understanding, decision-support and management of environmental resources in a territory such as the Seine Estuary. By means of regional indicators, they can contribute to more holistic approaches to territorial management operations.

19.4 CONCLUSION

The concept of environmental management demands engagement with the interface between society and nature, since the multiple activities (often concurrent and mutually conflicting) that take place within a region are governed by economic and social paradigms.

Even if environmental considerations are nowadays better taken into account during processes of economic and social decision-making, they are still often only brought in towards the end of the process, while the various actors may frequently lack important elements needed to establish priorities and anticipate problems. Current practices and procedures, at different scales, are poor at anticipating environmental consequences of territorial management, due to a lack of appropriate information technologies and, equally, of suitable conceptual tools.

Spatial management of an estuary such as that of the Seine can only be successful and balanced if suitable structures are established to arbitrate effectively and equitably between the many pressures that currently lead to conflict.

Sustainable development is frequently advocated as a solution to these problems, whereby a dynamic balance is sought between economics, ecology and the needs of society, at local levels of organisation but also compatible with national and international levels.

Implementation of sustainable development policies requires a global approach and interdisciplinary vision, so that policies can lead to improved decision-making. In this context, the TIS for the Seine estuary has many potential applications. It serves as a tool capable of collecting, organising, integrating, and analysing information about the environment, from which territorial indicators and syntheses may conveniently be obtained to support decision-making, and to help solve problems of regional management and development.

In particular, it allows the properties and geographic distribution of natural resources or areas of interest to be defined; it improves the compatibility and interoperability of diverse datasets; and it facilitates spatial analyses of environmental impacts that would otherwise be overlooked or discarded for reasons of cost or procedural complexity.

This TIS constitutes a relevant tool because it has as its first objective the representation of a region, in this way improving our understanding and permitting the description and analysis of natural and human phenomena produced by the landscape. Since it lies at the junction of several disciplines, this TIS brings convergence and standardisation to the description and representation of space. It aims to bring coherence to all the many aspects of the same reality and, structured accordingly, data relating to the same location can be integrated within a single analysis, in order to better define environmental objectives and provide support for arguments or reasoning concerning regional development and planning within the estuary. The TIS has thereby enabled information relating to the natural heritage of the Seine estuary to be related, aggregated, and synthesised, in order to create territorial indicators of use for understanding, decision-making and management of the region.

Nonetheless, “mastering GIS, and developing robust methods of analysis, implies the ability on the one hand to assimilate elements of different terminologies, and the concepts associated with them, so as to permit truly

multidisciplinary dialogue; while, at the same time, allowing questions to be formalised in terms that are compatible with the various elements of the information system" (Meillet, 1999).

Finally, it remains the case that these techniques carry limitations, even though they allow the integration of multiple sources of data. The user must always understand the consequences of their implementation, and minimise possible errors due to data quality, problems linked to the treatment of data, or due to sensitivities inherent in the selected methodologies (Marois, 1993). In other words, their use within the process of large-scale choice and decision-making requires those concerned to have a high degree of confidence in the relevance and reliability of the data that are exploited. The quality of data and of their interpretation thus prove to be the crucial *sine qua non* of any process of decision-making.

CHAPTER TWENTY

Developing an Environmental Oil Spill Sensitivity Atlas for the West Greenland Coastal Zone

Anders Mosbech, David Boertmann, Louise Grøndahl, Frants von Platen, Søren S. Nielsen, Niels Nielsen, Morten Rasch, and Hans Kapel

20.1 INTRODUCTION

Marine oil spill sensitivity mapping has become widespread. The purpose is to provide oil spill response planners and responders with tools to identify resources at risk, establish protection priorities and identify appropriate response and clean-up strategies. GIS is an important tool in the development of oil spill sensitivity maps and can also be used for presentation. Several different principles for information integration have been used in different countries (Anker-Nilssen, 1994; Dickens et al., 1990; Hall et al., 1997; Nansingh & Jurawan, 1999; Moe et al., 2000). An environmental oil spill sensitivity atlas was produced as part of the preparations for exploratory drilling off the West Coast of Greenland (Mosbech et al., 2000). We have adapted a Canadian sensitivity index system integrating physical, biological and human-use information and combined it with elements from a Norwegian sensitivity mapping system.

The Atlas covers the West coast of Greenland between 62° N and 68° N latitude. Although the area under study stretches only 700 km from north to south it encompasses approximately 18,000 km of coastline. It is the most populated area in Greenland with about 35,000 inhabitants living in 4 towns and 6 settlements. It is extremely important for fisheries and it is ecologically highly important for a number of seabird and marine mammal species.

The Atlas is a multidisciplinary GIS project integrating many kinds of scientific data and local knowledge (traditional ecological knowledge). Although studies on geomorphology and coastal spawning areas were initiated for the project it was a major challenge to compile and get the most out of the existing data from many sources. This paper will outline and discuss how the data was integrated, the principles used to identify and prioritise the sensitive areas, the final Atlas product ,and the dialogue during the community consultation.

20.2 METHODS

20.2.1 The Atlas

The following elements are included in the Atlas

- coast types,
- oceanography, ice and climate,
- biological resources (fish, birds etc.),
- fishing and hunting,
- selected areas (e.g. seabird breeding colonies),
- archaeological sites,
- logistics and oil spill response methods.

The Atlas covers the coastline in the scale 1: 250 000 and the offshore area in the scale of 1:3.5 million. In a PDF-version 34 maps cover the coastline and one set of maps shows index values for coastal sensitivity and symbols for the elements of classification (see map and legend example plates 20.1a and 20.1b and colour inserts following page 164). Another set of maps show coast types, logistics, and proposed methods of oil spill response for each area (see legend and map example plates 20.2a and 20.2.b, see colour inserts).

Although a limited number of printed copies of the Atlas have been produced, the main version is published on CD. Since the target group of this atlas is not necessarily familiar with GIS, it was decided to distribute the final product in a form that is simple and quick to use and with an easy-to-use interface. The atlas with all text, maps, tables, and images is distributed on CD and on the Internet as a number of linked PDF-documents, which can be read with the free Acrobat Reader application. This allows a large amount of background information to be included as hypertext and at the same time to have a succinct and operational document. Furthermore, on the CD all geographic data is available for users to pan, zoom and print seamless maps with the free GIS-viewer ArcExplorer.

The Atlas was developed with an ESRI ArcView project and an MS Access database. This database software was chosen because many of the existing data and institutional databases employ MS Access. Spatial information on the model parameters is stored in ArcView whereas all model parameter attribute values are in the Access database. Index calculations are performed with Visual Basic for Applications in the database.

An important component of the Atlas is a sensitivity ranking system, which is used to calculate an index value describing the relative sensitivity of coastal and offshore areas. The sensitivity index value is calculated based on information on resource use (human use), biological occurrences, and physical environment. The sensitivity index system is based on a Canadian system used in Lancaster Sound (Dickins et al., 1990) and modified to the west Greenland fauna and other specific requirements of the Greenland study area. As a supplement to the Canadian ranking system, a number of smaller areas have been selected for priority in case of an oil spill. The selection of these areas is based on the principles from a Norwegian system (Anker-Nilssen, 1994), which gives priority to oil spill-sensitive areas for the purposes of oil spill contingency planning. While the

Canadian index system covers the entire coast in 50-km units, and thus gives a general overview of the sensitivity, the Selected Areas system uses actual borders and thus pinpoints the sensitive areas and leaves the rest unclassified.

20.2.2 The Sensitivity Index Calculation

The shoreline zone in the study area has been divided into 279 shoreline areas, each consisting of approximately 50 km of shoreline or, in the case of archipelagos, groups of islands and skerries having roughly 50 km shoreline. The offshore zone in the study area has been divided into 12 offshore areas (including 1 major fjord). The boundaries of the offshore areas are based on bathymetry and ice conditions during the winter.

The importance of resource use and the abundance of a number of biological occurrences in each of the 279-shoreline and 12 offshore areas were rated on a scale from 0 to 5 by using a number of subindices. Site-specific significant habitats are indicated on each shoreline segment. For example, such sites include important bird colonies and terrestrial haul-out for harbour seals. Photos of the coastal setting for about 50 bird colonies have been included and can be accessed from links.

As a part of the project, classification of the coastline geomorphology has been conducted from aerial photographs, e.g. the occurrence of rocky shores and beaches. An index value (oil residence index) of the self-cleaning ability of the coast after an oil spill has been calculated based on this classification in combination with shoreline exposure to waves and ice. For example, oil on a rocky coast exposed to wave action will be cleaned faster than oil on a beach in a protected lagoon.

An oil spill sensitivity index value has been calculated for each of the 279 shoreline and 12 offshore areas based on:

i) the abundance and sensitivity of selected species (or species groups);
ii) resource use (human use), mainly fishing and hunting;
iii) the potential oil residency on the shoreline (Oil Residency Index) based mainly on wave exposure, substrate and slope of coast;
iv) the presence of towns, settlements and archaeological sites (for shorelines).

The sensitivity index value for each of the 279-shoreline areas and 12 offshore areas is given. All areas are ranked as extreme, high, moderate or low sensitivity areas and a corresponding colour code has been used. The detailed index value calculations for each shoreline and offshore area can be accessed by hyperlinks.

With the settings we used, the average contributions to the final sensitivity values for the shoreline areas are: biological occurrences 49%, resource (human) use 20%, oil residence index 14%, archaeological sites 12%, communities 4% and special status areas (Ramsar sites) 1%. However, this is a simplification since the oil residence index value is a factor in the calculation of the value for biological occurrences, and thus also has an indirect influence on the sensitivity values.

20.2.3 The Selected Areas

To supplement the rather general mapping of shoreline sensitivity using the 50-km long shoreline areas, a number of small sensitive localities have been pinpointed as priority areas. A total of about 80 areas along the coast and within fjords have been selected as priority areas in the case of an oil spill situation. The basis for their selection is, compared to the coastline in general, that they are:

i) of high value either environmentally or for resource use;
ii) sensitive to oil spills; and
iii) of a size and form that may allow effective protection in an oil spill situation with a manageable amount of manpower and equipment.

The last criterion is important because it elucidates the rather limited possibilities to protect the coastline during a large oil spill and shows that tough prioritising is necessary.

20.2.4 Example of Indexing and Data Integration: Seabird Colonies

The major part of the biological information incorporated in the Atlas derives from databases maintained by NERI and the Greenland Institute of Natural Resources. As far as possible automatic selection and integration routines were developed to link these institutional databases and the Atlas database. One of the databases is a file on all seabird breeding colonies known in Greenland, with information on the birds, the sites and all survey results from the sites (Boertmann et al., 1996). A selection from the database was used in the Atlas. This selection was based upon the geographical range between 62° and 68° N and on the most comprehensive surveys, as many colonies have been surveyed several times. However, inferior colonies have been omitted and criteria for inclusion are listed in Table 20.1. Most colonies have a mixed species assemblage and the total number of colonies (with different geographical location) selected is 158.

The seabird colony data is used to produce a relative seabird abundance input value to the Seabird Oil Vulnerability Index scoring system which is integrated into the overall Shoreline Sensitivity Index. The seabird oil vulnerability index component takes into account the sensitivity to oil spills of the bird species both on an individual level and on a population level, as far as possible based on scientifically derived information on the characteristics of each species (Anker-Nilssen, 1987, Mosbech, 2000). These sensitivities are dependent on the behaviour and ecology of the birds, but also the distance to neighbouring colonies, which is a measure of the ability to re-colonise a colony. Moreover they take into account the status of the breeding population within the region, whether they are decreasing, increasing or stable, and finally their international conservation status (Mosbech et al., 1996).

20.2.4.1 Comments on some of the criteria

The breeding population of common eider in West Greenland has decreased seriously for a century, and within the Atlas region large and dense colonies have disappeared. Large breeding populations are mainly found dispersed in extensive

archipelagos. To exclude sites with a few scattered nesting eiders the criterion for inclusion is ≥ 5 birds.

As gulls are only moderately sensitive to oil spills, only the largest colonies are included.

Black-legged kittiwake colonies with less than 50 pairs are excluded as they tend to be less stable over time.

Arctic terns usually breed in dense colonies on low islands. The population in West Greenland is generally decreasing. Small colonies of less than 30 pairs are excluded. Terns are moderately sensitive to oil spills, but colonies situated on low islands are very sensitive to disturbance e.g. from oil spill response activities.

All species of the family auks (alcids) are very sensitive to oil spills. This is caused by their behaviour as well as by their very low population turnover. Therefore, protection of their breeding sites is a high priority. Moreover, the breeding population of Brünnich's guillemot in West Greenland is seriously decreasing due to a very high hunting pressure, and the few breeding sites within the Atlas region are therefore all included.

20.2.4.2 Relative abundance of the species/species groups

Some of the species are pooled into groups, as they have a similar sensitivity to oil spills. The relative abundances applied to species and species groups appear in Table 20.2.

The relative abundance is the input from these site-specific shoreline species elements to the calculation of the sensitivity index for each shoreline area. Similar relative abundance values are calculated for all the biological and human use resources.

20.2.5 Example of Indexing and Data Integration: Archaeological and Historical Sites

Information on the archaeological and historical sites in Greenland has been collected for over 100 years and is contained in a database under development at the Greenland National Museum and Archives. There is information on about 1500 archaeological sites in the mapped area. All known prehistoric and historic sites are included in the present Atlas, but to protect the sites only the most basic information on each site is given e.g. the site type and dating of the site.

There are great differences in what is known about different archaeological sites in the Atlas area due to the source of the information. The major part of the information is derived from secondary sources (i.e. local informants) and may therefore be less accurate. Basic information on each site is often not reported and therefore the degree of sensitivity of each site is based on an estimate.

The sensitivity of each archaeological site is expressed on a scale 1-3;

1. Sites that are unlikely to be endangered.
2. Sites threatened either directly or indirectly. This group includes all sites close to the coastline that are presumed to represent value either as a historical source, as a recreational site or as a special historical highlight.

3. Threatened sites of significant importance that demand special measures be taken in case of a marine oil spill or other activities in connection to mineral or oil investigations and extraction.

Based on this assigned sensitivity each archaeological site is ranked on a scale from 0-5. For each segment (50-km shoreline area) these rankings are added and the results are grouped again on a scale from 0-5 similar to the relative abundance of the biological resources.

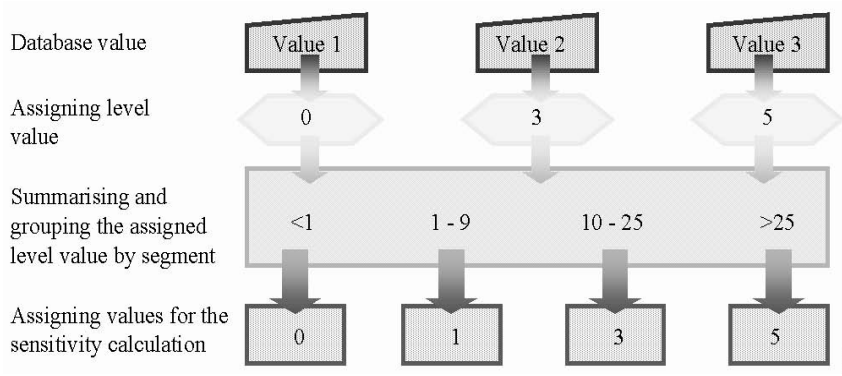

Figure 20.1 The Figure shows how the archaeological sites were given assigned values for the sensitivity calculation.

20.2.6 Integrating Local Knowledge

Local knowledge is included at several levels in the Atlas. Besides specific interview studies much information in the institutional databases is derived from locals helping researchers finding sites such as bird colonies and areas of archaeological significance. A specific interview study has been conducted to map the capelin (*Malotus villosus*) and lumpsucker (*Cyclopterus lumpus*) spawning and fishing areas and arctic char (*Salvelinus alpinus*) rivers (Nielsen et al., 2000). Capelin and lumpsucker spawn in the tidal zone and are therefore very vulnerable to oil spills. The study relied heavily on preliminary maps distributed for comments and the addition of supplementary information. Questionnaires and maps with preliminary information were sent out and returned with additional information, and these results integrated into new versions of the maps. Semi-directed interviews were conducted following the methodology of Huntington (1998). In the semi-directed interviews the maps were used to facilitate and guide the exchange of information among a group of local fishermen.

20.2.7 Community Consultation

A community consultation phase was carried out during the project. A draft version of the Atlas was mailed to local communities and user organizations. Later

meetings were held with all municipal councils and most settlement councils as well as the local hunter and fishermen associations. The purpose of the community consultations was not only to verify the information in the Atlas, but also to allow for comments and discussion of the method we had used and the result of the sensitivity ranking. A computer with the GIS and a printer, which could print overheads, was brought along and used where specific thematic maps were needed.

Maps on overheads explicitly showing the human use ranking were presented and facilitated fruitful discussions from which much supplementary information came forward. Although the sensitivity mapping was positively received the level of abstraction and complexity in the index calculation sometimes lowered the enthusiasm in discussions of the final rankings. As an example an extremely important capelin spawning area could be in an area with low sensitivity ranking, because it takes many sensitive elements to raise the final ranking of the coast to high sensitivity. Here the use of small Selected Areas provides a better tool to accommodate local expectations and wishes.

In the settlements, where Inuit hunters are the majority, the layman – expert divide was very pronounced and personal contacts were of crucial importance for establishing a fruitful dialogue. In some settlements there was concern that the publication of maps with "their" Arctic char rivers would tempt townspeople to come fishing. It was therefore decided to restrict the publication of this information on the Internet until proper regulation to protect fishing rights is in place.

The advent of oil exploration in this area introduces a "low probability – high potential consequence" risk. The oil spill sensitivity Atlas is a valuable tool to minimise the risk. However, it is also important to communicate the realistic limitations of this tool.

20.2.8 Versatile Distribution of the Atlas

The users of the atlas are diverse with different backgrounds and qualifications. The primary target groups are government administrators (both national and municipal) who are involved in planning oil spill response; their counterparts in the oil industry; and oil spill responders in industry, navy and the local fire brigades. Since the target groups of this atlas are not necessarily familiar with GIS it was decided to distribute the final product in a form that is simple and quick to use and with an easy-to-use interface. The atlas with all text, maps, tables and images is distributed on CD and on the Internet as a number of linked PDF-documents, which can be read with the free Acrobat Reader application. Furthermore, all geographic data is available for users to pan, zoom and print seamless maps from the CD with the free GIS-viewer ArcExplorer. There has also been a demand for large plastic-coated map sheets and a limited number of printed copies of the atlas.

The PDF-document consists of 434 pages including 34 map areas covering the entire area at a scale of 1:250 000, suitable for printing on paper. Each map area is covered by two types of maps. One contains the shoreline sensitivity results (plate 20.1) and another the physical environment and logistics (plate 20.2). The PDF-document includes extra information for decision-makers e.g. aerial photos,

photos of specific bird colonies and sensitivity index calculations for each segment, accessible by hyperlinks.

Adobe Acrobat is not a GIS program, but is a good map viewing system. Distributing the Atlas with Acrobat gave us the ability to decide how the final maps were presented for the end user. Another advantage to using Acrobat was the map-producer's ability to decide at what scale the maps should be used. In this way there is no risk of misinterpretation of the spatial data caused by using them at a scale for which they were not designed. The end user must print the maps at the exact scale at which they were meant to be printed – this option is not available with the GIS-viewer ArcExplorer. ArcExplorer gives the end user the ability to view and use the maps and their information without having to learn the basics of a GIS.

20.3 CONCLUSION

The Atlas was produced over a 7-month period and the relatively short campaign worked well. The involved persons could see the end already when they started which helped the facilitation of enthusiasm among relevant participants.

The integration of institutional databases worked well, and the approach makes updates of the sensitivity Atlas and developments/adaptations to other purposes easier. The task initiated valuable contacts and discussions among database managers in the relevant institutions, as well as discussions with a focus on the research opportunities of integrated GIS analysis of georeferenced databases from various fields.

The PDF-format is a good choice for distributing an atlas with a mix of formatted text, tables, maps and images which should be connected with hyperlinks. The quality of the maps is better than what is possible with use of today's Internet mapping solutions. The same documents can be used for printing, CD-distribution and Internet-access. Since Adobe Acrobat is not a GIS, a GIS-viewer was necessary to enable users with no GIS experience to use the feature tables on the CD. ArcExplorer was found to be useful since the software is free of charge and comes with an extensive user guide.

The Selected Area concept helped pinpoint where to focus oil spill response and facilitated communication during community consultations because a single hot-spot could be highlighted based on one single very important item. The need for Selected Areas to supplement the general oil spill sensitivity mapping is related to the size of the coastal units. We chose 50-km units, like in the Lancaster Sound Atlas (Dickens et al., 1990), because of the vast area and the relatively limited amount of information. If the size of the coastal units is reduced to as little as 3 km on average, as is the case for Newfoundland in The Canadian Atlantic Region Sensitivity Mapping Program (Anonymous, 1999), the need for Selected Areas disappears.

The experience from community consultations and collection of local knowledge is that local communities need personal contact on a continuous basis to overcome the layman-expert divide. Continuity and build-up of confidence are important prerequisites for exchange of information and ideas. Some restriction of the publication of information obtained from local sources should be accepted.

20.4 THE STUDY TEAM

The project was carried out by the National Environmental Research Institute, the Geological Survey of Denmark and Greenland, the Greenland Institute of Natural Resources, the University of Copenhagen (Institute of Geography), the Greenland National Museum, The Greenland Secretariat of the Danish National Museum, Danish Meteorological Institute, AXYS Environmental Consulting Ltd. and SL Ross Environmental Research Ltd. The Danish Energy Agency funded the Atlas.

CHAPTER TWENTY-ONE

Environment Canada's Atlantic Sensitivity Mapping Program

André Laflamme, Stéphane R. Leblanc, and Roger J. Percy

21.1 INTRODUCTION

Canada's Atlantic Region along with other regions across the country have focused on providing consistent and standardized applications related to coastal mapping and data integration/generation during a drill or spill incident. This consistency is crucial if personnel are to be brought in from different regions, as they are immediately familiar with the process and terminology. In an effort to protect the environment and mitigate potential impacts, Environment Canada's Atlantic Sensitivity Mapping Program (ASMP) was designed to provide this level of support to environmental responders. The ASMP has become a very powerful tool providing a consistent terminology through the entire range of pre-spill planning, preparedness, and real-time response activities.

This paper will describe the scope, objectives, and current status of this mapping initiative and highlight recent developments in combining the full range of activities from data generation and decision development to the generation of sensitivity mapping. The desktop mapping application provides an easy-to-use approach to the manipulation, display and output of a wide range of technical and supporting data and information stored in various databases. In the development of its mapping program, Environment Canada relied on crucial partnerships with organizations willing to share data and expertise. Response managers and environmental responders now have access to sensitive resource information that normally would be difficult to collate and present in a map form under the pressures of a spill response.

The objective of developing and maintaining the best possible sensitivity mapping system is to provide planners and managers with the full range of information they require as part of pre-spill activities as well as resource protection recommendations at the time of a spill. The data and information are based on consistent sets of terms and definitions that describe the shore-zone character, the objectives and strategies for a specific response, and the methods by which those

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

objectives may be achieved. These data are linked with other resource information in a GIS based system.

Standard or accepted terms, definitions, and shoreline segmentation procedures are already in place for describing the shore-zone character and shore-zone oiling conditions. In this program, a set of standardized objectives and strategy statements have been developed that can be entered easily into a database; these provide a better level of consistency than do phrases or sentences constructed by different recorders or evaluators. The suggested protection and treatment objectives and strategies are intended for consideration by the spill response management team. The actual type and volume of spilled oil, plus local environmental conditions and local priorities would be brought to bear on the decision process at the time of a spill. The suggested objectives and strategies provide a starting point and a framework for decision makers and planning and operations managers to discuss objectives and priorities. The concept of management by objectives provides a framework for decision-makers to set the goals of an operation at both the regional and a segment-by-segment level (Percy, LeBlanc, Owens, 1997).

The pre-spill database is integrated with the actual Sensitivity Mapping Program which is capable of displaying natural, cultural and man-made features vulnerable to oil spills. The computerized mapping system facilitates quick access and management of multiple data sets. A user-friendly interface allows queries and statistical analysis of data and display of graphical outputs. The system provides a tool for both planning and response; information can be accessed or modified using a laptop computer and real-time spill information or trajectory model outputs can be incorporated.

21.2 PARTNERSHIP

Following the Exxon Valdez spill in Alaska, the government of Canada realized the need for a system to provide access to sensitivity data for planning and response purposes. The Green Plan provided initial funding to develop, create and maintain a sensitivity mapping system to support environmental responders during marine spill incidents. Environment Canada was tasked to lead this project and was assigned the responsibility to gather and manage appropriate data sets from various agencies. Because of its mandate, Environment Canada has environmental emergency officers on duty on a 24/7 basis. Therefore, information must be quickly accessible in order to mitigate a potential impact on marine and coastal resources.

Without ready access to environmental data, the integrity of coastal and marine resources can be compromised during a spill incident if immediate action is not taken to protect them. Partnerships are crucial in order for environmental emergency responders to locate and identify sensitive resources at a spill site, especially within the first few hours/days of an incident. One of Environment Canada's foci is to approach and involve other federal, provincial, municipal agencies, private industry, local communities, etc. to make environmental data accessible. Most of the organizations involved during a spill incident are part of the Regional Environmental Emergencies Team know as REET.

REET has two main operating roles: *planning* and *response*. As part of the planning function, "team" members meet once a year to exchange scientific and technical information on such matters as contingency planning and spill response techniques. During this time, REET members also update and review their respective roles in any emergency response. In its response role, REET operates as a team of experts, advising the On-Scene-Commander, or OSC, in emergency situations. Chaired by Environment Canada, it is composed of scientific advisors, private contractors, community groups, etc.

21.3 GEOGRAPHIC APPLICATION

The coastal area covered by the Atlantic Region Sensitivity Mapping Program encompasses four provinces: these are New Brunswick, Nova Scotia, Prince Edward Island, and Newfoundland/Labrador. Approximately 12,500 unique shoreline segments covering more than 40,000 kilometres of coastline have been identified in Atlantic Canada. Labrador is the only area not presently covered by the shoreline classification; however growing interests and activities in this area will likely require the completion of the pre-spill database in the near future. Portions of the province of Quebec have been included in the mapping system: these are Chaleur Bay (on the north shore of the St. Lawrence River) and the Magdalene Islands, since these areas would likely be impacted by spills in the Atlantic Region. Despite the coastal applications of the mapping system, it also has the flexibility to cover the inland part of the Atlantic Provinces. Environmental data has been collected for the Maine and New Brunswick border. The Atlantic Region Sensitivity Mapping Program in conjunction with the Maine Department of Environmental Protection have agreed to exchange cross border information on coastal areas which can be used for planning and response during marine incidents that could impact both countries. As the information becomes available for inland areas, the mapping system will integrate the information in a format that is compatible with the existing data sets. Most of this information comes from federal, provincial, and municipal government, as well as local knowledge.

21.4 SHORELINE CLASSIFICATION AND PRE-SPILL DATABASE

The objective of the pre-spill database is to collate data and information that would be required and used by the spill response management team in the development of planning, priority and operations decisions. This database plays a fundamental role in the definition of resource protection priorities, and constitutes an introduction to the Shoreline Clean-up and Assessment Techniques (SCAT) process.

The database development procedure involves an initial segmentation of the shoreline followed by the creation of data templates for each segment. This process involves the use of various tools such as low-altitude videotape survey data, aerial photography, and pre-existing mapping materials to define sections of shoreline that have a uniform along-shore character. In Atlantic Canada, each segment has a unique two-letter prefix code followed by a sequential number

(Figure 21.1). The two-letter prefix is unique to one coastal area in Atlantic Canada which makes each code different (e.g.: Halifax Harbour has the following segment codes: HX-01 to HX-75).

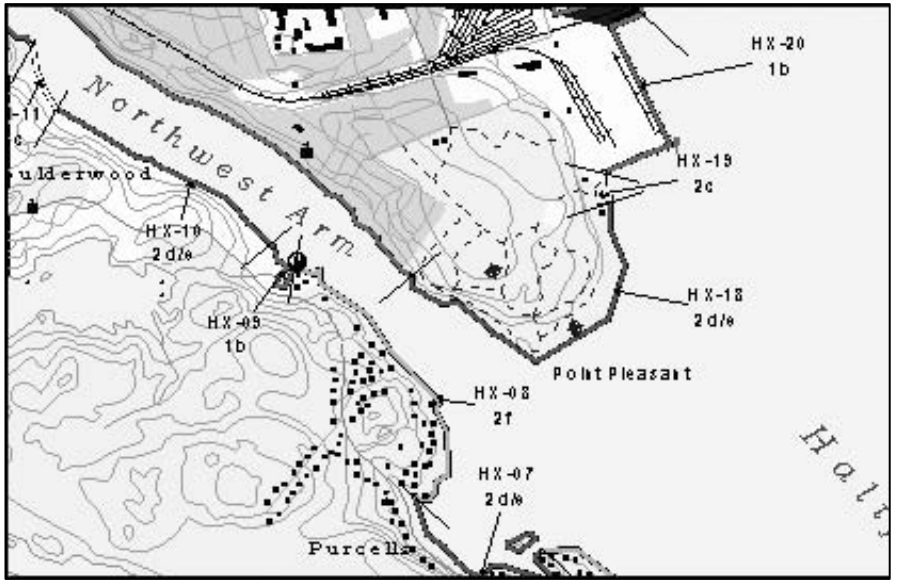

Figure 21.1 An example of the shoreline segmentation of the Northwest Arm area near Halifax, NS.

The description of the shore zone and the development of appropriate response strategies are presented in a systematic format based on four distinct templates: shore zone character, shoreline protection, shoreline treatment, and summary of response and requirements.

These templates contain a total of 143 different attributes which are unique for each shoreline segment. The Shore Zone Character template describes information such as shoreline material/type, nearshore environment, longshore current, oil traps and potential behaviour, resources at risk, etc. (Owens & Dewis, 1995). The shoreline material/type is further subdivided into five distinct categories: lower inter-tidal material, lower inter-tidal form, shoreline type (area located between the high and low tide mark), backshore material, and backshore form (Table 21.1)

The Shoreline Protection and Treatment/Cleanup Templates offer a variety of shoreline data including treatment and protection methods, objectives, strategies, and operational considerations. The last template is known as the Summary of Response Requirements. It is a summary of the protection and treatment templates and includes a response priority code (L = low, M = medium, H = high, VH = very high). The response priority code is defined based on the information available at the time of collection of the pre-spill database. Although it is a starting point in defining priorities, Environment Canada's Sensitivity Mapping Program is now in the process of incorporating other data sets in order to define a response priority

code which will better reflect the actual resource inventory for a specific shoreline segment.

Table 21.1 Shoreline material/type found in Atlantic Canada

Lower ITZ Material	**Lower ITZ Form**	**Backshore Form**
anthropogenic concrete	anthropomorphic breakwater	anthropomorphic breakwater
anthropogenic wood	anthropomorphic pier/jetty	anthropomorphic bridge
anthropogenic riprap	anthropomorphic pilings	anthropomorphic causeway
bedrock resistant	anthropomorphic seawall	anthropomorphic road
bedrock unresistant	anthropomorphic bridge	anthropomorphic dyke
boulder	anthropomorphic wharf	anthropomorphic pier/jetty
cobble	beach	anthropomorphic wharf
mixed coarse with sand	cliff	anthropomorphic railway
marsh grass	dune	anthropomorphic seawall
Mud	platform	barrier beach
pebble	salt marsh	beach
Sand	tidal flat	cliff
	delta	dune
Backshore Material	low-islets	flat
anthropogenic asphalt		peat bog
anthropogenic concrete	**Shoreline Type**	platform
anthropogenic riprap	bedrock	salt marsh
anthropogenic wood	boulder beach	spit
bedrock resistant	man-made solid	wetland bog
bedrock unresistant	mixed sand-gravel beach	delta
mixed coarse with sand	mud tidal flat	
mixed coarse-no sand	pebble-cobble beach	
marsh grass	salt marsh	
peat	sand beach	
sand	sand tidal flat	

These templates use a knowledge-based concept, as data and recommendations are entered, in part, from knowledge and experience rather than from an objective analysis. The templates are described in detail by Owens and Dewis (1995). The shoreline protection and treatment or cleanup techniques that are recommended for each segment are derived from the Environment Canada Field Guide for the Protection and Cleanup of Oiled Shorelines (Owens, 1996).

The description of the physical character of the shore zone for each segment is broken down into the lower intertidal zone, the upper intertidal zone (which corresponds to the nine accepted standard shoreline types (Figure 21.2)) and backshore coastal character.

The shoreline type is a description of that area of the shore zone where oil is most likely to be stranded and the coastal character is described since this is the area in which backshore operations will stage and deploy resources. The description also includes identification of features that are likely to affect the behaviour of persistent oil, such as alongshore traps, potential boulder or riprap

reservoirs, etc. Figure 21.3 gives an example of the Shore Zone Character template for a specific shoreline segment in the Atlantic Region.

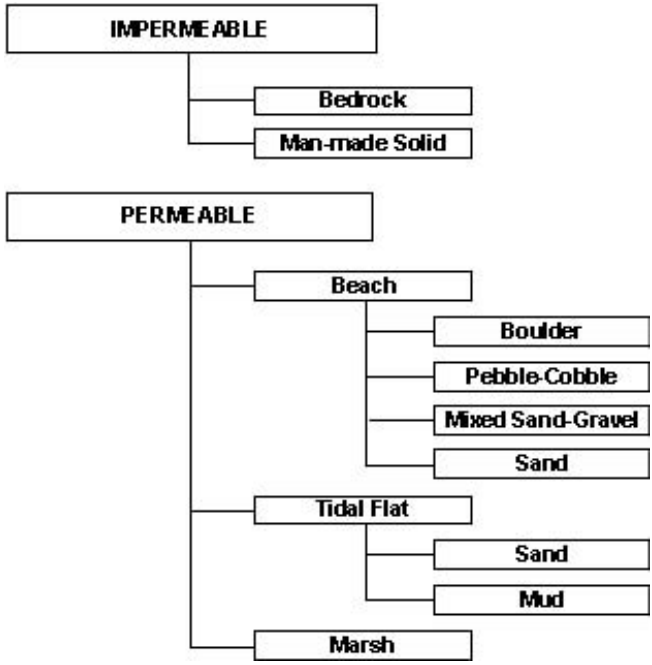

Figure 21.2 Nine standard shoreline types used to describe shore character.

Other areas outside Canada where the same shoreline classification approach has been applied include Hawaii (Honolulu-Waikiki), Russia (Sakhalin Island) and Alaska (Port Valdez). A number of countries around the world have shown interests in the Atlantic Region Sensitivity Mapping Program, including Bangladesh, Brazil, Spain, Israel, Chile, and France.

Videotape(s): GSC Open File # , Seg #58 (1989)

Figure 21.3 The shore zone character template is one of the four available in the pre-spill database. More than 143 attributes are available for each shoreline segment.

21.5 SENSITIVITY MAPPING SYSTEM

All computerized mapping systems require base map layers. Over the past years, Environment Canada purchased National Topographic Data Base (NTDB) digital maps from Natural Resources Canada - Centre for Topographic Information in Sherbrooke (Quebec). Three different scale were purchased: 1:50,000, 1:250,000 and 1:1,000,000. All three scales are used to represent specific information according to whether large- or small-scale maps are required. Once the base maps were visualised to reflect as much as possible the symbols and colours of the hard-copy versions, the digital maps were grouped to form one big region (Figure 21.4).

Figure 21.4 Atlantic Canada Sensitivity Mapping Sub-Regions (not shown are: Labrador).

The shoreline classification and the pre-spill database constitute the most important components in the mapping system. The classification describes the physical aspects of the shoreline and provides useful information on protection and clean-up methods. In addition, the mapping system allows for the display of various databases such as birds, fish, shellfish, aquaculture sites, parks, archaeological sites, etc. (Table 21.2). With all this information available, the mapping system can provide a detailed report for any given area.

The user has the option of defining a buffer zone which can be used to determine the sensitive resources within an area; to calculate features such as length of shoreline or area affected; or to display data in a graphical form (Figure 21.5). This last example contains shoreline lengths within a polygon for shoreline type, backshore type, biological resources, and human use resources. The information can be displayed in the form of bar graphs or pie charts, and a detailed report on the affected resources may also be generated. The report contains

information on various species or human-use resources, their sensitivity to oil spills and their seasonal vulnerability. A complete database of photographs related to sensitive birds, fish, shellfish, vegetation, and human use structures such as aerial photographs of small craft harbour can also be displayed. In addition to the Natural Resources digital base maps, the system can also display information from digital hydrographic charts or digital elevation models (Figure 21.6).

21.6 SUMMARY

The Atlantic Region Sensitivity Mapping Program's main focus is to provide a consistent and standardized application across jurisdictions. This consistency is crucial if personnel are to be brought in from different regions during a drill or spill, as they are instantly familiar with the process and terminology. The same sets of standard terms and conditions are applied to pre-spill database development, sensitivity and pre-spill mapping, SCAT data generation, and the response management decision process. Although the use of standard terms and definitions is almost essential for the description of oiled shorelines, the value of standardization extends into the decision process with regard to shoreline protection and treatment recommendations. This concept is very powerful as it provides a consistent terminology through the entire range of pre-spill planning and response activities.

Sensitivity mapping often has been viewed as an isolated activity in spill planning. Although the identification of resources at risk is a study that can stand alone, the application of that information into the response decision process involves a broader perspective. The integrated approach for spill response in Canada uses sensitivity information as one part of a larger body of relevant information that can and should be used by the decision team in the formulation of an appropriate response. For example, the pre-spill database includes information for each shoreline segment that describes potential oil traps or oil behaviour considerations, possible operational constraints, as well as the resources that are at risk.

The desktop mapping package provides an inexpensive and easy-to-use approach to data management and manipulation. The data can be updated quickly and easily with new information as this becomes available, or during a spill incident, and this new information can be presented immediately in map form.

The Atlantic Region Sensitivity Mapping Program keeps evolving to better serve the needs of environmental responders. All components described in this document will soon be integrated in a web-mapping format which will offer the same features and functionality as the stand alone version. The main advantage of designing a web mapping application resides in its broader accessibility and ease of use. Future developments include the completion of the pre-spill database for Labrador.

Epilogue: Meeting the Needs of Integrated Coastal Zone Management

Jennifer L. Smith and Darius J. Bartlett

The emergence of Integrated Coastal Zone Management (ICZM) represents a paradigm shift for a range of practitioners who work in the complex, dynamic area where land meets sea. The structure and implementation of geomatics technologies has been strongly affected by this shift, and GIS/RS practitioners have stepped up to meet the information needs of ICZM by creating coastal information systems featuring increased rigour, openness, and useability.

As a result of this forcing, coastal GIS/RS is increasingly differentiating itself from the marine sciences and emerging as a unique discipline. In 1999, Wright wrote: "it may be fair to say that marine applications of GIS have been more in the realm of basic science whereas coastal applications, due in part to the intensity of human activities, have encompassed both basic and applied science, as well as policy and management." This move towards an integrated approach is being realized in parallel with similar shifts in the approach of other actors in the coastal zone, including scientists, managers and planners. The principles of Integrated Coastal Zone Management make explicit what coastal GIS/RS practitioners have known for years: that the coastal zone is a uniquely complex system that requires new and innovative management approaches.

Here we outline the nature of this paradigm shift and the ways in which the authors in this volume have tackled the challenges of applying GIS to the integrated management of the coastal zone.

The principles of Integrated Coastal Zone Management

A thorough discussion of the inception and principles of Integrated Coastal Zone Management can be found in Cicin-Sain (1993) and Cicin-Sain and Knecht (1998). The following draws heavily upon these sources.

ICZM has been described as a process for decision-making: it should be continuous, iterative, and should recognize the contributions of stakeholders and the natural dynamism, both physical and ecological, of the coastal environment.

A primary goal of ICZM is to overcome the compartmentalized approach to managing coastal resources by harmonizing the decisions of diverse jurisdictions and levels of government. In particular ICZM aims to bridge the traditional divide between management of the land and of the water. ICZM, therefore, is also about building institutions that facilitate this integration.

ICZM is founded on principles of sustainable development, recognizing that the coastline is the fount of resources of great value to human communities and

0-41531-972-2/04/$0.00+$1.50
©2004 by CRC Press LLC

that these resources should be managed in ways that conserve their value for future generations. In addition to the extractive resources (such as fishing, hunting, aggregate extraction, and harvesting of algae), ICZM aims to recognize and conserve those resources that provide ecosystem services, such as seagrass beds that provide nursery habitat and mangroves that act as a defense against storm surge and erosion.

The outcome of these principles is a planning methodology that employs an ecosystem approach to management (considering interconnected elements of the ecosystem) and incorporates adaptive management to deal with uncertainty, variability, and change.

The role of GIS/RS in ICZM

The principle function of geomatics technologies in the coastal milieu has traditionally been that of a tool for converting data into information, which is in turn either published as basic science or fed into the balance sheet of the rational decision-making process. With the emergence of ICZM, however, the role of GIS/RS has evolved. In response to the ICZM imperative, coastal geographic information systems are increasingly integrative of scientific and socioeconomic elements, increasingly dynamic, temporal and predictive, and are often the tool that effectively brings stakeholders together.

GIS is often defined as a synergy of hardware, software, data, and people (ESRI 1990). Clearly, the changing role of the technology is accompanied by a changing role for the people who build and operate coastal information systems.

This volume contains a diverse collection of chapters, all of which address the application of GIS/RS and the role of its practitioners in the various facets of an integrated approach to coastal zone management. The authors in this book have begun the process of finding solutions to the challenges presented by ICZM, and are working towards these goals on several fronts.

Contributing to the capacity requirements of ICZM

Cicin-Sain and Knecht (1998) list four areas of critical capacity required for ICZM. In defining "technical capacity" the authors make direct reference to the role of coastal databases and information systems in gathering information on coastal ecosystems and processes, on the patterns of human use that occur in the coastal zone, and on the ongoing effectiveness of management activities. But GIS/RS also has the potential to contribute to the other areas of required capacity outlined by Cicin-Sain and Knecht: authors in this volume show how coastal spatial databases can assist in the formulation, implementation and enforcement elements of the *legal and administrative capacity* required for ICZM. For example, Both Pan and Lindsey *et al.* outline the use of GIS to fulfil legistlative imperatives; the TIS developed by Bourcier has the potential to provoke harmonisation of diverse jurisdictions and regulatory regimes. Some authors have outlined their contribution to the *human resources capacity* of coastal management initiatives, including bringing together multidisciplinary teams and fostering public awareness of and involvement in coastal issues. To this end, Bartlett and Sudarshana examine issues surrounding technology transfer; the standardised approach to risk mapping

developed by Laflamme *et al*. facilitates transfer of workers from one Canadian province to another in response to environmental emergencies; Nwilo describes programs that have facilitated exchanges and training for coastal zone managers in Africa; and many authors in this volume have found avenues for disseminating and interpreting their work to interested stakeholders. And, although GIS are typically expensive to implement, they can sometimes bring economies and recognition to coastal management initiatives, thus enhancing the *financial capacity* of the project in the long-term. Initiatives for advancing geomatics in the coastal zone, like those of Webster *et al*. and Nwilo, have attracted funding with spinoffs for coastal communities.

Integrating data from diverse sources

If the worth of a GIS is determined by how faithfully it represents the real world, creating a servicable GIS is challenging indeed when data of sufficient resolution, coverage and quality are difficult to acquire and unite for reasons of protectionism, conflict and variable format or standards. The ICZM imperative of integration across jurisdictions and institutions makes this issue doubly significant in the coastal zone. Authors in this volume, along with virtually every other coastal GIS practitioner, face this challenge daily and are working to find strategies that yield information systems that meet the needs of ICZM. Bourcier, Laflamme *et al*. and Mosbech *et al*., among many others in this book, have addressed the challenge of collecting and harmonizing data within a distributed, fractured, multi-agency and multi-jurisdictional region (the Seine estuary, the Eastern Canadian coastal zone and the Greenlandic coastal zone, respectively). Gomm considers issues specific to data integration across the land-sea divide, and Gourmelon writes about the process of coordinating a large number of institutions in the creation of a large-scale GIS.

Sometimes the greatest challenge to harmonising datasets is finding them. Longhorn describes the development of Coastal Spatial Data Infrastructures which, at their best, facilitate the formulation of standards, the sharing of data, and, ultimately, a more collaborative, open and connected network of coastal GIS applications.

Even in areas where standards and data-sharing protocols are in force, the increasingly rich and diverse database of many coastal regions leaves to GIS practitioners the task of determining the best available representation of coastal phenomena, as in Li *et al.*, who compared different data sources to arrive at the most accurate depiction of the coastline or Hwang and Ku, who outlined methods for choosing remotely sensed data at a resolution that best meets the needs of a coastal modelling excercise.

The work of all of these authors shows that geography can provide the scale and scope that is needed to unite diverse interest groups. Issues of data integration appear to be casting GIS developers as a uniting force and GIS as a nexus in the project of ICZM.

Adapting tools and technologies to serve the stakeholders of ICZM

We are now faced with the task of expressing the methods and results of what was, until recently, a specialized and technical discipline to a diverse group of scientists, managers, regulators, legislators, resource users and members of the public. These people are increasingly not just data *consumers* but also data *users*, who both demand and deserve to peer inside the black box of GIS technology and GIS-based decision support. GIS practitioners in this volume have responded by creating innovative visualisations, interfaces and forums for participation in the course of applying GIS to the coastal zone.

Involving stakeholders in both the formulation and the output of coastal GIS goes beyond the technical and presents intercultural and interpretive challenges. Bartlett and Sudarshana touch on the pervasiveness of Western metaphors in coastal GIS and the need to consider the cultural background of the stakeholders or collaborators. On Alaska's Pribilof Islands, Lindsay *et al.* collaborated across jurisdictions and cultures to construct a GIS that represents archeological features, important traditional resources, local placenames and the legacy of destructive industries. In another Arctic environment, Mosbech *et al.* gathered traditional knowledge to create an oil spill sensitivity database that considers resources of importance to local people. Both of these projects required that the researchers constructing the GIS consider the needs, concerns, and sensitivities of those people who will ultimately be affected by decisions based upon the outcomes of the exercise. Jude describes an exercise in visualizing the outcome of a coastal development: he applies GIS and RS in a way that makes the effects of change real and explicit to a non-technical audience.

Broad new user groups are now working directly with the data and software that has traditionally been the domain of experts. The Internet has excercised its all-pervasive influence here: Laflamme *et al.*, Green and King and Macharia describe web applications that bring GIS to a broader audience when and where information is needed. Longhorn discusses Coastal Spatial Data Infrastructures, that aid in making data accessible to a greater cross-section of users and in supporting the wider popularization of desktop GIS. Planning for consultation, infrastructures and dissemination is now seen as a critical phase in any coastal GIS initiative, and coastal GIS practitioners must keep the needs of stakeholders and future users in mind.

Improving tools and technologies

Because the land-sea interface is a complex ecotone, the scale of biophysically distinct areas in the coastal zone often necessitates a spatial resolution that has traditionally been difficult or expensive to acquire. GIS/RS practitioners working in the coastal zone were until recently either limited to a few data sources (such as analogue photogrammetry or bathymetric and topographic mapping by traditional survey and sounding means), or required to adapt the scale and resolution of their work to the quality of readily available remotely sensed data, i.e. satellite data at a 30m or greater resolution, often with poor depth penetration, particularly for turbid temperate waters. The challenge of acquiring high-quality data has been somewhat ameliorated by the increasing availability of quick-deploying hyperspectral sensors like CASI (Compact Airborne Spectrographic Imager) and

active laser sensors like LiDAR (Light Detection and Ranging) or active satellite sensors with specialised uses in the marine environment (such as RadarSat). Both Pan and Webster document their experiences and the technical challenges they faced in acquiring and applying data from these sensors, and both authors make explicit the great advances possible with such high (spatial and/or spectral) resolution data. Of particular importance to ICZM is the value of these fast-deploying sensors for monitoring change and perhaps even emergencies in the dynamic and heterogeneous coastal zone. High resolution data is one more piece in the puzzle of building rigorous, accurate and precise models of coastal zone processes.

Adapting the technology to represent complex dynamic systems

Tracking and analyzing spatio-temporal variation is a problem that has received much attention from geographers and GIS practitioners. In the coastal zone, it is compounded by the other challenges described here. Practitioners are faced with the need to deal with (and differentiate between) error and dynamism in an inherently dynamic environment. Bruce provides a detailed outline of the types of error and uncertainty encountered in coastal zone GIS and the various methods that have been developed to help practitioners quantify and work with this uncertainty. Li *et al*. describe methods for defining 'the coastline' in such a way that the variability of this elusive entity is accounted for. Schupp *et al*. have measured historical shoreline change in order to learn about future change. Webster *et al.* describe how dynamic coastal processes at different time scales (extreme tidal range, seasonal variability, and sea level rise) entered into the decisions that were made in the process of acquiring high resolution imagery and elevation data in a coastal area, then uses these data to plan for future changes. If change is the currency of ICZM, then developing data structures and modes of analysis that integrate dynamism into coastal GIS is critical.

Modelling for decision support

Applying GIS/RS in ICZM presents the challenge of using new technology in a real-life context, where models and findings are fed into a legislative and regulatory application and are subjected to not only academic but also governmental, public and vested private sector scrutiny. Coastal GIS practitioners have acknowledged the need to continue to make their models more robust at the same time as they become more complex and comprehensive. Populus *et al*. and Mayerle and Toro, for example, both undertook to model complex hydrodynamic processes with the explicit goal of using these models for decision support. Euan-Avila *et al.* considered land-based activities and their socio-economic drivers in modeling effects on water quality.

Conclusions

Researchers and practitioners are increasingly taking an interdisciplinary, integrative approach to applying GIS/RS in the coastal zone. As the body of work in this area grows, so too does our understanding of coastal processes and the role of humans in perturbing and managing these systems. GIS has much to contribute to Integrated Coastal Management, and GIS practitioners have many more challenges to face in constructing truly integrative coastal spatial information systems.

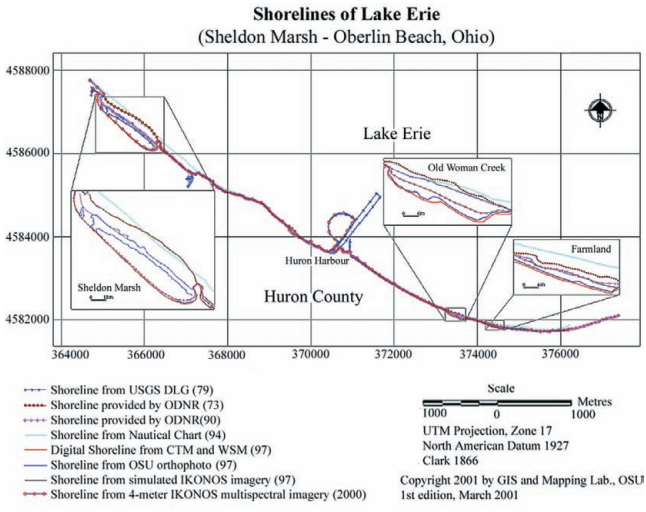

Plate 3.1 Shorelines compared and analysed in Chapter 3, Li et al.

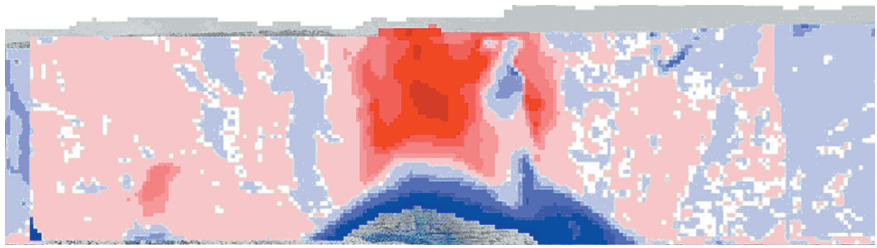

Plate 4.1 Changes between August 2000 and February 2001.

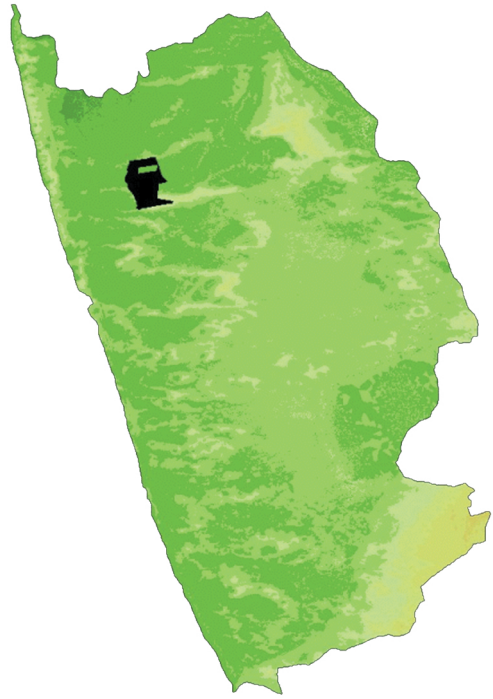

Plate 4.2 The Digital Elevation Model (DEM) for Kenfig NNR. Elevations are represented by different shades of green. Lower to higher ground is graded from darker to lighter shades.

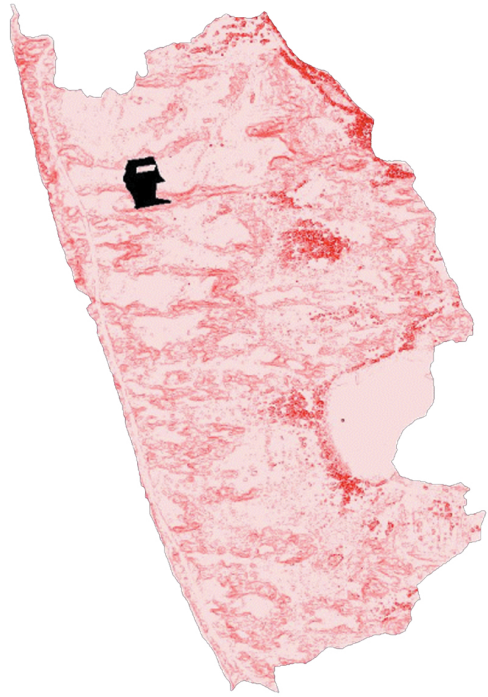

Plate 4.3 Slope data for Kenfig NNR. Slope "steepness" is represented by different shades of red, with darker shades representing steeper slopes. Clusters of red in circular shapes are individual trees.

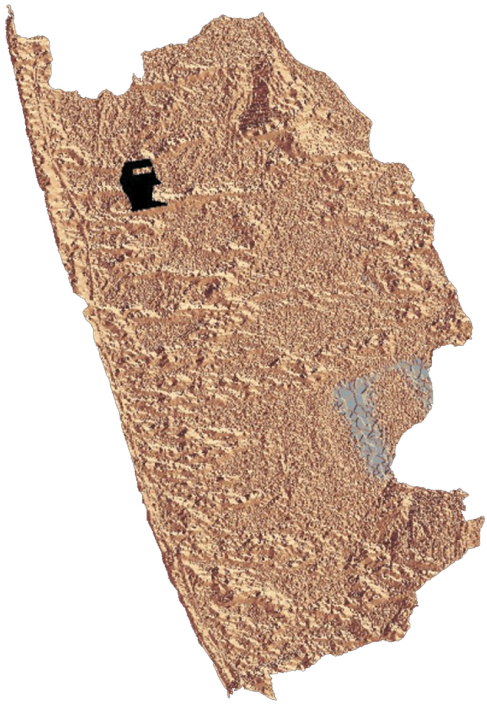

Plate 4.4 Aspect data for Kenfig NNR. Orientation of the slopes is represented by different shades of brown. Lighter shades represent a northerly orientation, and darker shades indicate a southerly direction.

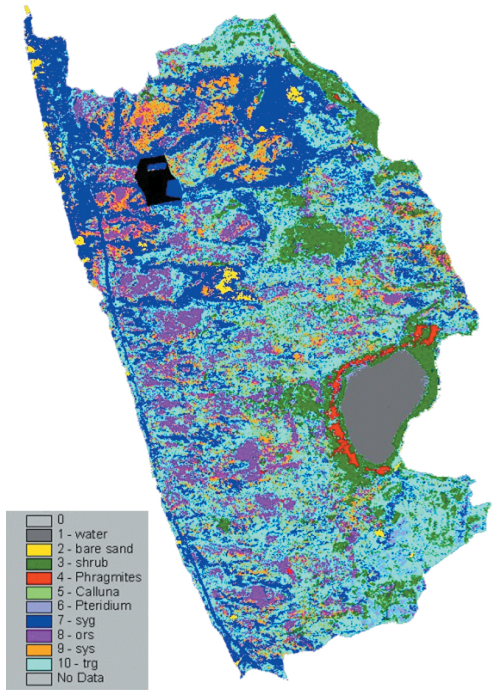

Plate 5.5 The classified habitat map of Kenfig NNR using CASI data.

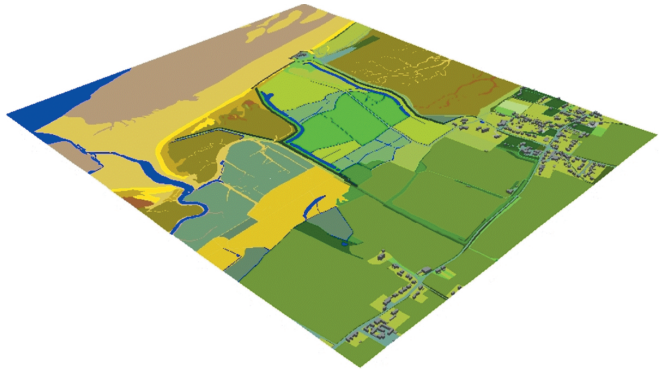

PLATE 8.1 ArcView 3D Analyst view of the site prior to the scheme. © Crown Copyright Ordnance Survey. An EDINA Digimap/JISC supplied service.

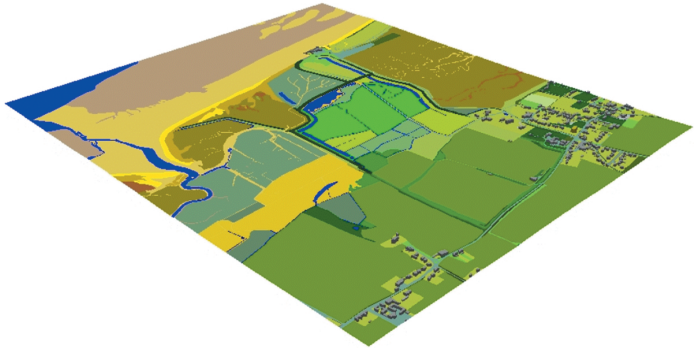

PLATE 8.2 ArcView 3D Analyst view of the site following construction of the scheme. © Crown Copyright Ordnance Survey. An EDINA Digimap/JISC supplied service.

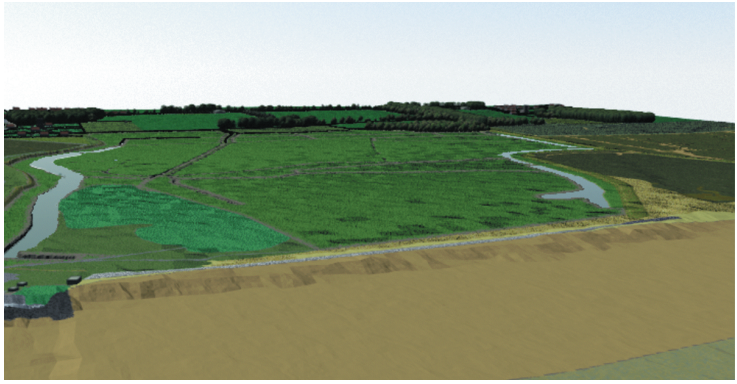

PLATE 8.3 Word Construction Set view looking south over Brancaster West Marshes prior to scheme construction. © Crown Copyright Ordnance Survey. An EDINA Digimap/JISC supplied service.

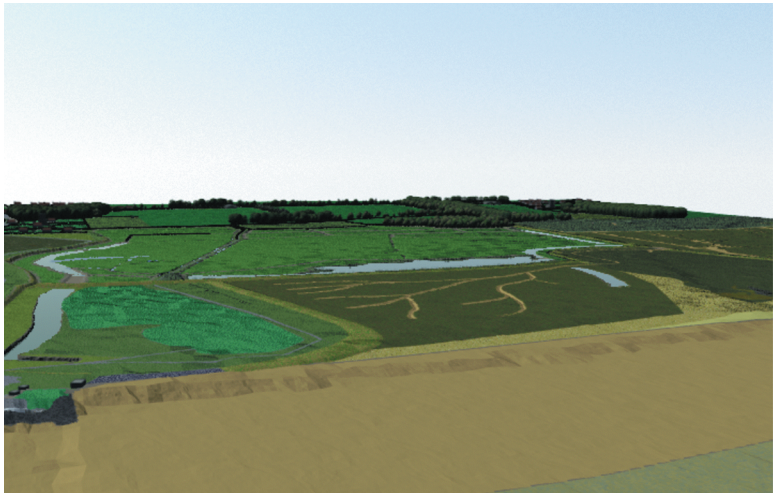

PLATE 8.4 World Construction Set view looking south over Brancaster West Marshes following construction. © Crown Copyright Ordnance Survey. An EDINA Digimap/JISC supplied service.

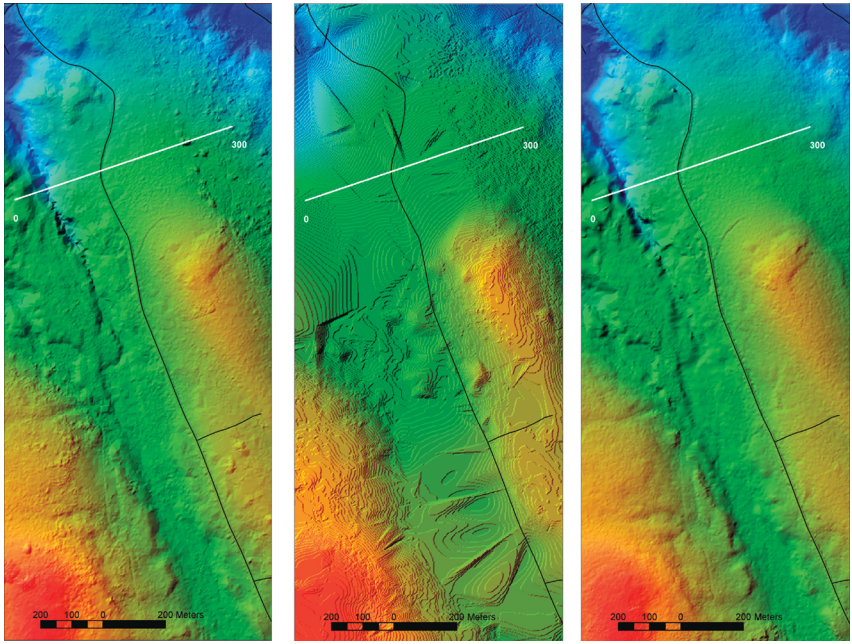

PLATE 15.1 Mosaic of 1 m CASI at low tide (left image), 2 m LIDAR DSM at low tide (centre image), and 3 m CASI at high tide (right image) for Port Lorne along the Bay of Fundy. Overall image is approximately 4 km across.

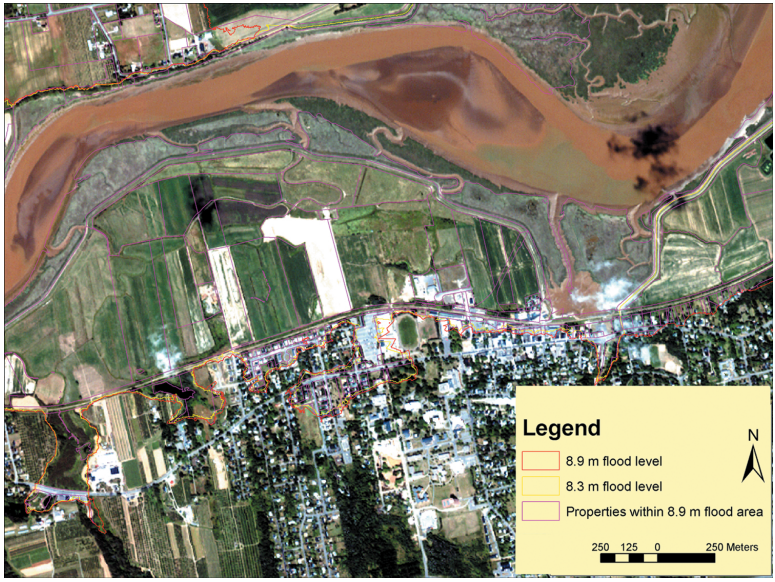

PLATE 15.2 Close-up of flood levels of one-in-twenty year (yellow) and one-in-one-hundred year (red) storm events with property boundaries (purple) that intersect the 100-year flood level displayed over an Iknonos image. Economic impact of such an event can be assessed by using GIS overlay functions to determine the value of infrastructure and properties affected. Includes material copyright Space Imaging, LCC.

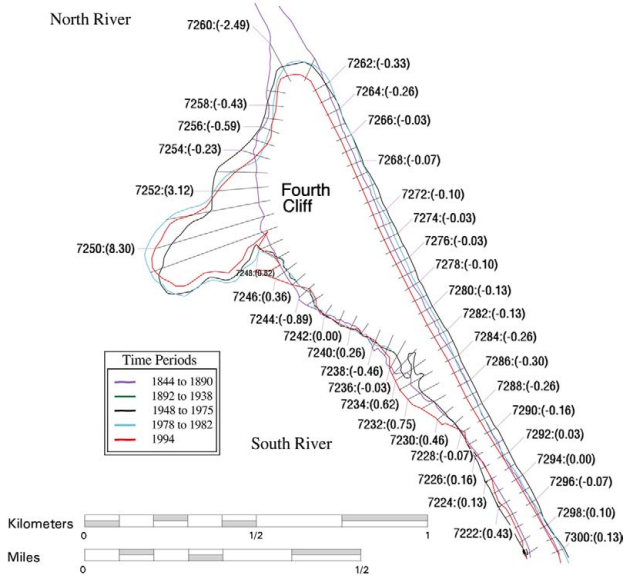

PLATE 16.1 Enlarged section of a shoreline change map for Scituate, Massachusetts, displaying historical shorelines, transects, and linear regression rate. (For clarity at page size, the orthophotograph underlay is not shown.)

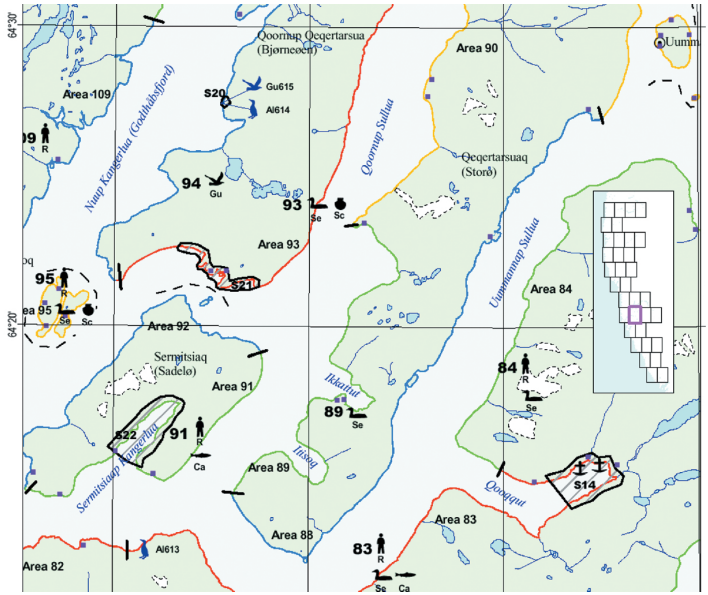

Figure 20.1A An example from the Atlas showing part of a shoreline sensitivity map. The shoreline areas (segments) have four different colours, indicating the level of sensitivity to oil spill. The black symbols indicate the important biological elements and resource use at the shoreline area, the blue symbols shows the site specific bird colonies.

Shoreline Sensitivty Maps

Shoreline Species

- Al Alcids
- Ar Arctic char
- Ca Capelin
- Co Cormorants
- De Deep sea shrimps
- Gu Gulls
- Ha Harbour seals
- Lu Lumpsuckers
- Sb Seaducks breeding
- Sc Scallops
- Se Seaducks
- Sn Snow crabs
- Tu Tubenoses

Site Specific Shoreline Species

- Al Alcids
- Co Cormorants
- Gu Gulls
- Ha Harbour seals
- Sb Seaducks breeding

Donald Garofalo

Chapter 19
Remote Sensing and GIS for Site-Specific Farming **241**
John G. Lyon, Andrew Ward, Bruce C. Atherton, Gabriel Senay, and Tom Krill

Index **255**

About the Editor

Lyon was interested early on in water resources, watersheds, and wetlands and other moderately disturbed systems as places to evaluate the condition of native vegetation communities. This interest was honed in his youthful wanderings in the mountains and alpine systems of the Pacific Northwest, California and Nevada, and Alaska. Systematic study of the Lower Columbia River and wetlands in undergraduate work at Reed College in his native Oregon, and graduate work at the University of Michigan yielded Bachelor's and Master's theses and a Doctoral Dissertation devoted to Great Lakes wetlands and other natural systems. Eighteen years as a faculty member and ultimately a full Professor of Civil Engineering and Natural Resources at Ohio State University were further devoted to scholarly pursuits of these interests. A body of work included remote sensor and GIS evaluations of water resources and wetlands, development of field methods for wetlands identification, and other efforts on hydrology, soil, agriculture, riverine, and Laurentian Great Lakes systems.

INTRODUCTION

GIS for Water Resources and Watershed Management

John Grimson Lyon, Editor

The chapter authors and the Editor are pleased to bring you this volume of outstanding contributions to water resources research. These authors and others have pioneered and developed viable applications of Geographic Information Systems (GIS) and continue to do so. As a result, the current state of water resources and watershed modeling has been advanced by the use of GIS and allied technologies (Maidment and Djokic, 2000). This volume reports their accomplishments and shares their insight with others who may find these contributions valuable to their own work.

A number of GIS applications to water resources and watersheds have been completed over the years, and they nicely illustrate the potential of the technology. Many of these efforts have resulted from the need to address difficult-to-achieve project goals. GIS applications are applied due to the variability of the resources over time and space, and the number of variables that must be evaluated.

Geographic Information Systems are databases that usually have a spatial component to the storage and processing of the data. Hence, they have the potential to both store and create maplike products. They also offer the potential for performing multiple analyses or evaluations of scenarios such as model simulations.

Data are stored in multiple files. Each file contains data in a coordinate system that identifies a position for each data point or entry. Characteristics of the data point are stored as "attributes." A database of individual files is developed and the combined files may contain characteristics or attributes such as stream locations, topography, water or soil chemical sampling, management practices, ownership, biota, point sources, and any other data that can be collected and have meaning for the analysis.

The GIS supplies value by virtue of the detail of the database, and how these data can be used to address the application of interest. Each variable or "layer" in the GIS supports the application with data on the characteristics of water resources or watersheds.

An important capability of GIS is the simulation of physical, chemical, and biological processes using models. GIS can potentially be used with deterministic or complex models based on algorithms simulating processes, or they can be applied with statistical models. The requirement is that the model to be applied has the capability to take spatial and/or multiple file or "layer" data as input to computations.

Geographic Information Systems are also amenable to evaluations as to quality. They may be used to evaluate the quality characteristics of the product, and to determine the inherent accuracy (Lyon, 2001). Many methods can assist the assessment of accuracy, and these methods can be used in experiments.

Advanced applications utilize GIS, remote sensor, and Global Positioning Systems (GPS) tech-

nologies to better address the project goals. These advanced approaches make use of more complex models and GIS technologies, data collection along with GPS (Kennedy, 1996; Van Sickle 2001), and remote sensing data collection and analyses.

There are a number of strengths that GIS technologies bring to water resources research. GIS allows for improved database organization and storage. The objectives of many watershed studies include watershed segmentation, identification of drainage divides and the network of channels, characterization of terrain slope and aspect, catchment configuration, and routing of the flow of water. Obtaining these variables has been difficult to do from paper maps and aerial photographs. These traditional methods are subject to errors related to manual operations. The work using traditional measurement methods has also proved to be time-consuming.

Once the GIS system is developed, it is straightforward to produce needed data, make maps, and provide simple or complex displays of model results.

The GIS also allows for integration of other sources of data. Historical maps and aerial photos can be of assistance. The U.S. Geological Survey (USGS), the U.S. Department of Agriculture, and the National Archives and Records Service hold originals of maps and photos. Copies of these can be obtained, corrected for inconsistencies, and scanned into a computer file for analyses (Garofalo, 2001).

The USGS also creates and sells Digital Elevation Model (DEM) data sets for the U.S. These data are sets of point elevations on a regular sampling grid. These point elevations are organized by USGS 1:24,000 scale or smaller scale quadrangles. The use of DEM products and custom DEMs are the subject of much of the book, and others (Maidment and Djokic, 2000).

The above USGS products are available at low cost. They may also be acquired at no cost from the USGS address on the Internet.

These USGS products do have the potential for being inaccurate. This may be due to systematic or nonsystematic errors, old source quadrangle maps, or other problems. Normally, the user will make any corrections or modifications for the needs of a given project. Corrections and methods to make corrections in DEM data are an important issue in this book.

It is also possible to purchase enhanced USGS products and other products from vendors who develop the improved DEM products. These enhanced or "value-added" products are quite good, and they represent a considerable cost savings as compared to generating the data anew or correcting available USGS versions. Vendors may also have unique products, or products that can be further enhanced to meet user needs. Examples would include customizing an existing data set to provide only information for a given watershed that is found on several map sheets, or developing a fine detailed DEM by use of airborne LIDAR measurements.

Another, potentially valuable data set is U.S. Department of Agriculture Natural Resource Conservation Service (NRCS, formerly Soil Conservation Service) soils data. Several programs have resulted in general soils data stored in digital form, and products are available at different scales and levels of detail. For example, the STATSGO data sets are files of soil survey soil type and boundary data, and the chapters present some of the capabilities of these and similar databases.

A number of projects have used satellite remote sensor measurements. The resulting remote sensor data provide valuable inputs to GIS, due to the difficulty of access to research areas or the size of the study areas. Supplying data on watersheds over sizable areas has been a valuable use of satellite systems, and has been conducted in a variety of ecosystems including Florida, Washington, the Great Lakes, and Africa as discussed in this book (Lyon, 2001).

GIS also allows for advanced analysis and modeling methods to be implemented in support of research efforts. The use of simulations of models provides detail on water movement and transport of materials.

GIS databases and technologies allow for optimization of model results. The running of model

scenarios supplies detailed information for the development of plans, management decisions, and informed leadership. Repetitive processing facilitates predictions and forecasting of events.

Certain characteristics of and applications in water resources research lend themselves to GIS databases and GIS analyses. As we know, water flows downhill and supplies a directional characteristic to the modeling efforts. The flow can be determined by gauging, and the simulations of water discharge and water quality above a gauge can be compared with the reality measured at the gauge.

The history of watershed and water resources research has included many models that utilize spatial data. These "traditional" models incorporate data with a spatial basis or the components of spatially averaged data. This is because applications have been dictated by need, and models exhibit sensitivity to these variables.

The future promises a variety of enhanced applications of GIS and allied technologies for water resources and watershed research. We will see better integration of data within databases, and the advent of more uses of three-dimensional visualization of data. Databases will become available in greater numbers and detail, and will be procured through the Internet and the World Wide Web.

The advantages of using GIS for watershed studies has been recognized. It is apparent that the capabilities of GIS are potentially valuable in a number of efforts. Over time the need for information has resulted in the development of appropriate algorithms to facilitate the utility of GIS and statistical or deterministic models. Much traditional modeling and analyses preceded the advent of GIS and many efforts are ongoing to join the approaches and optimize their capabilities. It is these kinds of efforts that have been brought together here to help share the experience of the authors with the readers.

The chapters presented here demonstrate a number of practical applications of theory and applications of GIS technologies to solving real-world problems. Some outstanding authors have contributed. They wish to showcase their high quality efforts, and share their knowledge and experience with other professionals. The result is an informative and practical book that will be enjoyed for years to come.

The book begins with two contributions from Martz and Garbrecht, who are well-known for their thoughtful work in watershed and water resources research. These papers help to characterize the variable that can be obtained through analysis of Digital Elevation Model (DEM) data.

Here, DEM data were preprocessed to identify drainage networks using the Digital Elevation Drainage Network Model (DEDNM). Application of the model and software allows extraction of topographic and topologic drainage network and watershed properties, using available DEM data from 1:24,000 scale USGS quadrangle maps. Data corrections such as removal of depressions and flat areas are addressed and methods discussed. Watershed characteristics are developed such as channel tracing by flow direction using codes to identify links, nodes and subwatersheds. Other computations to develop variables include calculations of slope and overland flow distances, elevations, and associated flow paths.

The second chapter by these two authors further develops the efforts to calculate watershed characteristics. Included are efforts to correct artifacts in DEM data using DEDNM, and use of other algorithms in the TOpographic PArameteriZation program (TOPAZ). The TOPAZ digital analysis system processes and analyzes DEM data to characterize topography, measure parameters, identify surface drainage, subdivide watersheds, and quantify the drainage network.

An additional contribution of this chapter is an evaluation of an automated approach to development of watershed data including segmentation, channel network identification, and subwatershed definition. This is completed for a small watershed in low relief terrain. The channel network generated by DEDNM is compared with a traditional blue-line method to determine the capability and accuracy of the automated approach.

The chapter by Tachikawa, Shiiba, and Takasao presents a TIN-DEM based topographic model which incorporates the advantages of grid-based methods and contour-based methods for generating watershed characteristics. The results were applied to the question of determining the structure of a distributed rainfall-runoff model, and determinations of source of flow and direction of runoff flow.

The chapter by Harvey and Eash provides a history and description of capabilities of the Basinsoft program. This program processes data through modules, and can quantify 27 different basin characteristics. Watershed characteristics can be generated for a given basin or multiple basins, and the repetitive steps can be automated.

The capabilities of Basinsoft were compared to manual measurement in this chapter. Twelve selected drainage basin characteristics were made from USGS topographic data for drainage areas upstream of 11 streamflow gauging stations in Iowa. Results of Wilcoxon signed ranks test indicated that Basinsoft quantifications were not significantly different from manual measurements for 9 of 10 drainage basin characteristics tested. This work was significant because it demonstrated statistically that GIS- and DEM- derived parameters were similar to those derived from traditional, manual measurement procedures. Such validation of automated procedures is a necessary and important step in GIS research and applications.

The chapter by Miller, Guertin and Goodrich presents a methodology for predicting channel shape from watershed characteristics that could be readily derived from commonly available GIS data. A high resolution database was constructed and tested for the Walnut Gulch Experimental Watershed in Arizona. Channel cross-sectional area and width were found to be significantly related to channel order, upstream watershed size, and maximum contributing flow length within a watershed.

The chapter by Mizgalewicz, White, Maidment and Ridd, describes procedures developed to model the water balance of the large-scale Mississippi River flooding event of 1993, and to utilize hydrologic and meteorologic data sets in a GIS database. The goals were to develop a comprehensive understanding of the climate and hydrologic conditions related to the floods. The chapter also presents ideas on how to use visualization software in the depiction of water storage change over the land surface during the flood period.

Starks, Garbrecht, Schiebe, Salisbury, and Waits address the development of hydrographic data layers from DEM. Included in their chapter is the evaluation of reliability of the soil property data extracted from soils coverage and Soil Survey data, and land use and land cover data derived from satellite sensors. The topographic information was developed from TOPAZ, a set of algorithms and software described earlier. The use of Soil Surveys and attribute data was examined, and data employed in the project were taken from the STATSGO database. The concept of critical source area (CSA) was also described and its utility addressed.

The chapter contribution by Thenkabail and Nolte demonstrates the use of remote sensor data, Global Positioning Systems (GPS), and ground data for input to a GIS. In this chapter, three large study areas in Africa were evaluated, and the capabilities of these technologies to locate resources was demonstrated. Fascinating information was developed on the presence of inland valley bottoms, their cultivation, and the proximity of roads to farm fields in a poorly mapped and developed area. The utility of the derived information was great, and the results can demonstrate how these technologies supply details unavailable from any source, and help to fix the location of resources in space and in time.

The chapter by Warner, García-Martinó, Scatena, and Civco is an interesting example of GIS and watershed modeling for use in low-flow watersheds. Low-flow or dry streams in watersheds are difficult to model and this paper demonstrates a thoughtful way to deal with the problems presented by such a watershed in Puerto Rico.

In his chapter, Holman demonstrates how land cover data from Landsat satellites can assist in modeling land cover and use in a rural and urban study area of large size. Numerous and interesting results were generated by evaluation of the database using GIS.

The chapter by Queen, Wold, and Brooks presents a GIS that was developed to manage and analyze landscape data for nine representative subwatersheds in the Nemadji basin of Minnesota. Output from the GIS was used in regression modeling of the relationships between the frequency of soil mass movements and the landscape characteristics. Significant results included the relationship between slump frequency and total forested area and percent nonforested land.

Guan, Moore, and Lostal illustrate in their chapter how a large data set can be accumulated by submitting individual results of projects to a shared database. They discuss the requirements of managing such a database, and making the data available to many users. They also examine the problems associated with changing hardware and software, and how to maintain a useful database over multiple-year time periods.

The chapter by Williams and Lyon presents the utility of historical aerial photos and GIS analyses to inventory and monitor a dynamic water resource over a more than 50-year period. The results address the hydrologic forcing function of fluctuating Great Lakes water levels and their influence over time on coastal wetlands resources. The results have allowed resource managers to examine the natural variability of the wetlands, and any potential influence of human activities.

How the influence of habitat conditions can be evaluated for a given wildlife species is shown in the chapter by Lunetta, Cosentino, Montgomery, Beamer, and Beechie. The issue of salmonid habitat and human activities is a potent one, yet little quantitative, spatial-based work has been done. The combination of GIS analysis and data from a variety of sources including Landsat satellites allowed this difficult issue to be addressed and quantitative information be brought to the dialogue.

In his chapter, Colby examines the role of GIS in pulling together a number of data sources to address watershed characteristics and runoff yields for a rural watershed in Puerto Rico.

The chapter by Cruise and Miller examines the capabilities of remote sensor data to facilitate hydrologic modeling. The combination of remote sensor data, GIS, and models provides the spatial, spectral, and numerical capacity to address topical interests. Results demonstrate that macroscale hydrologic modeling with conventional remote sensing tools can provide simulations of observed climatological features over fairly long time periods.

The chapter by Garbrecht, Martz, and Starks presents the results of preprocessing DEM data to treat problems associated with depressional and flat areas. The additional image processing technologies better capture the channel networks from overland or hillslope areas, and enable automated management of the water flow routing process in large drainages, and help generate network and subcatchment data necessary for rainfall-runoff modeling.

Garofalo demonstrates the practical value of using historical aerial photographs and photointerpretation techniques for historical analyses. This very informative treatment details how valuable information can be derived on hazardous waste disposal areas and the associated water resource characteristics. Use of these techniques can greatly assist users in developing hard-to-obtain factual information on most sites of interest, and for populating GIS databases.

The chapter by Lyon, Ward, Atherton, Senay, and Krill demonstrates a number of techniques that can be applied to agricultural and water resource applications (Ward and Elliot, 1995). The combination of advanced techniques such as remote sensing, GIS, GPS, variable rate applications, detailed soil chemical sampling, and related approaches has greatly improved decision making in agriculture. The use of site-specific or precision agriculture can be done in a cost-friendly manner, and greatly improve production and protect water quality.

CHAPTER 1

Channel Network Delineation and Watershed Segmentation in the TOPAZ Digital Landscape Analysis System

Lawrence W. Martz and Jurgen Garbrecht

INTRODUCTION

Research over the past decade has demonstrated the feasibility of extracting topographic information of hydrological interest directly from digital elevation models (DEM). Techniques are available for extracting slope properties, catchment areas, drainage divides, channel networks and other data (Jenson and Domingue, 1988; Mark, 1988; Moore et al., 1991; Martz and Garbrecht, 1992). These techniques are faster and provide more precise and reproducible measurements than traditional manual techniques applied to topographic maps (Tribe, 1991). As such, they have the potential to greatly assist in the parameterization of hydrologic surface runoff models, especially for larger watersheds (i.e., >10 km^2) where the manual determination of drainage network and subwatershed properties is a tedious, time-consuming, error-prone, and often highly subjective process. The automated techniques also have the advantage of generating digital data that can be readily imported and analyzed by Geographic Information Systems (GIS).

This chapter presents an overview and discussion of the original DEDNM (Digital Elevation Drainage Network Model) computer program developed to measure drainage network and subcatchment parameters directly from a DEM. A detailed discussion of the original program structure and algorithms is available in Martz and Garbrecht (1992). Improvements and modifications to the program continue to be made, although the essential approach to drainage analysis remains largely unchanged. DEDNM now functions as the core component in a more comprehensive digital landscape analysis system known as TOPAZ (TOpographic PArameteriZation) (Garbrecht and Martz, 1999).

DEDNM OVERVIEW

The main purpose of the program is to provide an automated, rapid, and reproducible evaluation of the topographic properties of large watersheds by processing raster DEMs. The primary application target for the program is the parameter determination for hydrologic surface runoff models. The following general objectives guided the program development:

1. Program input should be DEMs that are both commonly available to hydrologists and represent the land surface in sufficient detail for hydrologic analysis.
2. The program should not be limited by the nature of the topography represented in the DEM and should be applicable to both high and low relief terrain.

3. The program should extract all topographic and topologic drainage network and watershed properties relevant to the parameterization of hydrologic surface runoff models.
4. The program should incorporate established and proven algorithms from earlier research, and supplement these with new algorithms as required.
5. The program output should be structured so that it can be used directly for hydrologic model parameterization and be readily imported by a GIS.

The program first preprocesses the DEM to remove depressions and flat areas without modifying other parts of the DEM. Flow simulation algorithms are then applied to determine the catchment area of each grid cell, and to define the boundaries of the watershed to be analyzed. A continuous, unidirectional channel network is delineated by selecting all grid cells with a catchment area in excess of a user-specified critical source area.

Network evaluation involves tracing the course of the channels in the previously defined watershed, and identifying the junctions in the network. Channel tracing is directed by flow direction codes generated in the flow simulation analysis. The channels are traced initially to order the network according to the Strahler system, and to determine the length of each network link and the spatial coordinates of its upstream and downstream end. These data are used, in turn, to calculate the slope and catchment area properties of each link, and the number and average properties of the channel segments of each Strahler order. The channels are traced again to assign unique identification numbers to each node in the network. These node numbers are used to associate link, node, and subwatershed data, and can also be used to optimize flow routing in hydrologic models. A final trace is used to identify the subwatersheds of each source node and of the left and right banks. The individual subwatershed areas are then evaluated to determine their slope and overland flow travel distances.

The program generates both tabular and raster output (Table 1.1). The tabular output gives the watershed and drainage network properties of the total drainage network and of the individual network links. The raster output provides maps of the watershed and drainage network components which can be imported into a GIS, registered to other data layers, and used as templates to extract

TABLE 1.1. Summary of the Major DEDNM Program Outputs

Raster Output	
• DEM, depressions filled	• Template of main watershed
• DEM, depressions filled, relief on flat areas	• Channel network: links by Strahler order
• Extent of depressions and flat areas	• Channel network: links by node number
• Flow direction at each grid cell	• Subwatersheds: by node number and subarea code
• Drainage area at each grid cell	

Tabular Output	
• Main watershed (by Strahler order)	• Individual network links
1. Number of channel segments	1. Strahler order
2. Average channel length	2. Upstream and downstream node coordinates
3. Average channel slope	3. Upstream node number
4. Average upstream and direct drainage area	4. Channel length
• Individual subwatersheds	5. Upstream and downstream node elevation
1. Channel area	6. Upstream and direct drainage area
2. Left-bank, right-bank and source node direct drainage area	

additional, hydrologically-relevant information (i.e., soil type, land cover, climate, etc.) for individual subwatersheds and network components.

DEDNM is coded in FORTRAN–77. It is modular to allow easy modification and reorganization to meet specific needs. Each major operation is performed by a set of subroutines called from the main program. Program input is a raster DEM in a standardized format, DEM parameters (i.e., number of rows and columns, elevation range, etc.) and user-specified job parameters that control processing and output. DEDNM keeps all data in dynamic memory during execution to minimize time-consuming I/O operations. While memory requirements are minimized by performing all computations on and storing all elevations as integer data, the processing of large DEMs can create significant memory demands. An option to aggregate the DEM to a coarser grid cell size is provided to permit operation in limited memory or to permit more rapid preliminary analyses of large DEMs. DEDNM can be compiled to run on any hardware platform and, provided sufficient memory is available, can be easily configured to process any size of DEM.

DEM PREPROCESSING

The design objectives for DEDNM emphasize the analysis of generally available DEMs which represent landscapes at a resolution that allows the extraction of hydrologic variables. The 7.5-minute DEMs distributed by the United States Geological Survey (USGS) are typical of such data. They provide elevation values in 1 m increments for 30 m grid cells over areas corresponding to USGS 7.5-minute quadrangles. Much of the United States is now covered by such DEMs, and coverage continues to increase. DEMs with the same general structure and order of resolution are provided by other national jurisdictions and can be generated from SPOT data (Quinn et al., 1991; Tribe, 1991).

A fundamental problem in using DEMs of this order of resolution for hydrologic analysis is the presence of sinks in the data. Sinks are grid cells with no neighbors at a lower elevation and, consequently, with no downslope flow path to a neighbor. By this definition, sinks occur on both flat areas and in closed depressions. Sinks are quite common in DEMs with a spatial and vertical resolution similar to that of the USGS 7.5-minute DEMs. They also tend to be more common in low relief terrain than in high relief terrain. While a few of these sinks may represent real landscape features, the majority are spurious features which arise from interpolation errors during DEM generation, truncation of interpolated values on output, and the limited spatial resolution of the DEM grid (Mark, 1988; Fairchild and Leymarie, 1991; Martz and Garbrecht, 1992).

Figure 1.1 shows the spatial distribution of sinks in a DEM of an 84 km^2 low relief watershed used as a test data set in developing DEDNM (Garbrecht and Martz, 1997). The DEM elevations are in 0.9 m (3 ft) increments for 30 m grid cells. Ten percent of the watershed is covered by sinks, of which 25% are in closed depressions and 75% are on flat areas. The sinks are concentrated along valley bottoms where local slopes are gentle. The banded appearance of many of the flat areas suggests that they are artifacts of the limited vertical resolution of the DEM.

The ability to simulate flow across sinks is essential for effective hydrologic analysis of DEMs of this type. DEDNM provides this capability through a two-phase operation which has the same effective result as the flow modification method of Jenson and Domingue (1988). The first phase involves filling all closed depressions to the elevation of their local outlet using the method of Martz and de Jong (1988). The subwatershed of a depression is delineated and the lowest outlet on the edge of this area is identified. The elevation of all cells within the subwatershed and below the elevation of the lowest outlet are raised to the outlet elevation to simulate depression filling (Figure 1.2). Complex, nested, or truncated depressions are readily evaluated by the filling algorithm.

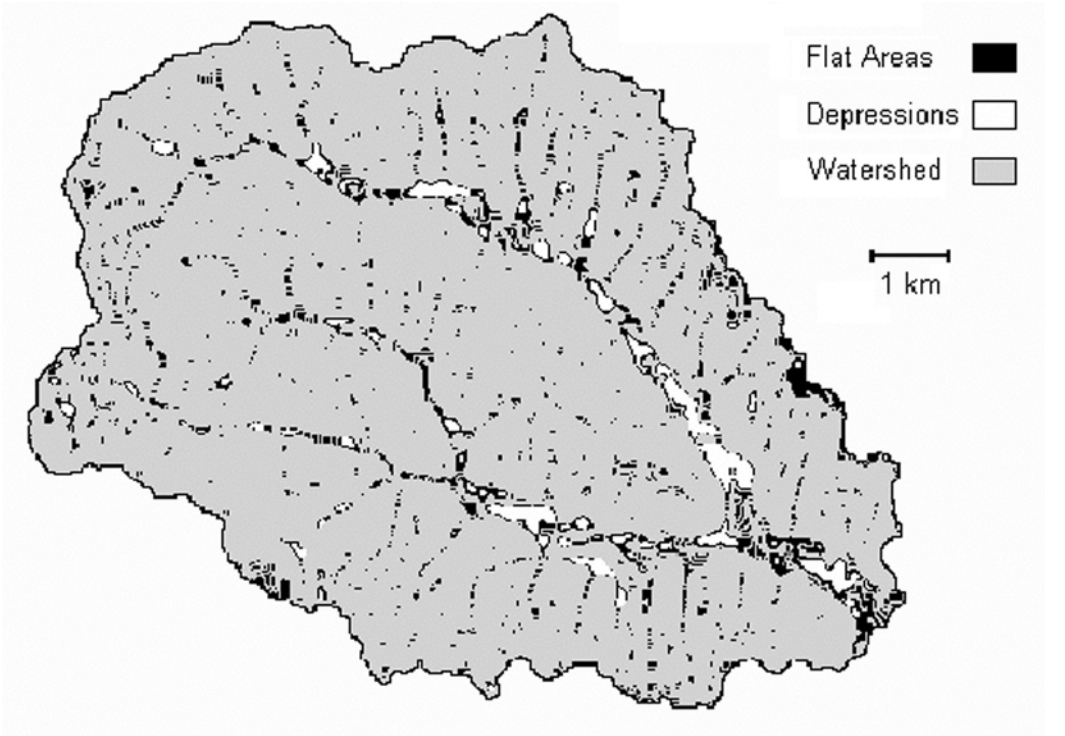

Figure 1.1. Type and spatial extent of sinks in DEM of Bill's Creek watershed in southwestern Oklahoma.

Subtracting elevations in the original DEM from those in the DEM modified by depression-filling gives the location, spatial extent, and depth of depressions.

The second phase imposes relief on all flat areas (both those created by depression-filling and those inherent to the DEM) to permit the unambiguous definition of flow paths across these areas. Two assumptions are implicit to this operation: (1) flat areas are not truly level, but have relief that is simply not detectable at the resolution of the DEM, and (2) this relief directs flow entering or originating on the apparent flat area along a reasonably direct path over the flat area to a point on its perimeter where a downward slope is available. Relief is imposed by adding an elevation increment of 1/1000th of the vertical resolution of the DEM to each cell with no neighbor at a lower elevation (Figure 1.2). This is repeated until no flat areas remain. This approach to the treatment of sinks is superior to the use of prior smoothing to remove sinks because it focuses directly on problem areas without reducing the information content of the DEM elsewhere. It also relies on an assessment of local boundary conditions that bear directly on flow patterns.

The current version of DEDNM incorporated into the TOPAZ digital landscape analysis system introduced two significant improvements for the treatment of depressions and flat areas. These improvements allow the breaching (i.e., lowering) of the outlet of some depressions and apply a two-phase relief imposition algorithm to direct flow across flat areas simultaneously away from higher and toward lower surrounding terrain (Garbrecht and Martz, 1997).

FLOW VECTOR AND DRAINAGE AREA ANALYSIS

Following the preprocessing operation, a flow vector code is assigned to each grid cell using the D8 method (Fairchild and Leymarie, 1991). The flow vector indicates the direction of the

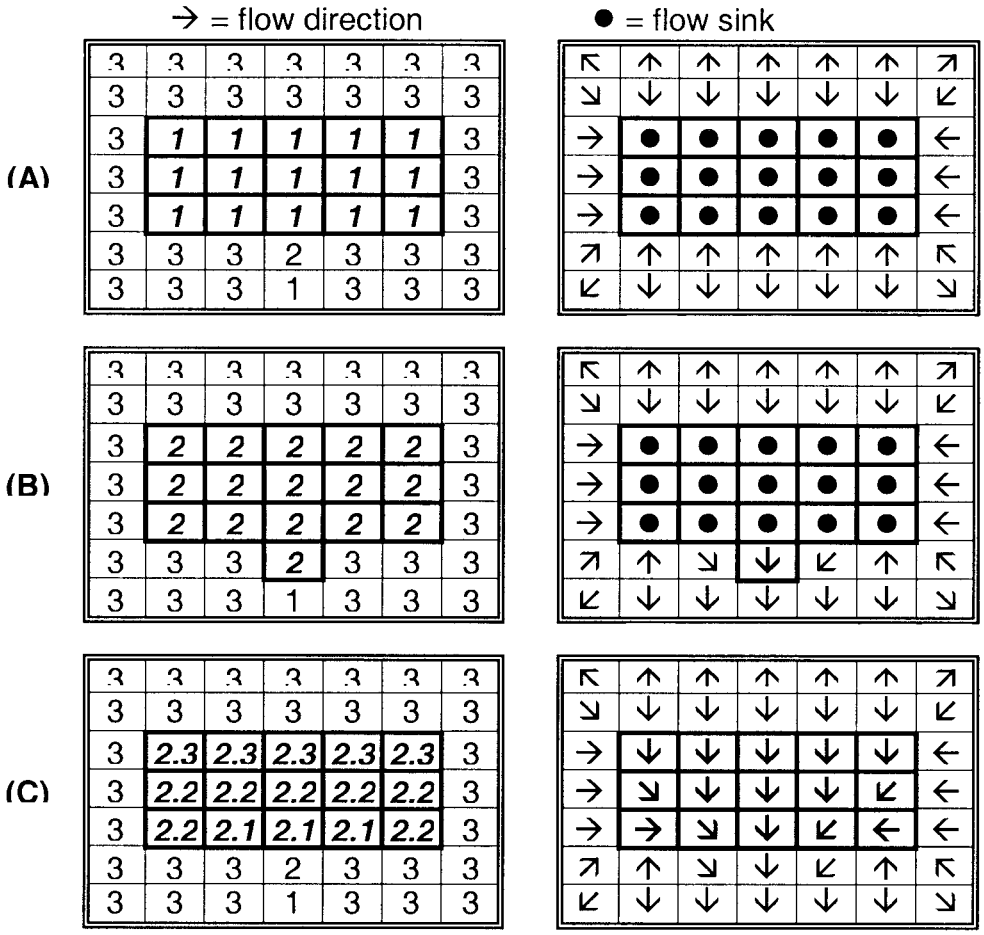

Figure 1.2. DEM preprocessing by DEDNM. Elevations (left column) and associated flow paths (right column) are shown for: (A) original DEM with depression; (B) DEM with flat area created by depression filling; (C) DEM with relief imposed on flat area (for simplicity of illustration, an elevation increment of 1/10th is used).

steepest downward slope to an immediately neighboring cell. Where more than one downward slope maxima exist, the flow vector is arbitrarily assigned to indicate the direction of the maximum first encountered. At cells on the edge of the defined DEM (i.e., cells in the outer rows and columns, or adjacent to a cell with a missing elevation value), the flow vector points away from the defined DEM if no other downward slope to a neighbor is available. All flow originating on or entering a cell is assumed to move in the direction indicated by the flow vector, and no divergent flow out of a cell is accommodated.

The catchment area of each grid cell is determined using the method of Martz and de Jong (1988). The flow vectors are used to follow the path of steepest descent from each cell to the edge of the DEM, and the catchment area of each cell along this path is incremented by one. After a path has been initiated from each cell, the catchment area value accumulated at each cell gives the number of upstream cells which contribute overland flow to that cell (Figure 1.3).

The boundary of the watershed to be analyzed is also determined from the flow vectors. The user specifies the location of the grid cell at watershed outlet, and all grid cells which contribute

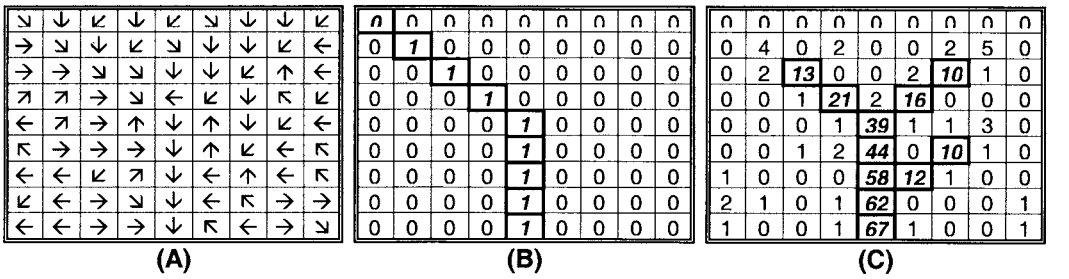

Figure 1.3. Catchment area determination by DEDNM: (A) flow vectors at each DEM cell; (B) catchment area at each DEM cell after the first flow path (highlighted) has been traced from the upper-left cell; (C) catchment area at each DEM cell after flow paths have been traced from all cells. Highlighted cells in (C) are those classified as channels using a critical source area of 10 cells.

overland flow to the outlet cell are identified. This provides a mask of the watershed that is used for subsequent operations.

CHANNEL NETWORK ANALYSIS

The channel network within the watershed is delineated from the catchment area grid. All cells with a catchment area greater than a user-specified critical source area are classified as part of the channel network. This yields a fully connected, unidirectional network. However, the network may contain some very short exterior links which represent valley side indentations, gully outlets, and other features that normally would not be classified as part of the channel network. The network is pruned to remove these spurious exterior links. The pruning involves tracing each exterior link downstream from its source to determine if a user-specified threshold distance (the minimum source channel length) can be traveled before a junction is reached. If so, the link is retained. If not, the link is a candidate for removal. Where two links less than the threshold length join, the shorter link is removed and the remaining link is reevaluated to determine if it now meets the threshold length criterion for retention. A slightly more involved analysis is required at junctions of more than two links.

Once the network has been pruned, the length, starting and ending cell coordinates, and Strahler order of each channel link are determined. Each exterior link is traced downstream from its source until a junction is reached. Each cell along the link upstream of the junction is marked as Strahler order 1, while the cell at the junction is marked as Strahler order 2. On reaching a junction, the link coordinates and link length are stored, and the trace terminates. Once all exterior links have been traced, interior links of successively higher Strahler order are evaluated.

Each junction where a cell was previously marked as being of the current Strahler order (initially order 2) is examined to determine if all links entering the junction have already been assigned a lower order. If this is the case, the junction is the upstream end of a channel segment of the current order, and a trace is initiated. The trace proceeds downstream from the junction, with each cell along the interior link being assigned the current Strahler order until another junction is reached. On reaching a junction, the length and the upstream and downstream coordinates of the link are stored, and the other links entering the junction are examined. If all other links entering the junction were previously assigned a lower order, the order of the downstream link will not increase and the trace continues. If this is not the case, the junction is flagged as being of the next

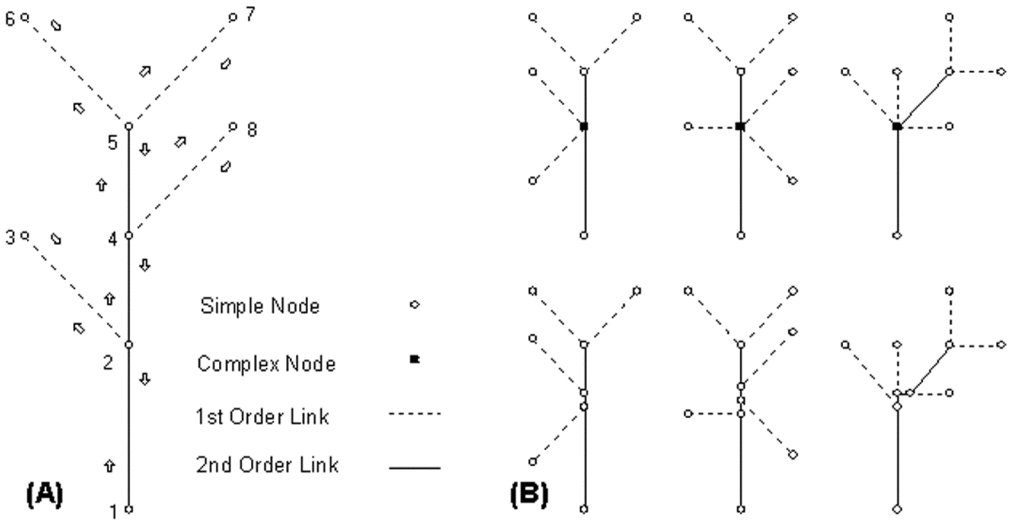

Figure 1.4. Node numbering by DEDNM: (A) the general method of assigning node numbers by tracing the network as shown by arrows; (B) the upper row shows networks with complex nodes (i.e., junctions of more than two channels) in the grid representation of the channel system and the lower row shows corresponding networks in which the complex junctions are effectively replaced by multiple simple nodes in the DEDNM node numbering procedure. The multiple simple nodes are assumed to fall within the grid cell containing the complex node which they replace.

highest order, and the trace terminates. Analysis continues until all links in the network have been ordered.

Following network ordering, the link coordinates are used to find the elevation and the catchment area at the upstream and downstream end of each link. These are used to calculate the longitudinal slope and direct drainage area, respectively, for each link in the network. In addition, the number of channel segments, and the average slope, length, and total and direct drainage area of the segments of each Strahler order are calculated.

A unique identification number is then assigned to each network node using the system described by Garbrecht (1988). Flow vectors are used to simulate a walk along the left bank of the channel beginning and ending at the watershed outlet. Each node is assigned a number the first time it is passed during the walk (Figure 1.4). These numbers can be used by hydrologic models to optimize flow routing, and are used by DEDNM to associate node, link, and subwatershed data. Channel networks often have some junctions where more than two links join. This situation is treated by assuming that more than one node occupies a single grid cell, and assigning one number to each assumed node. Some special analysis is required to ensure that the node number assignment remains consistent with the network ordering applied earlier. The method by which this is done is beyond the scope of this chapter, but some illustrative results are presented in Figure 1.4.

SUBWATERSHED DELINEATION AND ANALYSIS

Subwatershed delineation is accomplished in two stages. In the first stage, flow vectors are used to follow each link from its upstream end to its downstream end, and to identify the cells

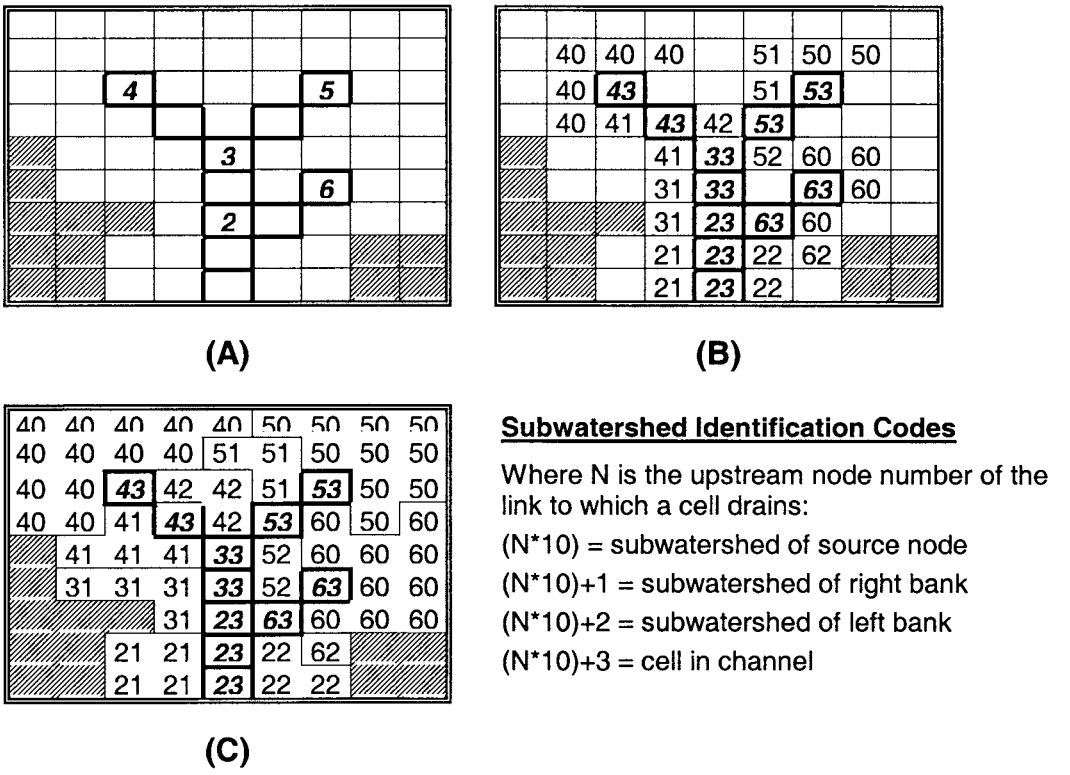

Figure 1.5. Subwatersheds defined by DEDNM from the flow vectors in Figure 1.3: (A) highlighted channel network cells and node numbers of sources and junctions; (B) subwatershed codes assigned to all cells adjacent to the network cells; (C) subwatershed codes assigned to all cells in the watershed. Shaded cells are outside the watershed.

which are immediately adjacent and contribute flow to the link. These cells are classified according to whether they are on the left bank, the right bank or, in the case of exterior links, contribute flow directly to a source node. A subwatershed identification code based on the previously assigned node numbers is applied to each classified cell. In the second stage, the entire grid is scanned and all cells in the main watershed that have not been assigned a subwatershed code are evaluated to determine if they contribute flow to a cell which has been assigned a subwatershed code. If so, it is assigned the code of the cell to which it flows. This is repeated until all cells have been assigned a code. The subwatershed identification process is illustrated in Figure 1.5.

Once the subwatersheds have been identified, they can be evaluated to determine their individual slope, aspect, and overland flow distance properties. These variables were measured directly in the original DEDNM. In the TOPAZ digital landscape analysis system, of which DEDNM is now a part, a separate raster processing program (RASPRO) now performs this and several other functions (Garbrecht and Martz, 1997).

CONCLUSIONS

The computer program DEDNM was developed with the primary objective to assist the rapid parameterization of hydrologic surface runoff models using DEMs similar to those provided by the USGS for 7.5-minute quadrangles. The set of algorithms developed for this purpose provide:

1. Raster maps including the corrected DEM, the flow patterns, the drainage network, and the extent of the main watershed and its subwatersheds.
2. Channel and subwatershed indexing by node identification numbers.
3. Tables of channel and subwatershed attributes, and of drainage network and subwatershed composition.

DEDNM is able to process limited resolution DEM data of low and high relief terrain to provide results that are both conceptually valid and consistent with the topographic characteristics of the landscapes to which it is applied. A more comprehensive evaluation of the capabilities of the program to reproduce the results of a traditional manual analysis of the blue-line network of topographic maps has been undertaken and is reported in the following chapter.

While the essential approach to drainage analysis introduced in DEDNM has remained largely unchanged, the software has been continuously modified and improved. One of the more significant changes has been the incorporation of DEDNM into TOPAZ, a more comprehensive digital landscape analysis system (Garbrecht and Martz, 1997), in which DEDNM provides the core function of network delineation and watershed segmentation from raster digital elevation data.

The TOPAZ digital landscape analysis system processes and evaluates raster DEMs to identify topographic features, measure topographic parameters, define surface drainage, subdivide watersheds along drainage divides, quantify the drainage network and parameterize subcatchments. The core drainage analysis provided by DEDNM allows TOPAZ to maintain consistency between all derived data, the initial input topography, and the physics underlying energy and water flux processes at the landscape surface. The primary objective of TOPAZ is to support hydrologic modeling and analysis, but it can also be used to address a variety of geomorphological, environmental and remote sensing applications.

CHAPTER 2

Assessing the Performance of Automated Watershed Segmentation from Digital Elevation Models

By Jurgen Garbrecht and Lawrence W. Martz

INTRODUCTION

Watershed segmentation and channel network definition is often required in distributed hydrologic modeling. Manual segmentation from maps is a tedious, time-consuming, and subjective task, particularly for large watersheds. The automated watershed segmentation and extraction of channel network and subwatershed properties from raster elevation data represents a convenient and rapid way to parameterize a watershed. The increasing availability of DEM coverage for many areas of the United States makes this automated watershed segmentation and characterization a promising approach for a wide range of hydrologic investigations. However, assessment of the generated watershed data beyond the usual visual inspection is required to develop confidence in the automated approach.

Early research on automated landscape analysis focused on algorithm development and treatment of unique situations, such as depressions, flat areas, or the connectivity of the network. DEM processing models which identify upward concave areas (Pueker and Douglas, 1975; Jenson, 1985; Band, 1986) often produce discontinuous network segments that must subsequently be connected (O'Callaghan and Mark, 1984) and may require additional adjustments to produce a reasonable pattern (Douglas, 1986). Other models rely on flow routing concepts. In this approach, the steepest downslope direction defines the flow paths (Jenson and Domingue, 1988; Martz and de Jong, 1988; Morris and Heerdegen, 1988). For either approach, problems arise in low relief terrain when the vertical resolution of the DEM is insufficient to identify either upward concave areas or a downslope flow direction. Little work has been done to extend DEM processing methods to low relief terrain, such as found in the central plains of the U.S.

This chapter investigates the performance of automated watershed segmentation, channel network identification, and subwatershed definition in low relief terrain for an 84 km^2 watershed. The landscape analysis computer program chosen from this study is the Digital Elevation Drainage Network Model DEDNM (Martz and Garbrecht, 1992, 2001). Program DEDNM is the main component of a larger landscape analysis program called TOPAZ (TOpographic PArameteriZation) (Garbrecht and Martz, 1999, 2000). The approach used by program DEDNM is similar to that of other DEM processing models that are based on flow routing concepts, but it includes enhancements for processing low relief landscapes where the rate of elevation change may be only a few meters per kilometer over large areas. The program is designed for the resolution of the USGS 7.5′ DEMs (1 meter or 1 foot elevation increments for 30 m grid cells) and targets parameters that are of

hydrologic interest. Even though program DEDNM was designed primarily for hydrologic and water resources investigations, it is equally applicable to address a variety of geomorphological, environmental, and remote sensing applications. The performance of program DEDNM is evaluated by comparing the generated watershed subdivisions, channel network, and other derived parameters to those obtained by traditional evaluation methods using USGS 7.5′ minute topographic maps.

THE APPLICATION WATERSHED

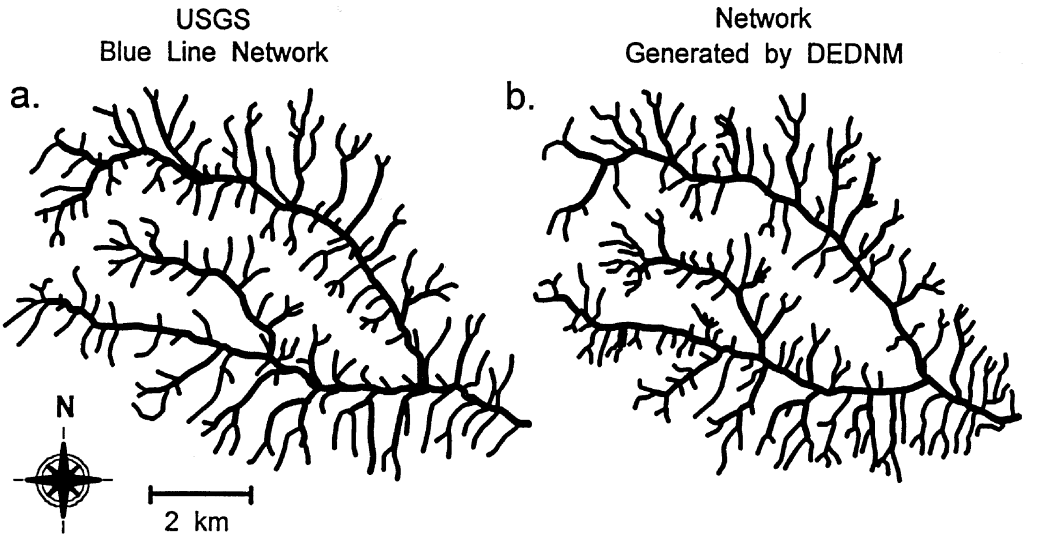
Bills Creek watershed drains an 84 km ^{2} area of the Little Washita River watershed, a USDA-ARS experimental watershed in southwestern Oklahoma. The terrain consists of gently rolling hills, and land use is predominantly rangeland with some cultivated areas. The source and the outlet of Bills Creek are at 420 m and 336 m above MSL, respectively. With a longitudinal distance of 16.5 km, the average main channel slope is about 0.005 m/m. Channel slopes as low as 0.003 m/m and flat flood plain areas extending over several hectares are not uncommon toward the outlet of Bills Creek watershed.

USGS 7.5′ DEM coverages from the geographic area under consideration are not available, and a previously generated DEM of the ARS experimental watershed is used to conduct this study. The DEM was generated in 1987 by the NASA Stennis Laboratory, Slidell, Louisiana, from USGS 7.5′ topographic maps. Elevation data are given for 30 m grid cells in 0.91 m (3-foot) increments. These DEM characteristics are similar to the USGS 7.5′ DEM coverages which have a 30 m grid spacing and a 1 m vertical resolution. A three-dimensional, vertically enhanced representation of Bills Creek watershed is shown in Figure 2.1 (see color section). With a vertical resolution of 0.91 m, parts of the gently sloping floodplains appear as flat areas and include a number of apparent depressions or pits which are artifacts of the DEM. Such spurious depressions are often encountered in low resolution DEMs of terrain with limited relief and usually arise from input errors, interpolation procedures, elevation rounding and limited DEM resolution. These produce under- and overestimation of elevation values of individual or groups of DEM cells which then can result in spurious depressions. The extent of the flat areas and depressions in Bills Creek watershed are illustrated in Figure 2.2 (see color section). They can be seen to be closely associated with channel bottom lands and drainage divides. The low channel slopes, flat areas, and spurious depressions in the DEM of Bills Creek watershed make it an appropriate low relief application for evaluating watershed segmentation and channel network generation capabilities of program DEDNM.

The channel network, defined by the blue-line channels on the USGS 7.5′ topographic maps (Figure 2.3a), is the map-based network against which the generated network is assessed. It should be recognized that a channel network is a dynamic drainage feature that can change in time as a function of climate, land use, and other land surface parameters. Thus, any channel network defined from topography alone is the reflection of past runoff and erosional activities and may not necessarily be representative of current runoff conditions. Other methods such as contour crenulation or slope analysis can also be used to define the channel network, but they also have limitations. The blue-line method (Morisawa, 1957) was selected because it is the simplest and one that most readers are familiar with, and despite its limitations, it is a standard that is readily available for most watersheds in the United States. The map-based network of Bills Creek watershed is of 5th Strahler order (Strahler, 1957) and of magnitude 180 following Shreve's (Shreve, 1967) classification.

BOUNDARY CONDITIONS FOR WATERSHED SEGMENTATION

Program DEDNM requires that two channel network parameters be specified for the automated watershed segmentation: the critical source area and the minimum source channel length. The crit-

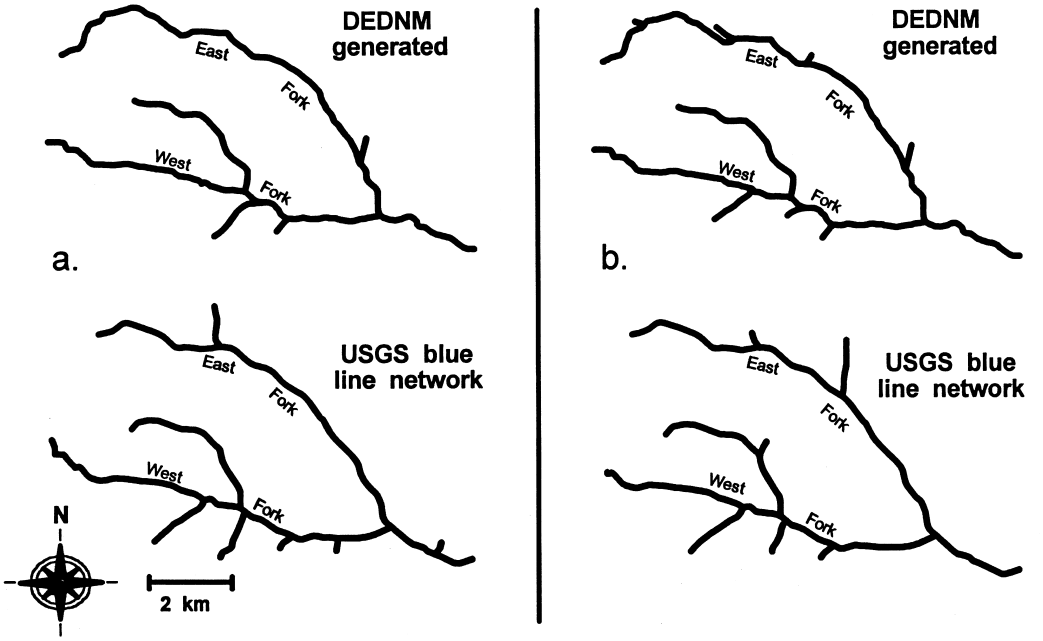


Figures 2.3a and 2.3b. Channel network of Bills Creek watershed: (a) blue-line network from USGS 7.5′ topographic maps; (b) generated network by DEDNM.

ical source area is the drainage area required to support a permanent channel. Its value is related to soil characteristics, vegetation cover, climatic conditions, and terrain slope. It also varies with map scale when maps are used as the basis for network definition (Scheidegger, 1966). For the present application, the critical source area was determined from the USGS 7.5′ topographic maps and was about 9 ha. The minimum channel length for source channels is a parameter that is necessary to control the identification of very short channels that satisfy the critical source area criterion, but have no real significance at the scale of the USGS 7.5′ topographic maps. Therefore, a threshold length below which first order channels are not generated is specified. This threshold length for Bills Creek was determined from the USGS topographic maps to be 130 m. With only these two input channel network parameters, the DEM can be processed by program DEDNM, and a segmented watershed, and channel network and subcatchment parameters can be extracted from the DEM. As part of this processing, the spurious depressions in the DEM are first removed by raising the elevation of the cells within the depressions to the elevation of the lowest outlet cell on the outside edge of the depression. The watershed segmentation and channel network and subcatchment parameter extraction is then performed on this depression-free DEM.

RESULTS

Program DEDNM generates raster maps of the channel network, subwatersheds, and other drainage parameters. The watershed segmentation is represented by the drainage boundaries of the subcatchments and the channel network. As examples of generated raster maps, the raster map of elevation contours, flow vectors, and subwatersheds boundaries, including the generated channel network, are displayed in Figures 2.4, 2.5, and 2.6, respectively (see color section). Program DEDNM also produces attribute tables that can be used for subwatershed parameterization, distributed surface runoff modeling, or other purposes. In the following discussion, network and sub-



Figures 2.7a and 2.7 b. Generated and measured channel networks for (a) channels of third and higher Strahler order; (b) channels of fifth and higher Shreve magnitude.

watershed raster and attribute data are compared to values derived from USGS 7.5′ topographic maps by traditional methods.

Evaluation by Visual Appearance

The channel network generated by program DEDNM (Figure 2.3b) is similar to the blue-line map-based network derived from the USGS 7.5′ topographic maps (Figure 2.3a). Differences are apparent, particularly at the level of source channels. Some source channels are generated at locations where there are none on the USGS maps, although contour crenulation suggests the presence of a channel in most of these cases. The reverse is also true; source channels with small upstream source area are shown on the USGS maps, but are not generated by program DEDNM. Other source channels differ by their length. The primary reasons for these differences are the ambiguity in the definition of a source of a channel, natural variation in channel characteristics within the network, and the use of only two parameters to generate the entire network. The two-parameter approach used by program DEDNM (critical source area and minimum source channel length) can reproduce average channel properties, but cannot account for random or spatial variability of these properties within the watershed. When such spatial variability is important, the user must either apply the program to each homogeneous subarea separately, or introduce a variable channel maintenance constant and minimum source channel length.

The differences between the two networks diminish for higher channel magnitude or Strahler order. This increasing similarity is demonstrated for third and higher Strahler order channels (Figure 2.7a), and for fifth and higher Shreve magnitude channels (Figure 2.7b). In both cases, the main channel, the East and West Fork, and several larger tributaries are well reproduced. The few

remaining differences are channels that exist in both networks, but are not represented because they did not meet the order or magnitude selection criterium used to generate the illustrations.

Comparison of Selected Channel Network Parameters

The selected parameters used to compare the generated and map-based channel networks are listed in Table 2.1 and represent the topologic, geometric, and hydrographic characteristics of the networks. The parameter values are representative of the average network characteristics of the entire network and do not reflect spatial variations within the watershed. As indicated earlier, spatial variability can be accounted for by either evaluating each homogeneous subarea separately, or introducing a variable channel maintenance constant and minimum source channel length.

The watershed Strahler order and the Shreve magnitude are nearly identical for the generated and map-based channel networks. The number of channel links and the link lengths are reproduced with a mean difference of less than 2%.

The channel slope values shown in Table 2.1 are length weighted values; i.e., long channels are assumed to be more representative of average network conditions. The mean slope of the generated channel links is about 23% lower than the slope derived from the map-based network. For interior links the difference is 10%, whereas for exterior links it is 27%, suggesting that exterior links are the primary reason for the discrepancy. Exterior links are the same as first order channels or source channels.

Table 2.1. Selected Network Parameters for Generated and Map-Based Networks and Corresponding Deviations

Parameter	Generated Network	Map-Based Network	Deviation %
Strahler order	5	5	0.0
Shreve magnitude	182	180	1.1
Number of channel links total	363	359	1.1
Exterior links	182	180	1.1
Interior links	181	179	1.1
Channel length [m]			
Total length	188706	187980	0.4
Mean link	520	524	–0.8
Mean exterior link	648	643	0.8
Mean interior link	391	407	–3.9
Channel slope [m/m]			
Mean	0.0170	0.0221	–23.1
Exterior links	0.0212	0.0289	–26.6
Interior links	0.0101	0.0112	–9.8
East Bills Creek	0.0055	0.0051	7.8
West Bills Creek	0.0066	0.0063	4.7
Drainage area [ha]			
Total area	8405	8442	–0.4
Mean links	23.2	23.7	–2.1
Above channel source	9.4	9.0	4.4
Drainage density [1/m]	0.0023	0.0022	4.5

The ambiguous and subjective definition of source channels, natural variations in source channel characteristics, the coarse vertical resolution of the DEM, and the use of only two parameters to generate the entire network are believed to lead to the observed differences. A more representative comparison of channel slope is achieved by computing the slope over long channel stretches, such as for the East and West Fork of Bills Creek. For these two channel stretches, the mean slope from source to watershed outlet is reproduced with less than 10% discrepancy. This illustrates that even though large differences in slope may exist for individual channel links, the average slope over long channel stretches is reasonably approximated by program DEDNM.

The total watershed area and mean direct drainage area feeding channel sources and channel links are reproduced within 4%. Finally, the drainage density of the generated network is within 5% of that of the validation network.

Comparison of Channel Network Composition

The channel network composition is quantified by the bifurcation, length, slope, and upstream area ratios, as defined by Horton (1945) and Schumm (1956). These ratios define the rate of change of a variable with channel order and incorporate a relative measure of the variable magnitude for each order. The channel network composition analysis complements the previous analysis of selected network parameters because it measures change of parameter value with channel order.

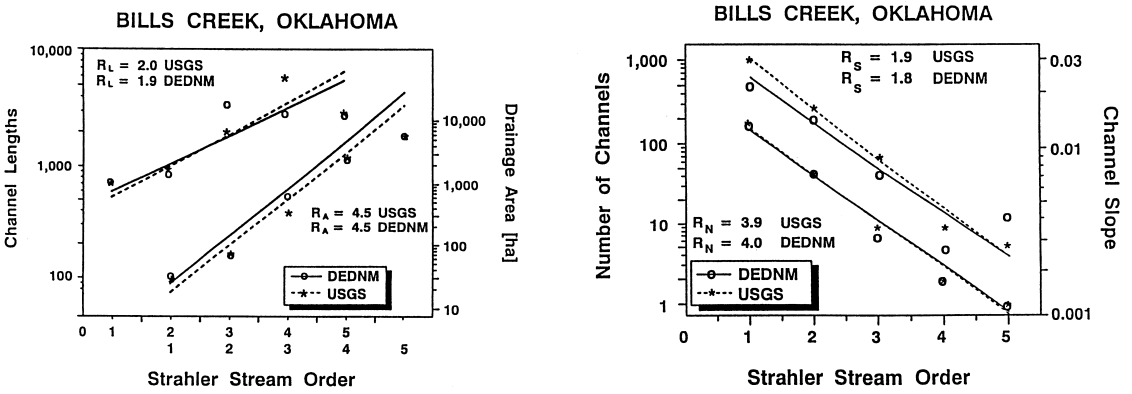
The average value of the four ratios for the generated network is within 4% of that obtained for the map-based network (Table 2.2). The slope and relative position of the regression lines in Figures 2.8a and 2.8b graphically represent the ratios. In all four cases, the regression lines are quite similar in slope and position. This close agreement shows that the general character of a system of channels is reproduced by the automated network extraction. Variations in parameter values for individual Strahler orders are primarily the result of the stochastic nature of the Strahler ordering system. As previously reported by Gregory and Walling (1973), and Scheidegger (1966 and 1970), the stochastic aspect of Strahler's ordering sometimes result in different order values for corresponding channel segments in two very similar networks. This is why direct comparisons of parameter values for individual Strahler order are not necessarily conclusive and are not performed here.

Table 2.2. Ratios of Channel Network Composition

Parameter	Generated Network	Validation Network	Deviation %
Bifurcation ratio	4.00	3.92	2.0
Length ratio	1.87	2.02	–7.4
Slope ratio	1.79	1.90	5.8
Area ratio	4.54	4.54	0.0

DISCUSSION AND CONCLUSIONS

In this chapter, the channel network generated by program DEDNM for an 84 km^2 low relief watershed is compared to the one defined by the blue-line method on the USGS 7.5′ topographic maps. The selected watershed included flat areas and depressions along the valley bottom, and flat areas near drainage divides. The depressions are usually artifacts of the DEM and have been removed by raising the elevation of the cells within the depression to the elevation of the lowest outlet cell on the outside edge of the depression. The watershed segmentation and channel network and subcatchment properties are generated from this depression-free DEM.



Figures 2.8a and 2.8b. Channel network composition: (a) length and area ratios, R_L and R_A; (b) bifurcation and slope ratios, R_N and R_S.

The visual appearances of the generated and map-based channel networks are very similar, and so are the channel network composition parameters which display an average discrepancy of less than 5%. Other selected network parameters that describe the channel network also show good correspondence. For example, the generated watershed Strahler order, the Shreve magnitude, the number of channel links, the channel link length, the drainage area, and the drainage density are within less than 5% of those of the map-based channel network. The average discrepancy for all parameters used in this study is also less than 5%. The largest differences are found for channel slope. The reason for the larger discrepancies in longitudinal channel slope values is primarily the ambiguous definition of first order channels in the map-based channel network, the coarse DEM resolution, and natural variations in channel characteristics within the network which cannot be reproduced by the two-parameter model of program DEDNM. Spatial differences between generated and map-based channel networks occur because channel generation criteria are applied uniformly to the entire network and, therefore, cannot reproduce spatial variability within the channel network. For investigations where spatial variation is important, program DEDNM should be applied to subareas that are homogeneous. In general, the close agreement between the various parameters describing the overall channel network and subwatershed characteristics demonstrates the ability of program DEDNM to overcome the problems associated with ill-defined drainage boundaries and indeterminate flow paths in low relief terrain.

Based on the experience of this application, further improvements have been introduced into program DEDNM. These include the capability to reproduce spatial variability in the generated channel network and subcatchments within the watershed and to treat spurious depressions by a combination of breaching and filling which is more appropriate given that spurious depressions arise from elevation over- and underestimation. These improvements are covered in a separate chapter of this book. Program DEDNM with these improvements and other additions are available in a software package called TOPAZ (TOpographic PArameteriZation) (Garbrecht and Martz, 1997).

CHAPTER 3

Development of a Basin Geomorphic Information System Using a TIN-DEM Data Structure

Yasuto Tachikawa, Michiharu Shiiba, and Takuma Takasao

INTRODUCTION

When developing a distributed rainfall-runoff model using Digital Elevation Models, it is important to consider the method with which a spatial distribution of elevations is represented, because the method of a surface representation determines the structure of a distributed rainfall-runoff model. Three principal methods for structuring a network of elevation data are square-grid networks, contour-based networks, and triangulated irregular networks (Moore et al., 1991).

Using contour-based networks, a watershed basin can be subdivided into irregular polygons bounded by contour lines and adjacent to their orthogonals (flow trajectories) that define the boundaries of drainage areas (O'Loughlin, 1986; Moore et al., 1988). Moore and Foster (1990) modified these methods and provided a structure for modeling overland flow, TAPES. For dynamic hydrologic modeling, contour-based methods have a great advantage in considering the directions of water flow, but they need heavy data storage and much computation time.

Square-grid networks are the most common form of DEMs used for topographic analysis of a river basin (O'Callaghan and Mark, 1984; Band, 1986; Hutchinson, 1989; Tarboton et al., 1989; Takasao and Takara, 1989; Takara and Takasao, 1991), and rainfall runoff modeling (Lu et al., 1989; Wyss et al., 1990; Quinn et al., 1991). Grid-based DEMs have advantages for their ease of computational implementation, efficiency, and availability of topographic databases. However, when considering the directions of water flow, these methods are not appropriate for hydrological applications because those trajectories represent only crudely the movements of water from one grid to one of the eight neighboring grids.

A more applicable approach for hydrological modeling is the Triangulated Irregular Networks (TINs). Palacios and Curvas (1986; 1991) made it possible to delineate river-course and ridge of a watershed basin automatically with these methods and to simulate surface runoff production. Jett et al.(1979), Jones et al.(1990) and Vieux (1991) also used TINs for representation of a watershed basin.

This chapter describes a TIN-based topographic model which incorporates the advantages of grid-based methods and contour-based methods. First, a topographic surface is represented by a TIN-DEM generated by a grid-DEM and a DLG (Digital Line Graph) of river courses. Then, these triangle facets are subdivided by the steepest ascent lines (flow trajectories), so each triangle has only one side through which water flows out. Using these triangles, the discretization of a basin similar to contour-based methods is realized.

TIN-DEMS DATA STRUCTURE

In the TIN-DEMs generating system for representing a natural topography of a basin, three datasets are produced: (1) a triangle network data set, (2) a vertex data set, and (3) a channel network data set. A sample triangle data set and its network are illustrated in Tables 3.1, 3.2, and Figure 3.1. Each of the triangles, squares, and vertices is indexed by a number which is given to specify it.

The vertex data set contains the x, y, and z values of the vertices. The triangle network data set contains the properties of triangles. Each triangle is described by an index of the square in which the triangle is contained; indices of its three vertices; indices of three triangles which are adjacent to the triangle; three 'side-attribute-indices' which specify whether water flows into the side, along the side, or out of the side; three 'side-component-indices' which specify whether the side forms a part of valley, channel, slope, ridge, or boundary of a study area; and unit normal vectors of a triangular facet. The indices of vertices, the side-attribute-indices, and the side-component-indices are ordered in a counterclockwise direction.

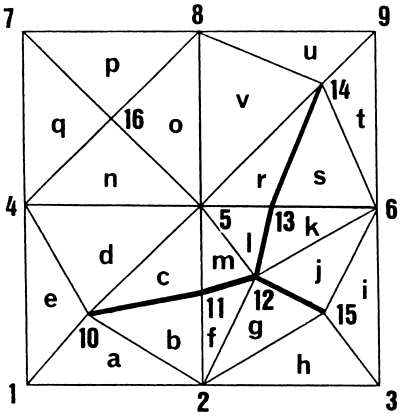

Figure 3.1. Sample triangle network.

Table 3.1. Triangle Network Data Set for Sample Triangle Network Shown in Figure 3.1

Triangle	No. of Squares	No. of Vertices	Adjacent Triangles	Side-Attribute Indices[a]	Side-Component Indices[b]	Unit Normal Vectors
a	1	1 2 10	null b e	3 1 2	0 2 2	–0.71 0.71 0.07
b	1	2 11 10	f c a	2 1 3	2 3 2	–0.71 0.71 0.07
c	1	11 5 10	m d b	3 3 1	2 2 3	–0.89 –0.41 0.09
.	.	.	.	.	.	.
.	.	.	.	.	.	.
.	.	.	.	.	.	.

[a]Side-Attribute Index: 1 = out-flow side; 2 = along-flow side; 3 = in-flow side.
[b]Side-Component Index: 0 = boundary of TIN-DEM; 1 = valley segment; 2 = slope segment; 3 = channel segment; 4 = ridge segment.

A side-attribute index of a side is set to be 1, 2, or 3, depending on whether water flows out of a side, along a side, or into a side, and the side is defined as an out-flow-side, an along-flow-side, or an in-flow-side, respectively. Whether water flows out of a side, along a side, or into a side is decided by the cross product of the steepest descent vector of a triangle and a side of the triangle. For example, in Figure 3.2 water on triangle abc flows out to the adjacent triangle through ab. In this case, the z-component of the cross product g x ab is positive, so the side-attribute-index of ab is set to be 1. Similarly, water flows into this triangle from the adjacent triangles through bc and ca. In this case, the z-components of g x bc and g x ca are negative, so side-attribute-indices of bc and ca are set to be 3. If water flows along a side, the cross product is equal to zero, and the side-attribute-index is set to be 2.

Table 3.2. Vertex Data Set

Vertex	x	y	z
1	25.00	100.00	301.25
2	50.00	100.00	287.55
3	75.00	100.00	288.89
.	.	.	.
.	.	.	.
.	.	.	.

A side-component-index of a side is set to be 0, 1, 2, 3, or

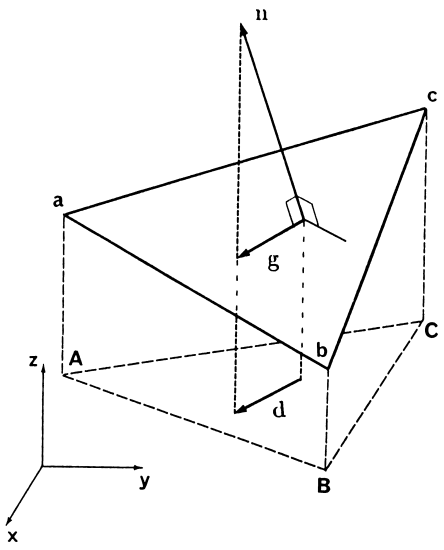

Figure 3.2. Sample triangle facet.

4, depending on whether the side constitutes a part of a boundary of a TIN-DEM, valley, slope, channel, or ridge, respectively. What value a side-component-index is set to be is decided by the side-attribute-indices of the sides which are held in common by the adjacent triangles.

If the common sides of the adjacent triangles are composed of an out-flow-side and an out-flow-side, the sides represent part of a valley. Similarly, if composed of an in-flow-side and an in-flow-side, the sides represent part of a ridge. The relation between a side-attribute-index and a side-component-index is shown in Table 3.3.

A sample channel data set and its network is illustrated in Table 3.4 and Figure 3.3. For a logical representation of a channel network in a computer, a channel network is represented by a set of links which are composed of the sections of a channel network between the terminal point of a channel network and a confluence, a confluence and another confluence, or a confluence and the upstream ends. Each link is also indexed by a number which is given to specify it. The channel network data set is represented by the index of a link, the index of the downstream link, the indices of the upstream links, the indices of vertices which form the link, and the indices of the triangles which are adjacent to the link.

BGIS (BASIN GEOMORPHIC INFORMATION SYSTEMS)

The BGIS consist of interactive software for generating TIN-DEMs data structure and topographic analysis software which contain an automatic delineation of source areas to arbitrary part

of a channel network and mapping of a distribution of elevations, slopes, aspects, flow path lengths, and upslope contributing areas. A schematic outline of the BGIS is shown in Figure 3.4.

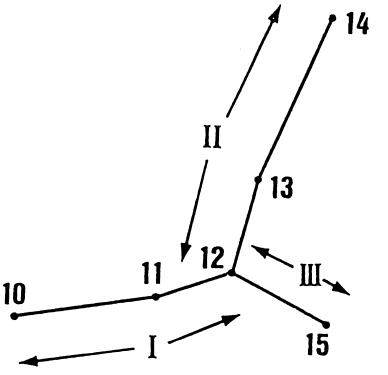

Figure 3.3. Sample channel network.

Source Data Sets

Source data sets are grid DEMs and DLGs of river courses. These data sets, produced by government agencies such as the United States Geological Survey (USGS) or the National Land Agency in Japan, are easily obtained. If source data sets for a particular study area are not available, they can be derived by digitizing contour lines and river courses on a topographic map by using a flatbed digitizer.

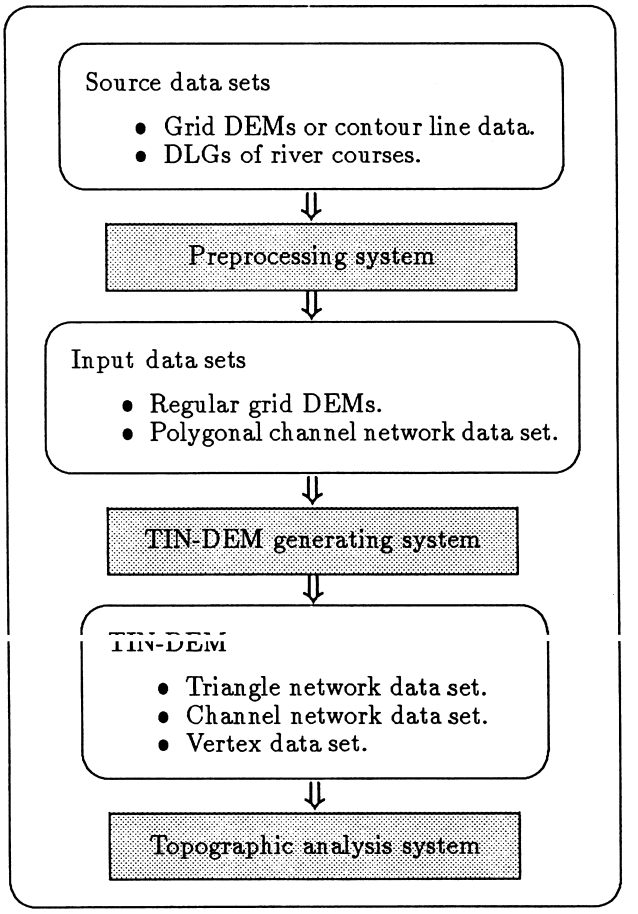

Figure 3.4. Schematic outline of BGIS.

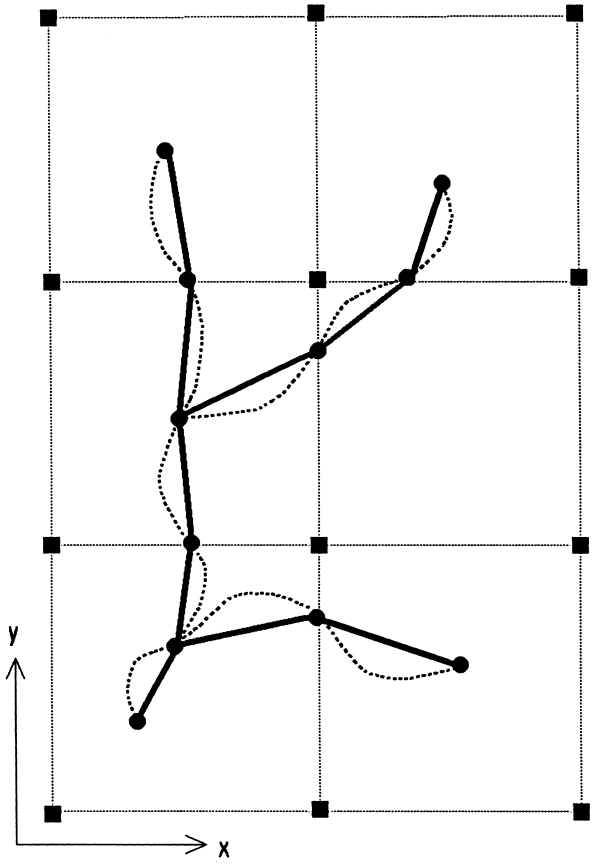

Figure 3.5. Schematic representation for making a polygonal channel network. Dashed lines denote a DLG of river courses. Solid lines denote a polygonal channel network.

Preprocessing System

From these source data sets, (1) a regular grid DEM, and (2) polygonal channel network data for a study area are produced. A regular grid DEM is interpolated from a grid DEM or contour line data. Polygonal channel network data are made up of polygonal lines which are derived by calculating the intersection of a straight line which connects two points on a regular grid DEM and a segment which connects two continuous points on a DLG of river courses (Figure 3.5).

TIN-DEMs Generating System

The two data sets made by the preprocessing systems are input into these systems and the three data sets noted in the TIN-DEMs DATA STRUCTURE section are generated. These systems include the following modules:

(a) a module for generating triangles from a regular grid DEM;
(b) a module for getting rid of pits;
(c) a module for joining discontinuous valley segments to a channel network; and
(d) a module for subdividing triangular facets.

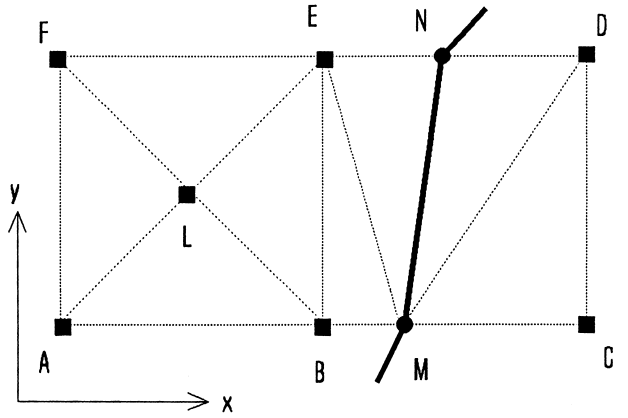

Figure 3.6. Automatic division of squares into triangles.

Module for Generating Triangles from a Regular Grid DEM

A data set which represents a basin with triangular facets based on a regular grid DEM and a polygonal channel data set are generated. For example, in Figure 3.6, the points A, . . . , F represent vertices on a grid DEM, and the segment MN represents a part of a channel network. For the square ABEF which has no channel segment in it, the point L is added in the center of the square, and it is subdivided to four triangles. The elevation of the added point L is interpolated using the elevations of four neighboring points. For the square BCDE which has one channel segment in it, it is subdivided to several triangles under the rule that the channel segment results in a side of a triangle. These two cases are processed automatically. In other cases, for example, a square which has more than one channel segment in it, and a square which has confluence points, upper ends of a channel network or a downstream end of a channel network in it, are subdivided using an interactive software. An operator can add new points if needed, make triangles manually, and see the result of a subdivision on a computer display. Figure 3.7 shows the example of a subdivision. The shaded area has already been subdivided into triangles. Squares which an operator needs to subdivide into triangles are not so many that the interactive handling of these subdivisions is not laborious and not time-consuming. After subdividing all the squares into triangles, side-attribute-indices, side-component-indices, and unit normal vectors of each triangular facet are computed, and the vertex data set, the triangle network data set, the channel network data set are produced.

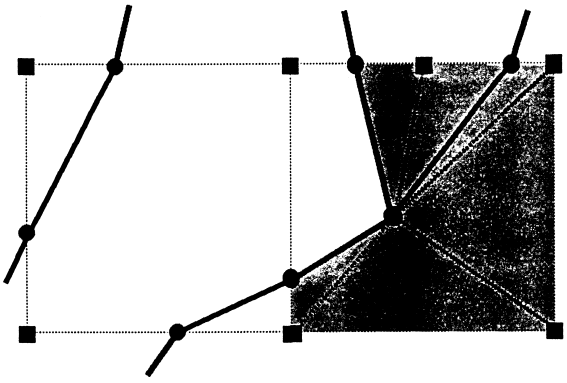

Figure 3.7. Interactive division of squares into triangles.

Module for Getting Rid of Pits

A pit is a vertex whose surrounding vertices have higher elevations. If a natural topography is so complicated to represent it using a grid DEM with a current grid spacing, sometimes false pitting occurs. In this module, a pit is found automatically and solved by adding a new

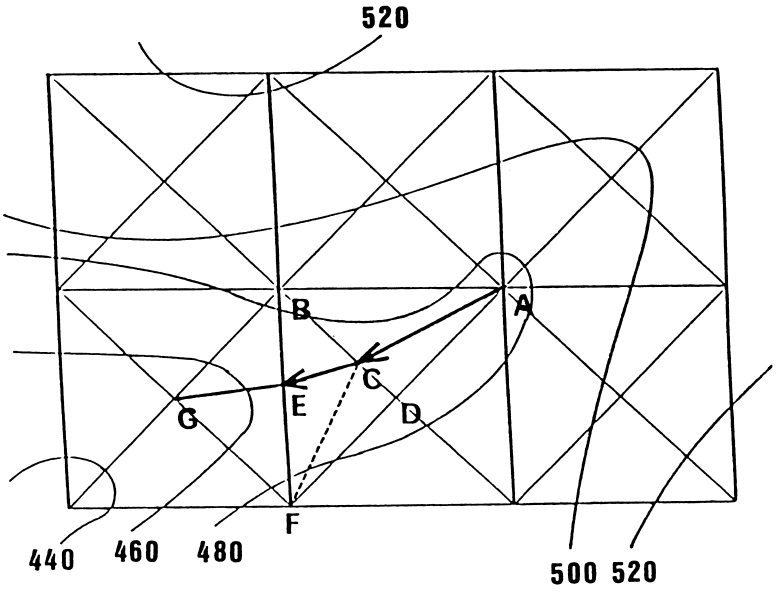

Figure 3.8. Schematic representation for getting rid of pits.

point and subdividing to triangles interactively. An algorithm for getting rid of a pit can be accomplished by following five steps:

Step 1: Find a vertex whose elevation is lower than the surrounding vertices (A, in Figure 3.8).
Step 2: Based on a topographic map, add a new point C, considering the direction of water flow, and give an appropriate elevation to the point referring to a topographic map.
Step 3: Using the point C, subdivide triangle ABD to triangle ABC and triangle ACD, triangle BFD to triangle BFC and triangle FDC.
Step 4: Update the vertex data set and the triangle network data set.
Step 5: If the new point C is a pit, return to step 1 and repeat Step 1–5 until no false pits exist.

Module for Joining Discontinuous Valley Segments to a Channel Network

In a current model of a watershed basin, many valley segments exist. If these valley segments do not join a channel network, the channel segment the triangles contribute to cannot be defined. For example, for triangle bgk and triangle ikg in Figure 3.9, the channel segment they contribute to cannot be defined. To correct this, the channel segment that the valley segments reach to is determined, after which, these valley segments are included in the channel network and the channel network is reconstructed. An algorithm for this procedure is as follows:

Step 1: Find the lowest vertex in the continuous valley segments g in Figure 3.9.
Step 2: Trace the path of steepest descent from the lowest vertex until it reaches either a channel network or the boundary of the DEM.
Step 3: If it reaches to the channel networks, subdivide to triangles along the path of the steepest descent (in Figure 3.9, triangle ceg into triangle chg and triangle heg, triangle cde into triangle cdh and triangle deh).
Step 4: Update the vertex data set and the triangle network data set.

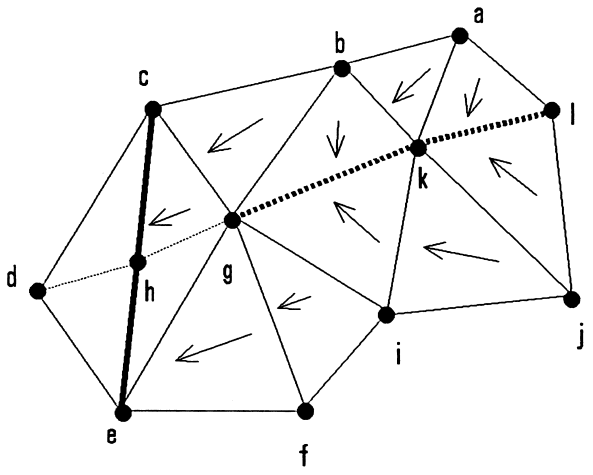

Figure 3.9. Schematic representation of discontinuous valley segment.

Step 5: Reconstruct a channel network and update the channel network data set. The channel networks before and after joining discontinuous valley to channel networks are shown in Figure 3.10.

Module for Subdivision of Triangles

Most of the triangles have two sides through which water flows out. To identify source areas, these triangles must be subdivided so that each triangle has only one out-flow-side contributing to only one adjacent triangle. An algorithm for this procedure is as follows:

Step 1: Trace a path of steepest ascent from a vertex, and find coordinates of an intersection on an opposite side.

Step 2: If the intersection is found on an opposite side (e on the segment bd in Figure 3.11), subdivide the triangle bcd to triangle bce and triangle cde, triangle abd to triangle abe and triangle aed.

Step 3: If the intersection exists on a ridge segment, stop. Otherwise continue until it encounters a ridge segment or a boundary of a TIN-DEM.

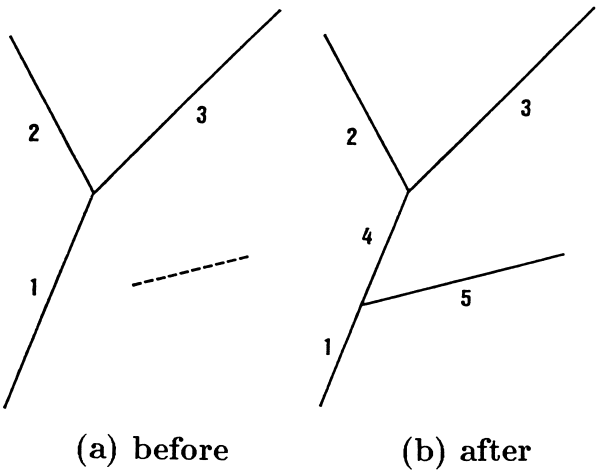

Figure 3.10. Reconstruction of channel network.

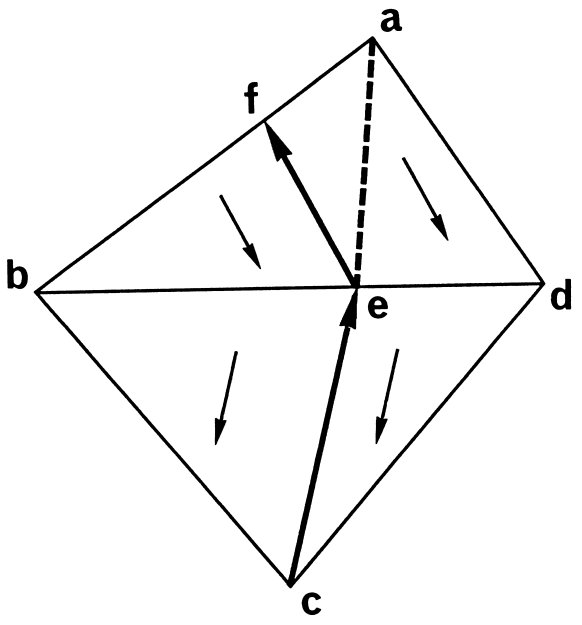

Figure 3.11. Subdivision to triangles which have one side through which water flows out.

This subdivision procedure is accomplished for all the vertices included in TIN-DEMs, but for new vertices added by this subdivision it is not necessary to apply this procedure.

APPLICATIONS

The BGIS was applied to three basins. Figure 3.12 shows a topographic map of the upper part of the Ara experimental basin. From this map, contour lines and a channel network were digitized manually by using a flatbed digitizer. Figure 3.13 shows the directions of water flow, ridges (bold solid lines), valleys (dashed lines), and the channel network (solid lines) for this study area. Figure 3.14 shows a three-dimensional representation of the basin, and the shaded areas represent the watershed basin delineated automatically.

Once the TIN-DEM data structure is generated, it is easy to identify source areas contributing to an arbitrary triangle. Each triangle has only one triangle which water flows into. When triangles which contribute to a particular triangle are found, a triangle from which water flows into it is found and added to a list of source areas recursively, until a triangle which has two ridge sides, or one ridge side and one along side, is added to the list. The channel network data set includes the numbers of the triangles which contact with a channel network, so by beginning this procedure with these triangles, all the triangles included in the watershed are identified.

Figures 3.15 and 3.16 show the Ara experimental basin (0.184 km^2) and the Ina basin (54.0 km^2). The number of vertices and triangles after processed by each module are represented in Table 3.5.

CONCLUSIONS

Geographic information systems in hydrologic modeling, the BGIS (Basin Geomorphic Information Systems) were presented for modeling a river basin using a TIN-DEM data structure. The BGIS are made up of interactive software for generating three data sets, (1) a vertex data set, (2) a triangle network data set, and (3) a channel network data set, and includes topographic analysis

Table 3.5. The Number of Triangles and Vertices after Processed by Each Module

	Ina Basin		Ara Experimental Basin	
Module	No. of Vertices	No. of Triangles	No. of Vertices	No. of Triangles
Module for generating triangles from a regular grid DEM	1123	2146	1058	2016
Module for getting rid of pits	1151	2202	1071	2042
Module for joining discontinuous valley segments to a channel network	1185	2240	1100	2100
Module for subdividing triangular facets	3900	7682	3304	6483
Grid spacing	250 m		25 m	
Number of pits	5		2	

software which makes an automatical delineation of source areas to an arbitrary part of a channel network and mapping of a distribution of elevations, slopes, aspects, flow path lengths, and upslope contributing areas.

This TIN-based topographic model incorporates the advantages of grid-based methods with their ease of computational implementation, efficiency, and availability of topographic databases, and combines the advantages of contour-based methods such as subdivision of a basin considering the direction of water flow. This form of discretization is advantageous for modeling water movement of a natural watershed basin.

CHAPTER 4

Basinsoft, a Computer Program to Quantify Drainage Basin Characteristics

Craig A. Harvey and David A. Eash

INTRODUCTION

Surface water runoff is a function of many interrelated factors including climate, soils, land-use, and the physiography of the drainage basin. A practical and effective method to quantify drainage basin characteristics would allow analysis of the interrelations of these factors, leading to an improved understanding of the effects of drainage basin characteristics on surface-water runoff. Historically, the quantification of drainage basin characteristics has been a tedious and time-consuming process. Recent improvements in computer hardware and software technology have enabled the developers of a program called Basinsoft to automate this process. Basinsoft requires minimal preprocessing of data and provides an efficient, automated procedure for quantifying selected morphometric characteristics and the option to area-weight characteristics for a drainage basin. The user of Basinsoft is assumed to have a limited amount of experience in the use of ARC/INFO, a proprietary geographic information system (GIS). (The use of brand names in this chapter is for identification purposes only and does not constitute endorsement by the U.S. Geological Survey [USGS].)

In 1988, the USGS began developing a program called Basinsoft. The initial program quantified 16 selected drainage basin characteristics from three source-data layers that were manually digitized from topographic maps using the versions of ARC/INFO, Fortran programs, and prime system Command Programming Language (CPL) programs available in 1988 (Majure and Soenksen, 1991). By 1991, Basinsoft was enhanced to quantify 27 selected drainage-basin characteristics from three source-data layers automatically generated from digital elevation model (DEM) data using a set of Fortran programs (Majure and Eash, 1991; Jenson and Dominique, 1988). Due to edge-matching problems encountered in 1991 with the preprocessing of the DEM data, the Basinsoft program was subsequently modified to quantify 24 selected drainage-basin characteristics from four source-data layers created from three types of data (topographic maps, digital line graph [DLG] data, and DEM data) (Eash, 1993, 1994). The early versions of Basinsoft relied primarily on Fortran programs and prime system CPL to manage data and calculate statistics, thus making them platform dependent.

In 1994, Basinsoft was redeveloped entirely using Arc Macro Language (AML), a postprocessing language written to run in ARC/INFO, to increase portability among systems using ARC/INFO version 7.0.2 or later (Environmental Systems Research Institute, 1994). The current (1997) version of Basinsoft processes four source-data layers representing selected aspects of a drainage basin to quantify selected morphometric drainage basin characteristics (Harvey and Eash, 1996). The 27 selected basin characteristics quantified by Basinsoft are listed in Table 4.1 as meas-

Table 4.1. Selected Drainage Basin Characteristics Quantified Using Basinsoft

Basin-Area Quantifications

TDA—Total drainage area[a,b], in square miles, an internal measurement maintained by ARC/INFO. TDA is acquired from the drainage-divide data layer (cover_bas) attribute table as the area measurement and it includes noncontributing areas.

NCDA—Noncontributing drainage area[a], in square miles, is the total area that does not contribute to surface-water runoff at the basin outlet. NCDA is obtained by computing summary statistics on the drainage-divide data layer (cover_bas) attribute table based on the item CONTRIB.

Basin-Length Quantifications

BL—Basin length[a], in miles, measured along a line areally centered through the drainage-divide data layer (cover_bas) from basin outlet to where the main channel extended meets the basin divide. This process uses ARC/GRID to calculate the centerline.

BP—Basin perimeter[a], in miles, measured along entire drainage-basin divide. BP is an internal measurement maintained by ARC/INFO and is acquired from the drainage-divide data layer (cover_bas).

Basin-Relief Quantifications

BS—Average basin slope[a,b], in feet per mile, measured by the "contour-band" method, within the contributing drainage area (CDA). Summary statistics are performed on the hypsography data layer (cover_con). The output from the statistics command is used in conjunction with the user-designated elevation-contour interval as input into the formula to calculate BS. BS = (total length of all selected elevation contours) (contour interval) / CDA.

BR—Basin relief[c], in feet, measured as the difference between the elevation of the highest grid cell and the elevation of the grid cell at the basin outlet. BR uses the lattice (grid) data layer (cover_lat) to determine the minimum elevation as the land-surface elevation at the basin outlet. The maximum elevation is determined from the lattice data layer (cover_lat) statistics INFO file item ZMAX.

Basin-Aspect Quantifications

BA—Basin azimuth[a,b], in degrees, compass direction of a line projected from where the main channel, if extended, meets the basin divide downslope to the basin outlet. Measured clockwise from north at 0°.

Basin Computations

CDA—Contributing drainage area[a,b], in square miles, defined as the total area that contributes to surface-water runoff at the basin outlet, CDA = TDA – NCDA.

BW—Effective basin width[a], in miles, BW = CDA / BL.

SF—Shape factor[a], dimensionless, ratio of basin length to effective basin width, SF = BL / BW.

ER—Elongation ratio[a], dimensionless, ratio of (1) the diameter of a circle of area equal to that of the basin to (2) the length of the basin, $ER = [4\ CDA / \pi\ (BL)^2]^{0.5} = 1.13\ (1/SF)^{0.5}$.

RB—Rotundity of basin[a], dimensionless, $RB = [\pi\ (BL)^2] / [4\ CDA] = 0.785\ SF$.

CR—Compactness ratio[a], dimensionless, the ratio of the perimeter of the basin to the circumference of a circle of equal area, $CR = BP/2\ (\pi\ CDA)^{0.5}$.

RR—Relative relief[d], in feet per mile, RR = BR / BP.

Channel- or Stream-Length Quantifications

MCL—Main channel length[a,b], in miles, measured along the main channel from the basin outlet to where the main channel, if extended, meets the basin divide. Summary statistics are computed on the hydrography data layer (cover_str) based on the item CODE.

TSL—Total stream length[c], in miles, computed by summing the length of all stream segments within the CDA using summary statistics on the hydrography data layer (cover_str) based on the item LENGTH.

Table 4.1. Selected Drainage-Basin Characteristics Quantified Using Basinsoft (Continued)

Channel-Relief Measurement

MCS—Main-channel slope[a,b], in feet per mile, an index of the slope of the main channel computed from the difference in streambed elevation at points 10% and 85% of the distances along the main channel from the basin outlet to the basin divide. A route system is developed based on the INFO-item CODE equal to 1 in the hydrography (cover_str) data layer. The 10% and 85% distances from the basin outlet are calculated and nodes are placed at those positions along the route. The nodes are converted to points and elevations are determined for each point from the lattice data layer (cover_lat) and attributed to a temporary data layer for use in the MCS formula. MCS = $(E_{85} - E_{10})$ / (0.75 MCL).

Channel or Stream Computations

MCSR—Main-channel sinuosity ratio[a], dimensionless, MCSR = MCL / BL.

SD—Stream density[a], in miles per square mile, within the CDA, SD = TSL / CDA.

CCM—Constant of channel maintenance[a], in square miles per mile, within the CDA, CCM = CDA / TSL = 1 / SD.

MCSP—Main channel slope proportion[c], dimensionless, MCSP = MCL / $(MCS)^{0.5}$.

RN—Ruggedness number[e], in feet per mile, RN = (TSL) (BR) / CDA = (SD) (BR).

SR—Slope ratio of main-channel slope to basin slope[c], dimensionless, within the CDA, SR = MCS / BS.

Stream-Order Quantifications

FOS—Number of first-order streams within the CDA[f], dimensionless. FOS is computed using Strahler's method of stream ordering and summary statistics on the hydrography data layer (cover_str).

BSO—Basin Stream Order[f], dimensionless, stream order of the main channel at the basin outlet. BSO is computed by intersecting the main channel with the drainage-divide data layer and determining the Strahler-stream order of the stream at the basin outlet.

Stream-Order Computations

DF—Drainage frequency[c], in number of first-order streams per square mile, within the CDA, DF = FOS / CDA.

RSD—Relative stream density[g], dimensionless, within the CDA, RSD = (FOS)(CDA)/$(TSL)^2$ = DF/$(SD)^2$.

urements or computations. Twelve of the drainage-basin characteristics constitute specific quantifications of area, length, relief, aspect, and stream order; the other 15 characteristics are computations that make use of the various quantifications to calculate other drainage basin characteristics or statistics.

Development of the Basinsoft program is continuing. Information presented in this chapter on Basinsoft is republished in a slightly condensed and modified version (reflects revisions to the current version of Basinsoft as of July 1997) from the report "Description, Instructions, and Verification for Basinsoft, a Computer Program to Quantify Drainage-Basin Characteristics" (Harvey and Eash, 1996). Information regarding the status of this program may be obtained by accessing the PixSell Home Page at http://www.pixsell.com or by sending an email to basinsoft@pixsell.com or by contacting PixSell, Bldg. 2105, John C. Stennis Space Center, Bay St. Louis, MS 39529.

Table 4.2. "Core" AMLs and Associated Functions

AML Name	AML Function[a]
basinsoft.aml	Driver AML, initiates other core AMLs.
basinit.aml	Initializes variables and creates an empty INFO table to hold drainage basin characteristics as they are quantified by Basinsoft.
bam.aml	Quantifies TDA, NCDA, and CDA.
clm.aml	Quantifies MCL and TSL.
azim.aml	Quantifies BP and BA.
orient.aml	Calculates and sets the global variable ".orient".
basinl.aml	Quantifies BL.
dfm.aml	Quantifies FOS, BSO, and DF.
brm.aml	Quantifies BS and BR.
crm.aml	Quantifies MCS.
computations.aml	Quantifies BW, SF, ER, RB, CR, RR, MCSR, SD, CCM, MCSP, RN, SR, and RSD.

[a]See Table 4.1 for description of drainage-basin characteristic quantifications.

BASINSOFT PROGRAM STRUCTURE

The AML programs comprising Basinsoft are initialized so that each program performs specific tasks and when necessary, passes information required by the following program for subsequent processing. By programming in this modular manner, additional or future modules are easily appended to Basinsoft by the user.

The "core" AML programs comprising Basinsoft, listed with their associated functions in Table 4.2, are referred to as modules in this chapter. Basinsoft.aml controls the modules found in the Basinsoft directory (Figure 4.1) and can be modified to control some of the utility programs found in the tools directory (Figure 4.1). Modules are executed each time Basinsoft is initiated. Drainage-basin characteristics are quantified within the modules. Examples of the directory structure required by Basinsoft are listed in Table 4.3 and shown in Figure 4.2.

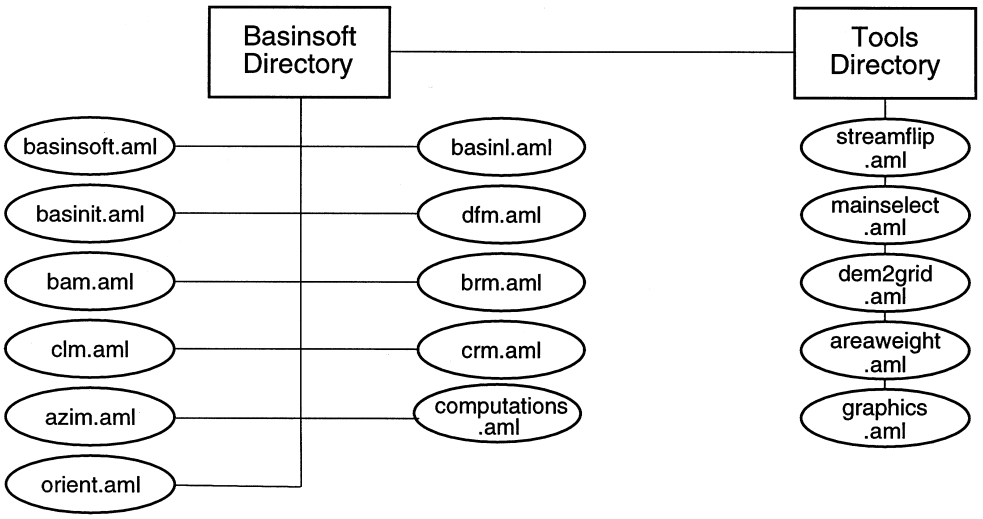

Figure 4.1. Example of Basinsoft program directory structure.

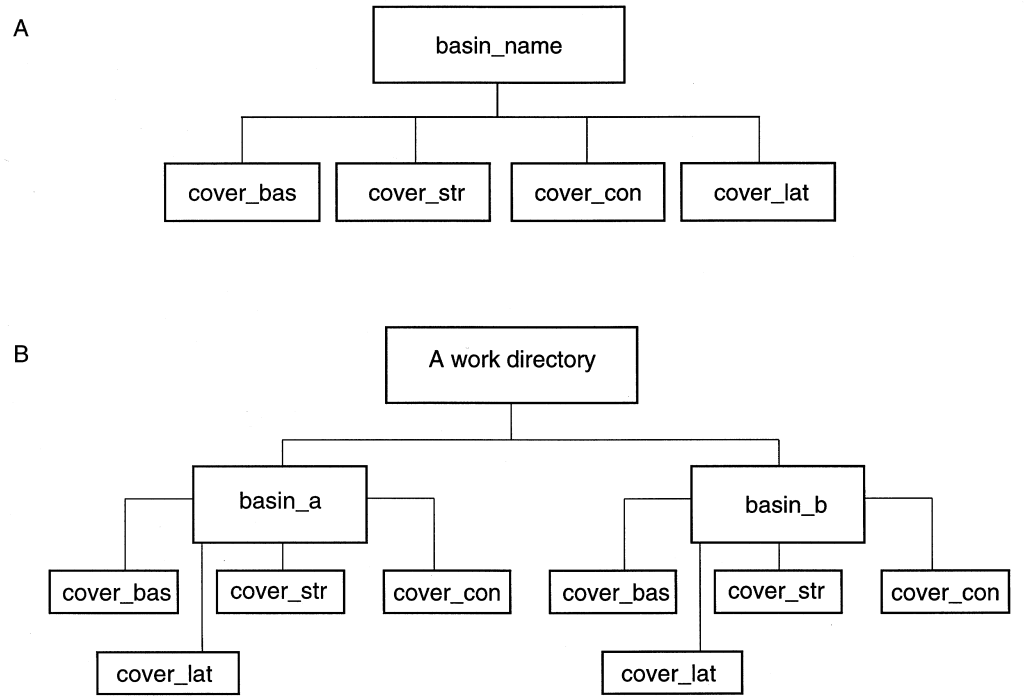

Figure 4.2. Naming conventions and directory structure required for processing multiple drainage basins—(A) generic directory structure of single basin, (B) actual directory structure for multiple basins (e.g., basin_a and basin_b) maintained under a work directory.

COMPUTER RESOURCES REQUIRED TO EXECUTE BASINSOFT

Basinsoft was developed and tested on Data General Avion model 300, 530, and 550 workstations using ARC/INFO version 7.0.2, and was subsequently ported to run on NT with ARC/INFO version 8.1. Basinsoft requires no compilation. Processing time to execute Basinsoft varies between 5 and 20 minutes on a Data General Avion 530 for drainage basins with areas less than 3,000 square miles. Processing time on other systems may vary depending on their hardware capabilities. These processing times do not include time for preprocessing, which will vary according to the type of source data available for generating the four source-data layers required as input to Basinsoft. The time to execute the TOPOGRID command may range from 5 minutes to more

Table 4.3. Naming Conventions and Description of Directory Structure Required by Basinsoft

Directory Name	Description of Directory
basin_name	This is the unique name defining a specific drainage basin (e.g., basin_a). The following data layers are source-data layers maintained under the basin_name directory.
cover_bas	Drainage-divide data layer.
cover_str	Hydrography data layer.
cover_con	Hypsography data layer.
cover_lat	Lattice data layer with areal extent clipped to drainage-basin boundary.

than 1 hour, depending on the size of the drainage basin and hardware capabilities. The basin-length module also is computer-time, memory, and disk-space intensive.

SOURCE-DATA REQUIREMENTS OF BASINSOFT

Basinsoft requires the user to provide four source-data layers. Figure 4.3 (see color section) shows examples of the four source-data layers, which are: (1) a drainage-divide (Figure 4.3A), (2) hydrography (Figure 4.3B), (3) hypsography (Figure 4.3C), and (4) a lattice elevation model (Figure 4.3D). These data layers are not required to be of any specific scale; however, the hydrography and hypsography data layers should be clipped to the areal extent of the drainage-divide data layer. The lattice elevation model is preprocessed into a lattice data layer—cover_lat, with the same areal extent as the drainage-divide data layer.

Several programs were developed to assist the user in preprocessing source-data layers in preparation for use with Basinsoft. These programs, which are found in the tools directory, perform various tasks such as creating a hydrologically accurate lattice elevation model, facilitating the creation of a hypsography data layer, and converting a 1:250,000-scale DEM to a lattice data layer. Several programs were developed to assist the user in assigning attributes to data layers according to a specialized attribute scheme required by Basinsoft.

PREPROCESSING OF SOURCE DATA FOR PROGRAM INPUT

Basinsoft was developed to run with minimal preprocessing; however, there are several steps required to prepare the source-data layers for subsequent processing by Basinsoft. Preprocessing steps include the generation of four source-data layers as described above and the assignment of attributes. The arc segments of the hydrography data layer must be edited using the streamflip.aml to orient the arc segments in a downstream direction. The main channel of the drainage basin must be delineated, attributed, and extended to the drainage-divide. AMLs were developed to assist the user with nearly all aspects of the preprocessing required by Basinsoft.

Preprocessing the Drainage-Divide Data Layer

The drainage-divide data layer (cover_bas) (Figure 4.3A) must be attributed with an INFO-item named CONTRIB. This item should have a value of ‘0’ (the default) for contributing drainage areas (CDA) and a value of ‘1’ for noncontributing drainage areas (NCDA); thus no attribute generation is necessary unless NCDA exist. A second INFO-item, BASINNAME, must be added to the drainage-divide data layer and attributed with an identifying name for the drainage basin.

Preprocessing the Hydrography Data Layer

The topology of the surface-water drainage network or hydrography data layer (cover_str) (Figure 4.3B) must be clean, and the main channel must be delineated and attributed with an INFO-item named CODE. The arc segments in the hydrography data layer (cover_str) must be oriented in a downstream direction. AML programs named streamflip.aml and mainselect.aml were developed to assist in performing these tasks and specialized attributing.

Streamflip.aml

The number of first-order streams (FOS) within a drainage basin is used to quantify three drainage basin characteristics. The number of first-order streams is determined within Basinsoft

using ARC/INFO's STRAHLER program. The STRAHLER program requires that all FROM/TO nodes of arc segments representing the hydrography be oriented in a downstream direction. The streamflip.aml was developed to help the user accomplish this editing. The AML will orient the FROM/TO nodes of each arc segment in a downstream direction.

Mainselect.aml

The main channel length (MCL) is used to quantify four drainage basin characteristics. By definition, MCL is measured along the main channel from the basin outlet to where the main channel, if extrapolated, were to meet the basin divide. The quantification of MCL requires the delineation or attribution of the main channel and, in most instances, the addition of an arc segment from the upstream node of the main channel to the drainage basin divide. An automated procedure named mainselect.aml was developed to assist in extending and defining the main channel. The mainselect.aml requires arc segments to be oriented in a downstream direction. The AML will assign a value of '1' to the INFO-item named CODE for arcs which represent part of the main channel, and a value of '0' (the default) to all other arcs in the hydrography data layer (cov_str).

Preprocessing the Hypsography Data Layer

Elevation contour or hypsography data may be available in the form of DLG data or may need to be generated from DEM data. Other sources of data, such as triangular irregular network (TIN) data or digitized vector data, may be used to generate elevation contour data.

Several steps are necessary if the hypsography data layer (cover_con) (Figure 4.3C) is to be created from DEM data. A utility AML, dem2grid.aml, located in the tools directory, was developed to convert DEM (raster) data to hypsography (vector) data. This task also can be accomplished interactively using standard ARC/INFO commands.

Preprocessing the Lattice Data Layer

If the hypsography data layer is developed using DEM data, and the utility AML dem2grid.aml is used to generate hypsography data, then the lattice elevation model (Figure 4.3D) is a by-product of executing dem2grid.aml. A lattice data layer needs to be generated. The lattice data layer, cover_lat, will have its areal extent defined by the drainage-divide data layer (cover_bas). An optional module, dem2grid.aml was developed to create the lattice data layer and the hypsography data layer (cover_con) from DEM data.

The elevation source data (lattice elevation model) (Figure 4.3D) may be unavailable, or may be available at an inappropriate scale. Under these circumstances it may be necessary to create or enhance the elevation data. One method is to use the ARC/INFO command TOPOGRID to create the lattice data layer. This command uses hypsography and a single-line hydrography network with options to use point elevation data and linear data as break lines in the topography to create a hydrologically accurate lattice data layer.

PROCESSING DATA LAYERS TO QUANTIFY DRAINAGE BASIN CHARACTERISTICS

Basinsoft processing can be performed on either single or multiple basins. The process of quantifying basin characteristics for a number of drainage basins is highly repetitive; therefore, it is possible to automate much of this task once the preprocessing has been completed. Processing

involves invoking the program Basinsoft.aml to quantify 27 selected morphometric drainage basin characteristics.

A single drainage basin can be processed from the ARC prompt. Basinsoft is executed with the appropriate basin name as a command line argument. Upon execution of Basinsoft, the drainage basin is processed and selected output is written into the basin_name directory (Figure 4.2A).

Multiple drainage-basin processing can be performed using the program multi_p.aml, an AML provided in the tools directory. The user modifies the AML to include a list of names of drainage basins to be processed. Strict adherence to the naming convention defined in Table 4.3 is necessary to automate this procedure. Upon execution, the program multi_p.aml loops through the list of basin names provided by the user, and output files are written into the basin_name directory (Figure 4.2B). The directory structure, as shown in Figure 4.2B, is needed to execute the program multi_p.aml.

BASINSOFT OUTPUT

Basinsoft output is generated in two formats. An INFO table named COVER_CHAR and a flat file named CHARS.TXT are generated in the basin_name directory (Table 4.3). The flat file is generated from the INFO table. Both files are output with the following format: characteristic_name = value. Table 4.4 shows an example output in the flat-file format. An optional graphic-output module named graphics.aml is available in the tools directory.

BASINSOFT VERIFICATION

To verify the accuracy of the drainage basin characteristics quantified using Basinsoft, manual measurements of 12 selected drainage basin characteristics were made from USGS topographic maps for drainage areas upstream of 11 streamflow-gauging stations in Iowa. Manual measurements were made at scales identical to the quantifications done by Basinsoft. The results of the comparisons are shown in Table 4.5.

The Wilcoxon signed-ranks test was applied to determine the statistical significance between median manual measurements and median Basinsoft quantifications of 10 of the 12 drainage basin characteristics listed in Table 4.5. No test was performed for noncontributing drainage area

[a]TDA, total drainage area, in square miles; NCDA, noncontributing drainage area, in square miles; BL, basin length, in miles; BP, basin perimeter, in miles; BS, average basin slope, in feet per mile; BR, basin relief, in feet; BA, basin azimuth, in degrees; MCL, main channel length, in miles; TSL, total stream length, in miles; MCS, main channel slope, in feet per mile; FOS, number of first-order streams; BSO, basin stream order; MAN, manual measurement; BSOFT, Basinsoft quantification;% DIFF, percentage difference between MAN and BSOFT; ND, not determined; WSRT, Wilcoxon signed-ranks test; NT, no test performed because all values for % DIFF = 0.

[b]Manual TDA measurements are streamflow gauging station drainage areas published by the U.S. Geological Survey in annual streamflow reports.

[c]In general, p-values greater than 0.05 indicate that there is not a statistically significant difference between the median of the manual measurements and the median of the Basinsoft quantifications, using a 95% level of significance for a two-tailed Wilcoxon signed-ranks test.

(NCDA) and basin stream order (BSO) because these characteristics either were equal to zero or there was no difference between manual measurements and Basinsoft quantifications for all 11 drainage basins. Results of the statistical comparison tests indicate that Basinsoft quantifications were not significantly different (p-value >0.05) from manual measurements for 9 of the 10 drainage basin characteristics tested (Table 4.5). Basin slope (BS) was the only characteristic tested for which Basinsoft quantifications were significantly different (p-value <0.05) from manual measurements.

The results of a comparison test for average basin slope (BS) using three methods of measuring elevation contour lengths are listed in Table 4.6. The results indicated that Basinsoft quantifies basin slope with acceptable results; however, ARC/INFO was unable to generate appropriate elevation contours from 1:250,000-scale DEM data for comparison with manual measurements of elevation contours from 1:250,000-scale topographic maps. Comparisons for basin slope (Tables 4.5 and 4.6) appeared to indicate that the 1:250,000-scale DEM data were too coarse for ARC/INFO to accurately reproduce elevation contour data with the sinuosity found on the 1:250,000-scale topographic maps. Figure 4.4 shows elevation contours generated from DEM data using ARC/INFO (Figure 4.4A) are much more generalized than elevation contours digitized from topographic maps of the same scale (Figure 4.4B). Thus, the total length of contours generated from DEM data are underrepresented when compared to contours shown on topographic maps (Table 4.6). This contour overgeneralization illustrates how the total length of the elevation contours are underestimated by Basinsoft using the "contour-band" method to quantify basin slope (Table 4.1).

Understanding the reason for differences between the manual measurements and quantifications made by Basinsoft is important in determining the type of comparisons which may be relevant in analysis of this type of data. The data in Table 4.6 indicated that it was not preferable to compare Basinsoft quantifications of contour data generated from DEM data by ARC/INFO with either digitized contours or contours generated from DLG data; however, measurements based on elevation contours digitized from contour maps and those based on elevation contours generated from DLG data were similar.

Basinsoft quantifications of main channel slope (MCS) have the greatest range in percent dif-

Table 4.6. Comparison of Elevation-Contour Length Measurements Used to Quantify Basin Slope

Source Data (All Data Were 1:250,000-scale)	Method of Measurement	Elevation-Contour Length (CL) Mesurement, in Miles	Contributing Drainage Area (CDA), in Square Miles	Contour Interval (CI), in Feet	Average Basin Slope Quantified Using CL * CI/CDA, in Feet per Mile

Topographic map (Figure 4.4B)	Basinsoft quantification of elevation contours digitized from topographic map	35.05	11.89	50	147.4
DEM data (Figure 4.4A)	Basinsoft quantification of elevation contours generated using ARC/INFO	12.73	11.89	50	53.5

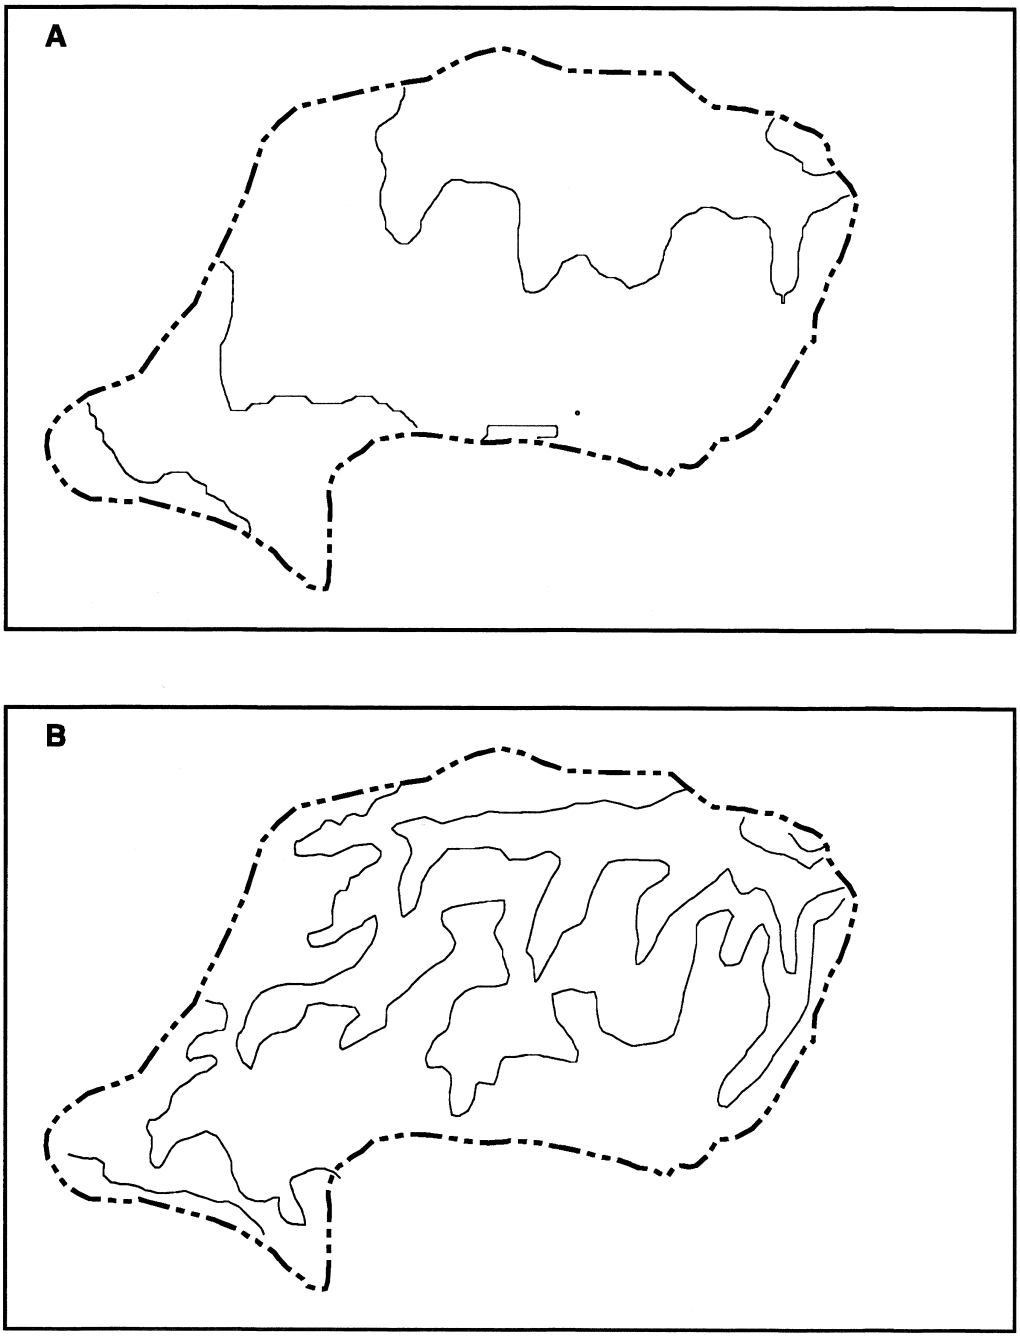

Figure 4.4 A-B. Elevation contours generated (A), with a 50-foot interval from 1:250,000–scale DEM data using ARC/INFO and (B), with a 50–foot interval digitized from a 1:250,000–scale topographic map.

ference between manual measurements and Basinsoft quantifications of the 10 selected drainage basin characteristics listed in Table 4.5. There are two main components of the MCS equation, length and elevation (Table 4.1). Quantification differences for MCS ranged from –26.5% to +36.5% (Table 4.5). However, quantification differences for main channel length (MCL) ranged from –5.6% to +0.9% (Table 4.5). These quantification differences indicated that the variation between manual measurements and Basinsoft quantifications of MCS were due mainly to differences in the determination of the streambed elevation at points 10% and 85% of the distance along the main channel from the basin outlet.

The approximate time required for an experienced ARC/INFO user to process three of the drainage basins listed in Table 4.5 using Basinsoft was 8 hours. The three basins represent large, intermediate, and small drainage areas. Manual measurements made from the same scales of topographic maps as used by Basinsoft for these three drainage basins required approximately 50 hours.

Preliminary comparisons between basin characteristic measurements made from various scales of cartographic data for these three drainage basins appear to indicate that several of the basin characteristics (BS, MCL, TSL, MCS, FOS, BSO) are map-scale dependent (Eash, 1993; Eash, 1994). Map-scale dependency refers to the effect on a measurement when that measurement is made from a cartographic data source of some specific scale as compared to that same measurement made from a different scale. Thus, interbasin comparisons of Basinsoft quantifications may be unreliable if different scales of cartographic data, or different sources of digital data (that is, raster versus vector), are used in generating the four source-data layers for each drainage basin.

Source-data layers obtained from larger-scale cartographic data and processed using Basinsoft may provide the best drainage basin quantifications for a study area. However, the scales and sources of cartographic data available for a study area may be a limiting factor in generating the four source-data layers required by Basinsoft. In general, Basinsoft can process most scales and sources of cartographic data available for a study area once the preprocessing is complete for the four source-data layers (Majure and Soenksen, 1991; Majure and Eash, 1991; Eash, 1993).

OPTIONAL PROGRAMS

Optional programs included in the tools directory (Figure 4.1) for use with Basinsoft are described below. The tools directory contains several variations of some programs, such as dem2grid.aml, which was developed to process one DEM at a time. The dem3grid.aml and dem4grid.aml process three and four DEM files at a time, respectively.

Area Weighting

A program to weight data by area, named areaweight.aml, is located in the tools directory. This program can be used as a module or as a stand-alone program to quantify characteristics from a variety of data, such as climatic data (annual precipitation and the two-year 24-hour precipitation intensity), which are stored in multipolygonal data layers (Eash, 1993). Minimal preprocessing is needed to execute this module. The areaweight.aml requires statewide or large area multipolygonal data layers representing the distribution of a characteristic, such as precipitation values, land-use values, pedologic values, geologic values, etc. The multipolygonal data layer must be larger than and encompass the drainage-divide data layer. Output is written to an auxiliary file specified by the user on the command line.

Dem2grid

The optional dem2grid.aml preprocessing program, located in the tools directory, is designed to convert a DEM file to a lattice data layer and project it into a user-specified projection. This module creates the required lattice data layer. There are several variations of this program in the tools directory. The various forms of dem2grid simultaneously preprocess up to four DEM files at a time.

Graphical Output

The graphical output module, graphics.aml, is located in the tools directory and can be used as a module or as a postprocessing program. Graphical output can be used in the interpretation of output generated by Basinsoft and can be useful in quality-control checking for obvious errors. The graphical output is in the form of an ARC/INFO graphics file which can be readily converted to a postscript file. Figure 4.5 (see color section) shows an example of graphical output. Data contained in the graphical output include: (1) tables of the basin characteristics quantified, (2) variables used by Basinsoft, and (3) a plot of the drainage-divide data layer, elevation contours, main channel, basin-length measurement line, points depicting the 10% and 85% distances along the main channel from the basin outlet, and a point at the basin outlet (outfall).

CONCLUSIONS

A computer program named Basinsoft has been developed by the U.S. Geological Survey to quantify 27 morphometric drainage basin characteristics using a geographic information system. Basinsoft was developed entirely using AML to increase portability among systems. Basinsoft uses ARC/INFO AMLs written for ARC/INFO version 7.0.2 or later. Basinsoft requires four source-data layers representing the drainage-divide, hydrography, hypsography, and a lattice elevation model of a selected drainage basin. Minimal preprocessing is required to prepare the source data used by Basinsoft. Optional programs and modules were developed to enhance the usability and functionality of Basinsoft.

Statistical comparison tests indicate that Basinsoft quantifications are not significantly different (p-value >0.05) from manual topographic-map measurements for nine of ten basin characteristics tested. Results also indicate that elevation contours generated by ARC/INFO from 1:250,000-scale DEM data are substantially overgeneralized when compared to elevation contours shown on 1:250,000-scale topographic maps and that quantification of basin slope thus is underestimated using the DEM data. A comparison test indicated that the Basinsoft module used to quantify basin slope is valid and that differences in quantified basin slope are due to source-data differences.

Basinsoft provides an automated computer procedure for the quantification of drainage basin characteristics and reduces the amount of time required to quantify drainage basin characteristics when compared to manual methods of measurement.

ACKNOWLEDGMENTS

The authors express their gratitude to the Spatial Data Support Unit (SDSU), Office of the Assistant Chief Hydrologist for Technical Support, USGS, for providing support in the development of Basinsoft; especially to Bob Pierce, Chief, SDSU, for providing technical support to the project, and to Mark Negri, Computer Specialist, SDSU, for providing programming expertise during the development of Basinsoft.

CHAPTER 5

Deriving Stream Channel Morphology Using GIS-Based Watershed Analysis

Scott N. Miller, D. Phillip Guertin, and David C. Goodrich

INTRODUCTION

Because of the time and degree of technical skill required for the completion of geomorphology studies, individual projects have historically been limited in size and scope. With the advent of geographic information systems (GIS), these technical problems have been assuaged. The GIS capability of storing large and diverse quantities of spatial data allows for the complex analysis of many sites to be carried out quickly, efficiently, and with a high degree of repeatability (Burrough, 1986). However, GIS-based projects often fail to integrate field-collected data with GIS spatial data. This project was designed to relate the GIS characterization of spatially distributed watershed characteristics with field measurements of point-attribute data (channel cross-section surveys). These data sets were related using statistical analysis to derive relationships between watershed characteristics and channel shape.

Watershed characterization based on geometric and physical properties was carried out in a GIS on 222 subwatersheds within the Walnut Gulch Experimental Watershed. At the same time a field measurement program was completed in which channel shape characteristics were measured at the outlet of each subwatershed. Statistical analysis between the two data sets showed a strong relationship between channel shape and watershed characteristics. It was shown that the derivation of hydrologic model parameters may be effectively carried out in a GIS on a large number of data points in a relatively short amount of time.

With its long history of data collection and observational data, Walnut Gulch serves as an excellent location on which to conduct research into geomorphologic and hydrologic processes (Renard et al., 1993). Relatively little work, however, has focused on the characterization of the entire watershed. This lack of data has limited the ability to model landscape processes on a basin scale (Lane et al., 1994). Additionally, most of the research on the relationship between channel and watershed characteristics has been conducted on intermittent and perennial streams. A knowledge gap therefore exists for this type of data on aridland watersheds and the processes acting on ephemeral channel systems such as exist on Walnut Gulch (Osterkamp et al., 1983; Lane et al., 1994). Instead of limiting this work to a small section of the watershed, it was decided to characterize as much of the watershed as possible. Sample sites were located randomly across the entire 148 km^2 watershed within all soil types and many hydrologic conditions. Strahler ordering analysis (Strahler, 1952) and other measures of channel and watershed characteristics were utilized to describe the watershed as quantitatively and thoroughly as possible.

Analyses of basin characteristics have been carried out in a GIS environment for many years (Burrough, 1986; Garbrecht and Martz, 1995), but many of these processes were found to be

incompatible or unworkable for the data collected during this project. Therefore, a suite of GIS analysis tools and ARC/INFO Macro Language (AML) programs was developed to facilitate the GIS investigation (trade names are mentioned solely for the purpose of providing specific information and do not imply recommendation or endorsement by the U.S. Department of Agriculture). Channel shape, required for hydraulic routing, cannot be accurately predicted (or extracted) from DEMs. Therefore a principal goal of this project was to develop a methodology for predicting channel shape from watershed characteristics that could be readily derived from commonly available GIS coverages. During this process, field research was synthesized with GIS applications and photogrammetry to more thoroughly describe the channel and geomorphologic characteristics than had previously been attempted.

SITE DESCRIPTION OF WALNUT GULCH

Located in southeastern Arizona (approx. 110°W, 31°45′N) and comprised of rolling hills and some steep terrain, the elevation of Walnut Gulch Experimental Watershed ranges between 1190 and 2150 m A.M.S.L. Some urbanization exists in and around the town of Tombstone, but cattle grazing and recreational activities are the major land uses. Vegetation within the watershed is representative of the transition zone between the Chihuahua and Sonoran deserts, and is composed primarily of grassland and shrub-steppe rangeland vegetation.

Underlying Walnut Gulch is the geology of a high alluvial fan contributing to the San Pedro River watershed (Renard et al., 1993). Due to the enormous thickness and extent of the alluvial fill, the groundwater reserves are substantial, and can be found at depths ranging from 50 to 145 m (Libby et al., 1970). Some geologic control over the hydrology exists in the western regions of the watershed where metamorphic and orogenic activity has resulted in the fracturing and faulting of the bedrock. In 1994 the USDA Soil Conservation Service completed a detailed soil survey, finding that the watershed is dominated by 30 principal soil types (Breckenfield et al., 1995). Major soil units are Elgin-Stronghold (*Ustollic Paleargid, Ustollic Calciorthid*), Luckyhills-McNeal (*Ustochreptic Calciorthid*), McAllister-Stronghold (*Ustollic Haplargid, Ustollic Calciorthid*), and Tombstone (*Ustollic Calciorthid*).

The climate of Walnut Gulch can be classified as semiarid or steppe. Mean annual temperature in the city of Tombstone is 17.6°C, with a mean annual precipitation of 324 mm. Annual precipitation is highly variable in both timing and total depth. Rain occurs mainly during two seasons: summer rains are the product of monsoonal, highly localized, convective storms; winter rains are generally low-intensity events that cover a larger proportion of the watershed. The majority of runoff occurring on Walnut Gulch is the product of summer storms, and is therefore episodic and of relatively high intensity (Renard et al., 1993).

FIELD DATA COLLECTION

A field measurement program was undertaken wherein 222 channel cross-sections were surveyed for morphometric assessment. To account for basin-scale variability, a large number of randomly selected points were used, and multiple measurements were taken at each site to account for local variability in channel shape. These randomly located sample point locations were prestratified by soil type using a GIS procedure: each major soil type was assigned a weighted proportion of the sample points based on the areal extent of the soil coverage. At each site three cross-section surveys were taken to characterize the channel section just above the outlet of the subwatershed. Width and depth were measured at breakpoints (changes in slope). The three sur-

veys were then combined to determine the average width and depth for the channel segment, and these results were combined to derive average cross-sectional area.

A strict protocol was followed at each sample location in order to ensure proper measurement and consistency between sites. Upon arrival at a site, an inspection of the bank morphology, vegetation, and soil characteristics along the entire reach was completed to ensure that cross-sections were located where they would be most representative of the channel section. A site description was recorded in a logbook for future analysis, and potential problems related to channel complexity and morphology were noted where applicable. Bankfull indicators, including slope breaks, changes in bed or bank materials, a shift in vegetative type, debris lines, and bank staining were noted in order to determine the bankfull depth (Osterkamp et al., 1983; Gordon et al., 1992; Harrelson et al., 1994). Wherever possible, evidence indicative of a constructive, rather than destructive process, was used to determine bankfull depth. In the southwestern United States, channel processes are governed by rapid and violent runoff events, and many of the channels on Walnut Gulch are actively degrading. Channels that were clearly degrading and out of equilibrium were not subjected to channel measurement since an adequate determination of bankfull depth was not possible.

At each of the site locations a minimum of three cross-sections was surveyed. If the channel reach was complex, up to five cross-sections were measured to ensure adequate representation. At each of the cross-sections a light line was pulled level across the channel top at the bankfull depth. The line was leveled and pulled taut to reduce sag. Measurements of channel depth and distance from the left bank (looking upstream) were taken at each break in slope across the cross-section.

Channel width was more easily measured with precision than channel depth. Although determining the stage to which floodwaters rise proved difficult, the possibility for error was greater when measuring depth. This is due to a number of factors. First, depth was only measured at break points, which are to some degree subjective. Second, there was always a slight amount of sag in the line when it was stretched across a channel, lending a source of imprecision to the depth measurements. Third, more random deposition or scour of the stream channels tends to impact local channel depth measurements to a greater degree than width measurements.

GIS DATABASE DEVELOPMENT AND ANALYSIS

Given Walnut Gulch's history as a research site into various aspects of hydrology and natural resource management and its extensive rainfall and runoff database, it was decided that the GIS database would be created at a resolution not ordinarily attempted. Throughout the database development, an answer to a basic question was sought: what are the highest levels of precision and accuracy that could be achieved? There can be a tendency by GIS developers to overestimate the level to which data may be discretized. By attempting to create maps with a higher resolution than is allowable by the data, errors may be introduced, and a false level of analysis can be attempted (Burrough, 1986). Fortunately, data available for Walnut Gulch were of a quality that allowed for a very high level of resolution and positional accuracy.

Of particular relevance was the stream channel coverage. In many GIS studies, the channel network is derived from a DEM in a raster environment and then translated into vector data. Alternatively, channels may be digitized from USGS topographic maps, but channels drawn on these maps are partly based on DEMs. Traditional GIS technique dictates that the majority of channels be digitized as single vectors bisecting the channel position, with a few of the larger drainages characterized with two lines to illustrate relative width. Since a correlation was to be made in this study between channel shape and watershed variables, a channel network map was constructed whereby only the smallest channels were digitized as single vectors. Channels wider than

approximately 1.5 meters were drawn as polygonal features. This highly detailed procedure relied on the 1:5,000 orthophotographs as the base from which the stream positions and characteristics could be extracted. Most of the channels on Walnut Gulch were thus characterized in the GIS database as polygons, with associated width characteristics. In addition, where channel islands and bars were visible on the orthophotographs they were digitized. Thus, the channel network theme layer provides a detailed record of the channel system and its hydrologic characteristics as existed at the time the aerial photographs were taken (April 1988).

An important variable for the understanding of geomorphologic relationships is stream order. In this case the intensive channel network map was a drawback: because most of the channels were digitized as polygonal features it was not possible to automatically order the streams. To take advantage of GIS arc-node topology, the stream channels were vectorized. First, the map was translated into GRASS and rasterized with a one-meter resolution. The GRASS module "r.thin", which draws a parallel bisector through polygons, was executed on the stream map (Geographic Resources Analysis Support System, 1991). Upon completion of the vectorizing process, the maps were appended together and edited to remove spurious vectors created as a by-product of the thinning process.

The vector stream channel map was then re-exported into ARC/INFO, which supports both vector and routing functions. An ordering routine was created that takes advantage of the "from" and "to" node data structure that ARC/INFO imposes on vector maps. All the streams first had to be oriented in the downward direction (i.e., pointing downstream). Once the streams were all pointing in the downstream direction, the ordering program was initiated. By assigning all vectors that had an open-ended "from" node an order value of one, it was possible to stimulate a cascading effect, whereby all vectors were assigned a stream order based on their relationship and connectivity to other channels.

A 10 m resolution DEM provided the basis for the articulation of subwatersheds and the creation of many theme layers important to the statistical analysis of field data. Created from a large number of spot elevation points, contour data, and a thinned version of the channel network using the ARC/INFO tool "topogrid" (Environmental Systems Research Institute, 1994), the DEM was resolved to a 10 by 10 meter gridded surface. Using the "selectpoint" option within the "watershed" command in GRID, subwatersheds were delineated above each of the 222 channels surveyed in the field. From the DEM theme layers for flow direction and flow length were created for each watershed. Watershed characteristics that were derived with the GIS included: watershed area; maximum flow length; average slope; elevation characteristics; and watershed shape variables.

STATISTICAL ANALYSIS

Descriptive statistics implied that stream order was significantly related to channel shape variables. An analysis of variance showed that significant differences exist for channel width, depth, and cross-sectional area between each stream order. Multiple analysis of variance proved average watershed soil clay content to have no influence on channel shape. Relationships between channel shape variables and watershed parameters were investigated using simple linear regression analysis. Having found strong relationships between these variable sets, multiple regression analysis was employed to further refine these relationships.

RESULTS

For the purposes of evaluating the relationship between channel morphology and the contributing area, the relationships describing the channel cross-sectional area were of primary interest, and

Table 5.1. Relationship of Channel Morphology Variables to Stream Order

Order / N	Average Width (cm)	Average Depth (cm)	Average Cross-Sectional Area (m^2)
1 / 58	279.65	26.32	0.802
2 / 65	404.32	34.57	1.47
3 / 40	563.03	40.10	2.54
4 / 26	960.39	54.94	5.63
5 / 20	1967.42	52.58	10.58
6 / 13	3329.99	79.69	26.21

deterministic models were derived using regression analysis. Channel cross-sectional area is a function of both channel width and average depth and thus reflects the total channel response to its hydrologic regime. Channel width can be extracted from a high resolution GIS such as exists for Walnut Gulch. Therefore, given a strong statistical relationship between cross-sectional area and watershed parameters, it would be possible to fully articulate channel geometry (width, depth, cross-sectional area) for all channels throughout Walnut Gulch. This ability to model channel shape accurately when a minimum of field data are available may benefit the application of a host of hydrologic models that incorporate hydraulic channel routing (i.e., the USGS DR3M model—Alley and Smith, 1982; KINEROS—Woolhiser et al., 1990; HEC–1, Army Corps of Engineers—Feldman, 1995).

Horton (1945) investigated the role of stream order on channel shape and hydrologic processes. He found that stream order was highly correlated to many watershed and channel variables, and that stream order could be used as a predictive tool for these variables. Strong relationships between stream order and channel shape were also found to exist on Walnut Gulch (Table 5.1). In this project, statistically significant differences were found to exist between the means of channel width, depth, and cross-sectional area for each step in stream order. Stream order, which is closely related to contributing area, was found to exert a strong effect on channel shape, and was used to stratify the data into subcategories for further analysis.

Channel characteristics were related strongly and in a semilog fashion to stream order. Average channel width, depth, and cross-sectional area were all directly related to order, with a break in the trend occurring between the fourth and fifth order channels, but only for channel width and depth; cross-sectional area maintains a semilog relationship throughout each step in order. The average value for channel depth shows a decrease between channel orders four and five, which is out of trend for every other increase in order (Figure 5.1). However, there is a significant increase in channel width between the fourth and fifth order channels, effectively counteracting the decrease in depth so that the relationship between cross-sectional area and stream order remains consistent

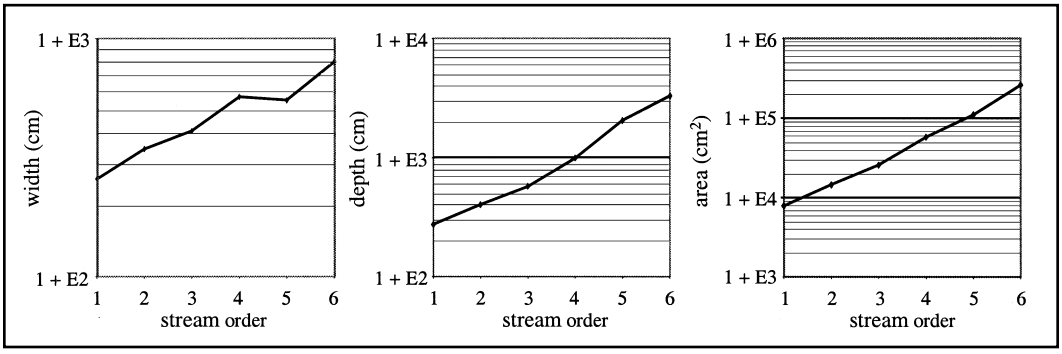

Figure 5.1. Semi-log plots of channel morphologic properties as a function of stream order.

across each order. The overall effect on channel shape is an increase in the channel width:depth ratio, while the relationship of cross-sectional area to order (and, hence, upstream watershed area) remains consistent (Figure 5.1).

Statistical Properties of Channel Shape

Channel width appears to be more sensitive to the influence of watershed parameters than channel depth. Measured values of width have a large spread in their data, while the values for depth show a more central tendency with a lower variation. Without exception, channel width proved to have a higher coefficient of determination than depth (e.g., $R^2 = 0.33$ for depth and 0.72 for width when related on a log-log basis to watershed area) when regression analysis was performed. In fact, depth proved to be resistant to any deterministic model based on the variables used in this study. Some of this resistance to forming a deterministic relationship may be a function of the difficulties associated with precisely measuring depth in the field. Fluvial characteristics are undoubtedly important to this tendency: as flow energy increases in a channel, the channel will adjust its shape to accommodate the increased level of power and erosive energy. This can be accomplished through the widening and/or deepening of the channel. In the loosely consolidated soils of Walnut Gulch, the channels appear to respond to elevated flow energy by increasing their channel width proportionally more than depth.

Responding to the runoff they receive from uplands, stream channels constantly adjust their shape to achieve equilibrium with the flow volume. Changes in channel morphology may result in either degradation or aggradation, with a resultant change in the width:depth ratio, but the net effect is a change in the channel cross-sectional area. As such, the measurement and analysis of channel cross-sectional area is an effective method of illustrating the manner in which channels are responding to watershed characteristics.

A strong relationship exists between channel area and the maximum flow length within a watershed ($R^2 = 0.79$). Table 5.2 shows the results of regression models involving channel area. Long flow lengths within a watershed have been directly related to discharge (Leopold et al., 1964). With higher flows, the channel will become enlarged, either through bed scour or bank erosion, to accommodate the larger flows, resulting in an increased channel cross-sectional area. Following the same reasoning, a strong relationship between channel cross-sectional area and watershed area would also be expected. Data collected in this research support that logical extension. A log-log relationship ($R^2 = 0.68$) exists between channel cross-sectional area and watershed area. A strong relationship ($R^2 = 0.77$) exists between channel cross-sectional area and the watershed area: perimeter ratio, a measurement of the rotundity of a basin, and hence an indicator of basin response. Neither average watershed slope nor the relief ratio correlated strongly with channel cross-sectional area. The log of cumulative drainage length (total length of all channels in a subwatershed) had a moderate relationship to the log of channel cross-sectional area ($R^2 = 0.62$).

In order to improve on the relationships derived using simple linear regression, channel variables were related to watershed characteristics using multiple linear regression. Multiple regres-

Table 5.2. Results of Linear Regression Analysis between Channel Area and Watershed Variables

Variable	Watershed Characteristic	R^2	Coefficient	Constant	Se_{yx}
Channel area	maximum flow length	0.79	0.001	1.83	3.46
Log channel area	log watershed area	0.68	0.49	–2.44	0.34
Channel area	area:perimeter ratio	0.77	0.03	0.17	3.60
Log channel area	log cumulative channel length	0.62	0.51	–1.38	0.40

Table 5.3. Results of Stepwise Backwards Multiple Linear Regression Analysis for Channel Cross-Sectional Area as a Function of Watershed Variables[a]

Case	Regression Model	R^2	Se_{yx}
1	Ca = 0.686(So) + 0.065(Aw) + 0.909(Lm) – 0.006(h)	0.849	3.36
2	Ca = 0.40(So) + 0.009(Aw) + 0.821(Lm) – 0.006(h)	0.851	3.35
3	Ca = 0.72(So) + 0.095(Aw) +0.001(Lm) – 0.007(h) – 0.001(Dl)	0.851	3.34
4	Ca = 0.616(So) + 0.001(Lm) + 0.001(S)	0.849	3.42

[a] where: Ca = channel cross-sectional area (m^2); So = stream order; Aw = subwatershed area (m^2); Lm = maximum flow length (m); h = relief (m); Dl = sum of drainage lengths (m); S = basin slope.

sion analysis of channel cross-sectional area revealed the relatively strong role that channel order played in the determination of channel cross-sectional area. Systematic exploration of the watershed data, using both stepwise forward and backward regression analysis, showed that channel area was heavily dependent on stream order and the area of and maximum flow length within the contributing watershed (Table 5.3). Depending on the subset of parameters investigated, it was possible to extract a significant regression model with a number of different independent variables. To avoid collinearity, multiple pools of data were used during the regression analysis. For example, the relief ratio, a product of the maximum flow length and maximum elevation change, was considered separately from those two variables. The same separation was used for basin shape variables and watershed size. Note that a constant was not used in the analysis, and the equations were driven through the origin.

CONCLUSIONS

Strong statistical relationships were derived between channel variables measured in the field, such as width, depth, and cross-sectional area, and a host of watershed parameters, including channel order, watershed area, shape, drainage properties, and elevation characteristics that were defined using a GIS. Channel cross-sectional area was related in a deterministic manner to multiple watershed variables, yielding models with strong coefficients of determination ($R^2 > 0.84$). Channel shape (and, hence, bankfull stage) may thus be predicted from watershed characteristics readily extracted from common GIS coverages.

Field data were successfully integrated with GIS-derived results. Channel cross-sectional area and other field-measured channel morphometric parameters were found to be strongly related to watershed characteristics extracted from a high-resolution GIS. It is preferable to collect field data when developing parameters for application in hydraulic routing models, but field collection can be costly and time consuming. The channel coverage created for Walnut Gulch contains information on channel width. Using the values for width that can be extracted for the GIS, in conjunction with the developed regression models, values for channel depth and cross-sectional area may be calculated for all channel segments within the watershed. Relationships developed upon verification outside Walnut Gulch have the potential to overcome the inability of DEMs to parameterize channel cross-section properties. In this fashion hydrologic models can be parameterized using a GIS to aid in the understanding of hydrologic processes in the southwestern United States.

CHAPTER 6

GIS Modeling and Visualization of the Water Balance during the 1993 Midwest Flood

Pawel J. Mizgalewicz, W. Scott White, David R. Maidment, and Merrill K. Ridd

INTRODUCTION

The characterization of the water balance during a major flooding event is useful to scientists, land-use planners, and government agencies who need such information to develop strategies for coping with future floods. Recent technological developments in the form of computer mapping and analysis databases have provided the means to accurately analyze flood-related data sets, such as streamflow and precipitation measurements, over extended periods of time. This study investigates the use of geographic information systems (GIS) to model spatially distributed and time-varying hydrologic and meteorologic data sets, and the use of scientific visualization techniques in the interpretation of the results. The data sets referred to deal specifically with the 1993 Midwest flood which affected a large part of the Upper Mississippi River Basin.

The study area encompasses the main stem of the Mississippi River above Cairo, Illinois, and the main stem of the Missouri River below Gavins Point Dam near Yankton, South Dakota. Also included are the many tributaries of these rivers such as the James, Des Moines, Illinois, and many other rivers and streams. This region of nearly 700,000 km^2 was previously defined by the Scientific Assessment and Strategy Team (SAST) as the area most affected by the spring and summer floods of 1993 (SAST, 1994). States included in this study are Illinois, Indiana, Iowa, Kansas, Minnesota, Missouri, Nebraska, North Dakota, South Dakota, and Wisconsin (Figure 6.1). Exactly 180 Hydrologic Unit Code (HUC) subbasins (8 digit) cover the study area.

The goal of this project is twofold:

1. Develop, demonstrate, and document procedures used to model the water balance of a large-scale flooding event, such as the 1993 Midwest floods, utilizing hydrologic and meteorologic data sets in a GIS database; and
2. Develop a comprehensive understanding, in terms meaningful to scientists as well as policy and decision makers, of the climatic and hydrologic conditions related to the 1993 floods and the spatiotemporal dynamics of the events. This understanding will result from the use of visualization software in the depiction of water storage change over the land surface during the flooding period.

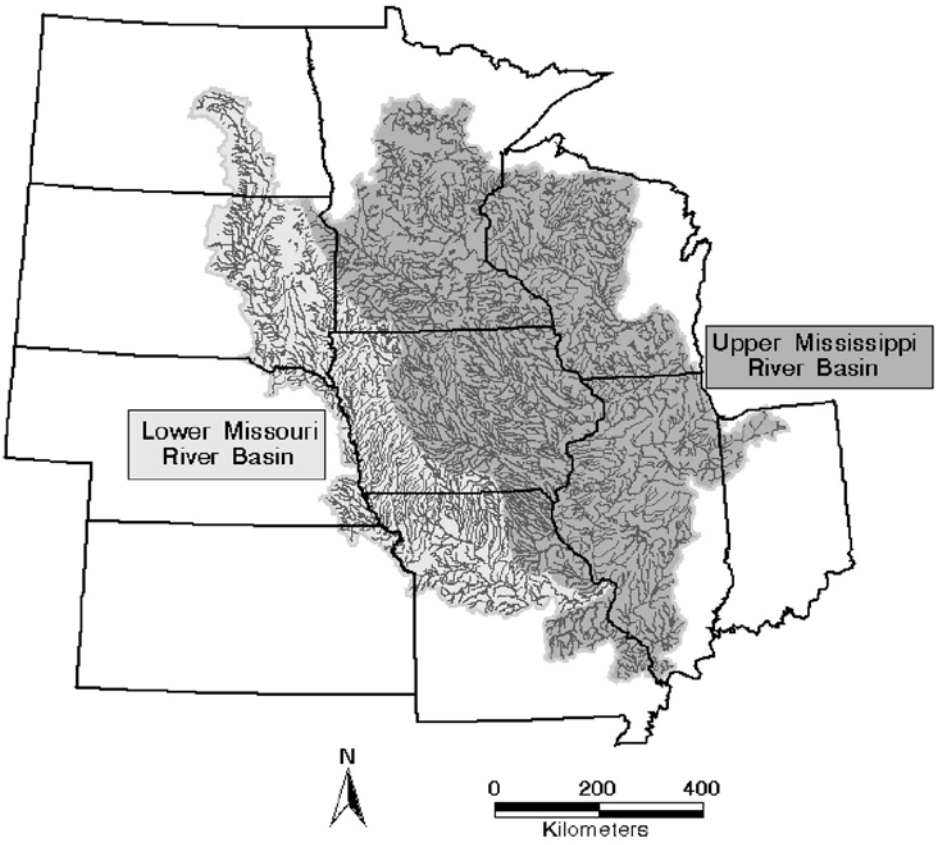

Figure 6.1. Study area—Upper Mississippi and Lower Missouri River Basins.

SURFACE HYDROLOGY CONSIDERATIONS

The water balance of a particular area represents a measure of the inputs to the hydrologic system and the outputs from that system over a specified period of time. In the case of this study, daily water balance maps were desired, therefore a decision was made to partition the study area into incremental drainage units based on the location of stream gauge stations. These drainage units or gauging station zones provided the basis on which areal interpolation of precipitation measurements were made. The outlets of the 180 HUC boundaries rarely corresponded with a stream gauge site, thus necessitating the subdivision of the study area into customized zones. The creation of the gauging station zones is shown in Figure 6.2. There are three possible zones: (1) no inflow; (2) one inflow; or (3) two or more inflows.

The equation for calculating the water balance of each gauging station zone is:

$$dS/dt = I - Q \tag{1}$$

where S is the volume of water stored in each gauging station zone, t is the time index, and I and Q are inflow to the gauging station zone and outflow from the gauging station zone, respectively. The term on the right $(I - Q)$ can be rewritten to account for the area of the gauging station zone:

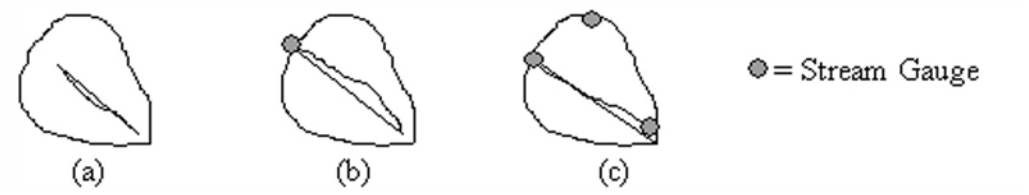

Figure 6.2. Gauging station zone configurations based on (a) no inflow, (b) one inflow, and (c) two or more inflows.

$$I - Q = (P - E)A + SQ_{in} - Q_{out} \tag{2}$$

where P is the rate of precipitation, E is the rate of evaporation, A is the area of the gauging station zone, SQ_{in} is the sum of the inflows recorded at gauges whose flows enter the zone and Q_{out} is the outflow at the downstream end of the zone.

The change in storage (ΔS) can be found by combining Equations 1 and 2 and integrating each term over a time interval of one day (Δt):

$$\Delta S = P\Delta tA - E\Delta tA + SQ_{in}\Delta t - Q_{out}\Delta t \tag{3}$$

In order to express ΔS in terms of average depth over the gauging station zone area, Equation 3 can be rewritten as the following ($\Delta y = \Delta S/A$):

$$\Delta y = P\Delta t - E\Delta t + (1/A)[SQ_{in}\Delta t - Q_{out}\Delta t] \tag{4}$$

where Δy is the change in storage depth per unit area of a gauging station zone. The values of Δy were computed on a daily basis (01/01/93 through 09/30/93) for each zone.

GIS AND WATERSHED DELINEATION

The raster GIS program GRID, a module available in the ARC/INFO® software package, allows for several hydrologic modeling procedures including the determination of flow direction, flow downstream accumulation, and watershed delineation. One of the strengths of this cell-based modeling package is the availability of map algebra functions. With map algebra, the variables in a logical expression actually are map (raster grid) layers. Algebraic manipulation of these grids can be performed at the local or individual cell level, neighborhood level (cells surrounding the cell of interest), zonal level (entire cell groups change in value), or at a global level (entire grid changes in value) (Tomlin, 1990).

Prior to delineating the gauging station zones, several data sets were acquired from the GCIP Reference Data Set (GREDS) CD-ROM, produced by the U.S. Geological Survey. This CD-ROM is a collection of several geographic reference data sets of interest to the global change research community (Rea and Cederstrand, 1994). ARC/INFO export files of 8-digit HUC boundaries and current streamflow gauge sites were obtained from this CD-ROM, as was a 15″ digital elevation model (DEM) of the region (500 meter resolution). RF1 river reach files in ARC/INFO export format for the Upper Mississippi and Missouri Rivers were downloaded via the Internet from the USGS node of the National Geospatial Data Clearinghouse (http://h2O.er.usgs.gov/nsdi/wais/water/rf1.HTML).

The first step in creating the gauging station zones was to edit the RF1 vector coverage to re-

move circular arcs and isolated lakes. Once a definite stream network was available, the vector coverage was converted to a raster grid, and then embedded into the 15″ DEM, which had been corrected for spurious sinks or pits. This embedding procedure "raised" the elevation of the off-stream grid cells surrounding the network in the DEM relative to the stream grid cells. By embedding these stream cells, a more precise network was created on the DEM that exactly matched the original paths of the RF1 vector coverage. This stream "burn in" technique has been shown to be particularly effective in areas of low relief (Maidment, 1996). The resulting grid was then clipped with a polygon coverage of the study boundaries. A 50 km buffer had been applied to this boundary coverage to account for drainage outside of the study area.

The next steps involved the actual delineation of the stream network within their embedded channels on the DEM. In ARC/INFO's version of this process, the flow direction is first determined by examining the neighborhood of eight grid cells that surround the cell of interest. The flow direction function identifies the lowest cell value in the neighborhood, and assigns a flow direction value to the corresponding cell in an output grid, thus creating an implicit stream network between cell centroids. Once this process was complete over the entire study area, a flow accumulation grid was made. The flow accumulation function in ARC/INFO uses the flow direction grid to determine the number of "upstream" cells. A new value is assigned to the cells in an output grid showing the number of cells that contribute or flow to downstream cells. High values indicate confluences of streams, whereas values of zero indicate watershed boundaries (Maidment, 1995). A conditional statement was then set up in ARC/INFO which isolated those cells that met a certain threshold of flow accumulation. Stream links were created, and the stream network was then in place.

After a suitable terrain model had been made, the next step was to precisely locate the USGS gauge stations on the stream grid. The point coverage of station locations was converted to a grid, and then viewed as a background grid against the stream grid. Unfortunately, most of the gauge cells did not lie directly on top of a stream cell, so the stream cell closest to a gauge cell was given a unique value (the USGS-assigned station number) to differentiate it from adjacent nongauge stream cells. Initially, 460 gauge cells were located on the stream grid; however, it was later determined that a number of these stations contained incomplete streamflow records. A total of 50 gauges were removed which did not have complete records. This left 410 gauges, which were unevenly distributed over the stream network. Some streams had many gauges, whereas other stream segments contained one or less. The gauge locations were viewed along with the HUC coverage to provide a better spatial representation of the gauges with respect to watersheds. It was decided that those gauges whose contributing drainage areas (an attribute in the ARC/INFO point coverage of the gauges) were less than 1,000 km^2 would be removed from the collection. Also removed were gauges that were concentrated in a particular watershed. Most HUCs contained between one and three gauge stations, but several contained more than three. Unless the HUC was large in area, those extra gauge stations exceeding three were also removed from the collection. Approximately 260 gauge stations on the stream grid were retained, and these gauge locations were for the most part uniformly distributed throughout the stream network.

The gauging station zones were then determined using the flow direction grid and the edited stream gauge grid (Figure 6.3). The resulting grid contained approximately 260 subbasins defined on the basis of the stream gauge locations. Each gauging station zone was checked against its corresponding HUC to ensure that the two sets of boundaries were mutually compatible.

GIS DATABASE AND MAP CREATION

Streamflow daily values for the 1993 water year were provided by the Water Resources Division of the USGS. After removing the 1992 values and reformatting the data into comma-delim-

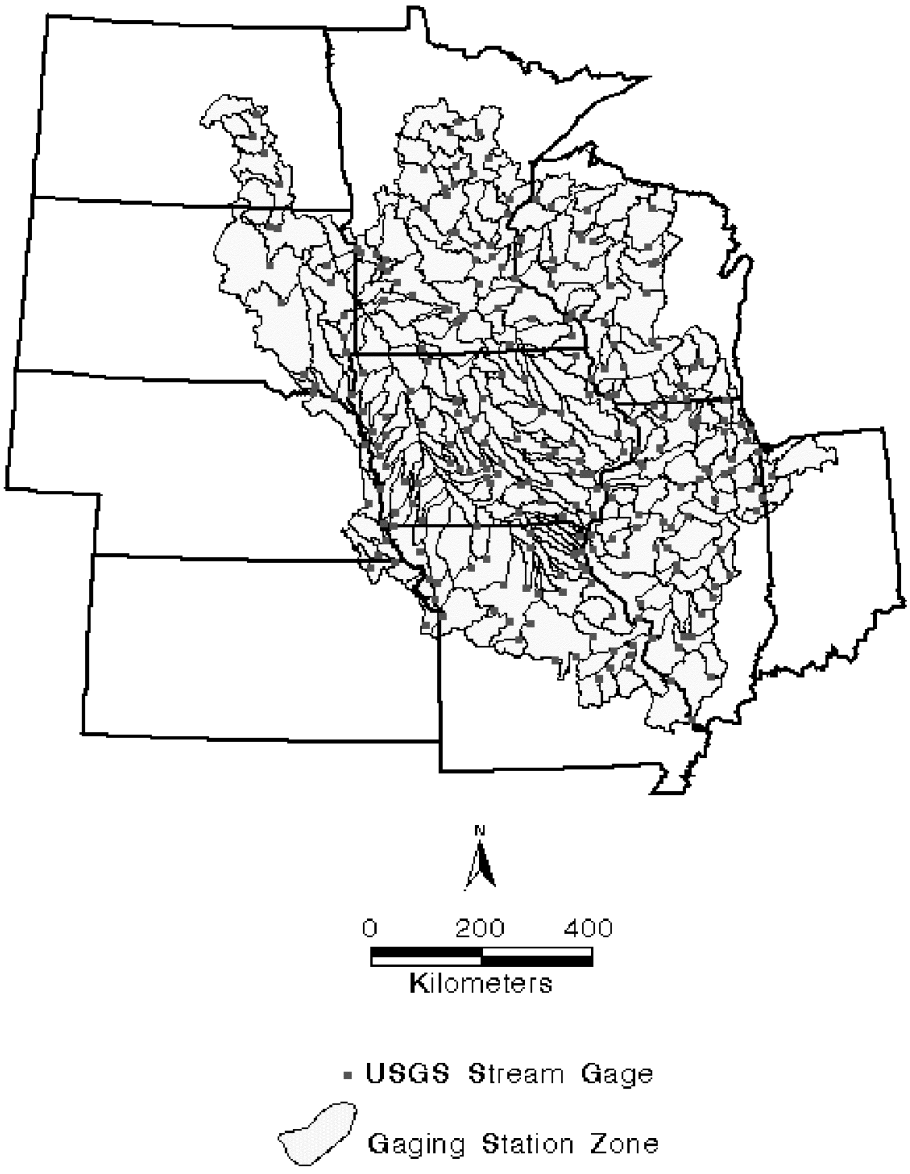

Figure 6.3. Map of gauging station zones defined on the basis of the location of USGS streamflow gauge stations.

ited ASCII text, the values were incorporated into the attribute table of the gauge station point coverage. This point coverage reflected the edits made to the stream gauge grid. Complete daily records for the gauge stations were assigned to the point coverage for a total of nearly 71,000 daily values from January 1 to September 30, 1993 (273 days).

Precipitation values obtained from National Climatic Data Center Summary of the Day files were treated in a manner similar to the streamflow data. A total of 1,078 climate stations were mapped. This number includes stations within the study area, and those within a 50 km buffer of

the study area. Stations in the buffer zone were included so that a more precise interpolation of the precipitation measurements could be achieved for the regions at the study area borders. Over 290,000 precipitation measurements were incorporated into the point attribute table of the stations coverage. Some of the climate stations had missing precipitation measures, so an Arc Macro Language (AML) program was written to eliminate those stations with missing data.

A total of 273 daily precipitation grids with 4 km cell resolution was interpolated from the gauged precipitation data using the inverse distance weighting method. The ARC/INFO GRID function "zonalaverage" was subsequently used to obtain an average value of precipitation depth, as well as potential evapotranspiration (PET), over the gauging station zones. PET monthly values were compiled from the National Weather Service. Since values of PET vary slowly from month to month and the study area was saturated during the 1993 floods, it was felt that evaporation was most likely constant (i.e., one PET value per month) over the month in each gauging station zone.

The resulting grids show unique gauging station zones with average precipitation and evaporation depth values in each zone. Net streamflow grids show daily values averaged over each gauging station zone. These grids were created by subtracting Q_{out} from the sum of Q_{in}, and dividing the answer by the area of the gauging station zone. The final map series involve a combination of all of the preceding maps. Daily storage change (Δy) grids were produced using the map algebra functions in ARC/INFO GRID and Equation 4. Essentially, the equation changed from

$$\Delta y = P\Delta t - E\Delta t + (1/A)[SQ_{in}\Delta t - Q_{out}\Delta t] , \tag{4}$$

to

$$S\ Grid = P\ Grid - E\ Grid + (1/A)[NS\ Grid] , \tag{5}$$

where *S Grid* is a grid of daily storage depth change, *P Grid* is a daily precipitation grid, *E Grid* is a daily evaporation grid, and *NS Grid* is a daily net streamflow grid. Maps of cumulative storage depth were obtained by summing the grids. The resultant 273 grids show water storage depth of each gauging station zone in the study area on a daily basis.

Balancing the water inputs into the basin (precipitation and streamflow), and the outputs from the basin (evapotranspiration and runoff) meant that the database had to be extended to include the whole calendar year of 1993. The number of precipitation, streamflow, evaporation, and subsequent daily water storage grids was increased from 273 to 365 each to take into account the rest of the year (10/01/93 to 12/31/93). It was therefore assumed that the amount of water entering the basin on 01/01/93 was the same as the amount leaving the basin on 12/31/93, and an evaporation multiplication factor was introduced to make the necessary calculations. Based on these calculations, it was found that the water storage in the UMRB study area, when the basin is considered as one modeling unit, rose by approximately 110 mm in about a two-month time period (from the end of May to the beginning of August). However, the range of water storage depths was not geographically consistent throughout the basin. As one might expect, the highest storage depths increases took place in the most downstream units of the UMRB, where calculations show that the depth was nearly 300 mm for the two-month period described above.

VISUALIZATION

The final products of this study consisted of maps that represented the water storage depth which occurred on each subbasin or gauging station zone as a result of the heavy precipitation events between 01/01/93 and 12/31/93. Each day's maps represented a snapshot of how much pre-

cipitation occurred in the study area, and how it affected the land surface. Although the GIS can perform many of the tasks necessary to determine water storage, a final step remains in order to fully understand the temporal aspects of the flooding events. This visualization step involves the use of various computer software packages, coloring and animation procedures, and output types.

GIS software packages have provided the spatial sciences with an excellent set of tools for performing hydrologic analyses. The main problem with the technology today is its relative inability to handle temporal information. This chapter has described a method of incorporating temporal data into the attribute files of GIS layers, but the final product, as described up to this point, remains a series of static portrayals of a dynamic event. To overcome this problem, various visualization methodologies are being investigated as additional components to the GIS-based hydrologic modeling process. Buttenfield and Mackaness (1991) described GIS-related visualization as the interface of three processes: (1) computer analysis (data collection, organization, modeling, and representation); (2) human cognition (perception, pattern identification, and mental imaging); and (3) graphic design principles (construction of visual displays). MacEachren (1994) further described the concept of "geographic visualization" as stressing map use that can be conceptualized as a three-dimensional space. Both descriptions of visualization imply that maps and associated images can now be constructed that incorporate 3-D and 4-D perspectives. This ideally suits geographic visualization techniques as an end product to temporal representation using a GIS.

Currently, the authors are investigating several methods of geographic visualization. Most involve some form of geographic animation as a way of representing the temporal aspects of the flood. Initially, the 273 maps of water storage depth, averaged over each gauging station zone from 01/01/93 to 09/30/93, will be color-coded based on the depth of water storage in each zone. Blue is the most likely color, and will range in shades from light or pale (no water saturation of the land surface) to dark or bright (saturated land surface). These choropleth maps will be chronologically arranged from 01/01/93 to 09/30/93, and then put into an animation software package. Viewing these maps in sequence will provide the user with a dynamic display of water leaving gauging station zones and saturating downstream zones. Figure 6.4 (see color section) shows a sequence of four daily maps (07/29/93–08/01/93) with corresponding water storage in 8-digit HUC boundaries.

Another means of visualizing flow through the basin would be through the use of the stream network. The representation of the network in the GIS does not really account for its changing form and velocity during the flood months of 1993. A series of 273 numbers representing streamflow velocity could be assigned to the cells representing stream gauge locations along the rasterized network (500 m resolution), but the actual channel dimensions remain the same throughout the time period. Visualization procedures can be used in conjunction with the streamflow values to produce a dynamic representation of streamflow velocity through the basins. The flow velocity can be represented by some type of hydrologically significant symbol which appears to speed up or slow down depending upon the streamflow value at the gauge location. This iconic representation of streamflow will increase in size as flow becomes faster downstream. Combining the symbology of flow velocity with the choropleth map described above is also feasible.

The authors are also experimenting with various means of stream channel visualization. As previously mentioned, the streams reside in the GIS as a 500 meter wide grid network. Of course, the streams vary in size in the Upper Mississippi and Missouri River basins from creeks a few meters wide, to the Mississippi River at Cairo, Illinois, which is nearly 1 km wide during normal flow conditions. Vector representation of the stream network would allow some flexibility in the appearance of the channels, and this method is currently being investigated with the GIS software packages ARC/INFO and ArcView. Satellite and radar imagery will also be incorporated into a vi-

sualization package to provide a more realistic view of the flooding events. By using imagery draped over a DEM of the study area, three-dimensional viewpoints can be achieved which provide even greater flexibility in terms of visualization and human cognition of the floods.

SUMMARY AND CONCLUSIONS

In this study, geographic information system software has been utilized as a first step to visualizing the water balance that was in place during the 1993 Midwest floods. A series of daily maps for 1993 are being produced that combine streamflow, precipitation, and evaporation measurements. This series of maps, while informative and meaningful to the group of people who understand GIS, needs to be made available to the public in a different form. The second step will be the development of a dynamic representation of this temporal data through the use of geographic visualization procedures. The final product of this research will be useful to many different people who study such natural hazards as flooding. Methodologies developed in this study can be used to investigate future floods, and will hopefully provide the end users with several different views of the 1993 Midwest flood which will enable them to make wise decisions regarding floodplain management and land use practices.

ACKNOWLEDGMENTS

This research has been supported by a grant from the U.S. Geological Survey to Drs. Maidment and Ridd. Thanks are also due to Dr. William Kirby, of the USGS Water Resources Division in Reston, VA, for supplying the authors with necessary data sets, and to Dr. Barbara Buttenfield for providing some ideas about geographic visualization.

CHAPTER 7

Selection, Development, and Use of GIS Coverages for the Little Washita River Research Watershed

Patrick J. Starks, Jurgen D. Garbrecht, F.R. Schiebe, J.M. Salisbury, and D.A. Waits

INTRODUCTION

The Little Washita River Watershed (LWRW) in south central Oklahoma (Figure 7.1) is the largest and one of the longest-studied research watersheds operated by the United States Department of Agriculture's (USDA) Agricultural Research Service (ARS). The watershed drains an area of 611 km^2 and has been studied since 1961 for rainfall runoff, impact of flood control structures, water quality, sediment transport and best management practices. A series of Geographical Information Systems (GIS) raster coverages have been developed to support present and future ARS research on the LWRW and to complement the historical and current databases. The selection of the

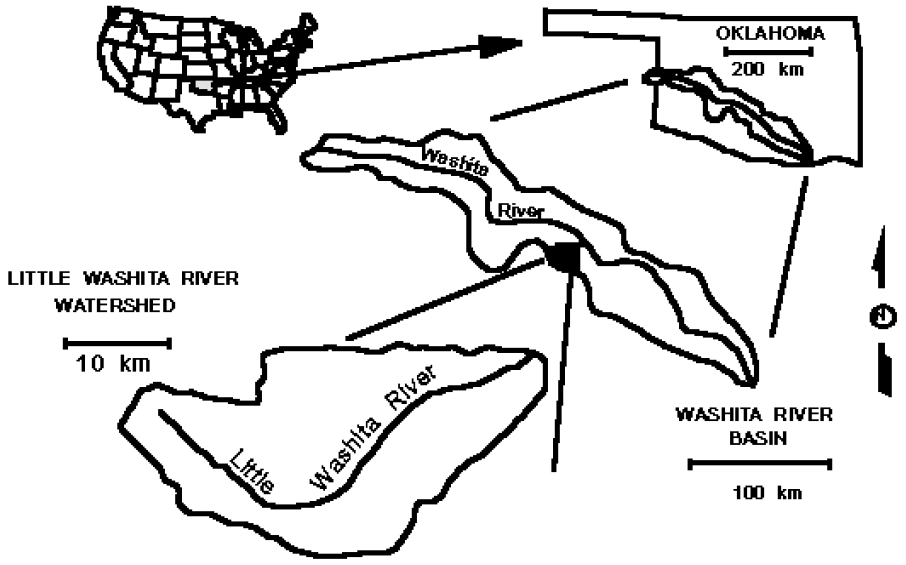

Figure 7.1. Location of the Little Washita River Watershed.

GIS coverages was guided by hydrologic research needs (Goodrich et al., 1994) and an effort to support both distributed and lumped parameter watershed modeling. The coverages are grouped into three categories: topography, soils, and land cover.

The object of this chapter is to present topics relating to the development and use of the three categories of GIS coverages. The selected topics address: (1) the development of hydrographic data layers from the Digital Elevation Model (DEM); (2) reliability of the soil property data extracted from the soils coverage and county soil survey data; and (3) land cover identification from Landsat satellite remotely sensed data.

DIGITAL ELEVATION MODEL AND TOPOGRAPHIC GIS DATA

Automated extraction of topographic parameters from DEMs has established itself in GIS over the past decade. This is attributed to the importance of and need for landscape derived data and to the increasing availability of DEMs and software products that derive topographic data from DEMs. In the field of water resources and hydrology, the main uses of digital landscapes are watershed segmentation, definition of drainage divides and channel networks, determination of catchment geometry, and parameterization of landscape properties such as terrain slope and aspect (Jenson and Domingue, 1988; Mark, 1988; Moore et al., 1991; Martz and Garbrecht, 1992). Such landscape evaluation tasks are generally tedious, time-consuming, error-prone, and often subjective when performed manually from topographic maps, field surveys, or photographic interpretations (Richards, 1981). The automated techniques are faster and provide more precise and reproducible measurements than traditional manual techniques applied to topographic maps (Tribe, 1991). Digital data generated by automated techniques also have the advantage that they can be readily imported and analyzed by GIS.

Most of the topographic coverages presented here were automatically derived from the DEM of the LWRW using software TOPAZ (Garbrecht and Martz, 1999). TOPAZ (TOpographic PArametriZation) is a software package for automated digital landscape analysis. It uses raster DEMs to identify and measure topographic features, define surface drainage, subdivide watersheds along drainage divides, quantify the drainage network, and parameterize subcatchments. TOPAZ is designed primarily for hydrologic and water resources investigations, but is equally applicable to address a variety of geomorphological, environmental and remote sensing applications. TOPAZ is discussed more fully elsewhere in this volume. Topographic GIS coverages of the LWRW, DEM resolution and quality, and degree of watershed segmentation and drainage density are addressed below.

Topographic GIS Coverages

A DEM with a horizontal and vertical resolution of 30×30 meters and 0.3 meter, respectively, is available for the LWRW. The DEM was developed in 1996 by the U.S. Geological Survey, Rolla, MO, from digitized contour data. The quality of the DEM corresponds to a Level 2 DEM; thus it has been processed at production time for consistency and edited to remove identifiable systematic errors. This DEM is the basic GIS coverage representing the landscape topography of the LWRW.

DEM preprocessing is necessary before deriving additional hydrographic and topographic data because DEMs commonly contain localized depressions and flat surfaces, many of which are artifacts of the horizontal and vertical DEM resolution, DEM generation method, and elevation data noise. Depressions and flat surfaces are problematic for drainage identifications. Depressions are sinks at the bottom of which drainage terminates, and flat surfaces have indeterminate drainage.

Therefore, TOPAZ preprocesses the input DEM to rectify these features and allows the unambiguous determination of the drainage over the entire digital landscape. Rectifications are strictly limited to cells of depressions and flat surfaces so as to minimize the impact on the overall information content of the elevation data. Further details on the rectification procedure are given below. With this rectified DEM the hydrographic and topographic coverages listed in Table 7.1 can be derived using software TOPAZ.

Table 7.1. Topographic GIS Coverages and Data Source

GIS Coverage	Source and Development Procedure
Digital Elevation Model	USGS, contour interpolation
Watershed boundary	TOPAZ, downslope flow routing concept
Drainage network	TOPAZ, downslope flow routing concept
Subcatchment drainage boundaries	TOPAZ, downslope flow routing concept
Terrain slope	TOPAZ, surface derivative
Terrain aspect	TOPAZ, surface derivative

The watershed boundary, subcatchment drainage divides, and drainage network computed by TOPAZ are based on the D8 method, the downslope flow routing concept, and the critical source area (CSA) concept. The D8 method (Douglas, 1986; Fairfield and Leymarie, 1991) defines the landscape properties for each individual raster cell as a function of itself and its eight immediately adjacent cells. The downslope flow routing concept defines the drainage on the landscape as the steepest downslope path from the cell of interest to one of its eight adjacent cells (Mark, 1984; O'Callaghan and Mark, 1984; Morris and Heerdegen, 1988). The CSA concept defines the channels draining the landscape as those raster cells that have an upstream drainage area greater than a threshold drainage area, called the critical source area (CSA). The CSA value defines a minimum drainage area above which a permanent channel is maintained (Mark, 1984; Martz and Garbrecht, 1992). The CSA concept controls the watershed segmentation and all resulting spatial and topologic drainage network and subcatchment characteristics.

DEM Resolution and Quality

The spatial resolution and quality of the DEM data are important considerations when deriving hydrographic data from DEMs. The choice of an appropriate resolution must be made under consideration of the landscape characteristics that are to be represented and the use of the derived data products. In the case of the LWRW it has previously been shown (Garbrecht and Martz, 1993) that the network and drainage divides can be adequately derived from a DEM with a 30×30 meter horizontal resolution.

A more difficult question was that of the quality of the elevation data. Accuracy standards, data noise, interpolation errors, and systematic production errors often create spurious depressions, flat areas, and flow blockages which cause problems for the identification of drainage features (Garbrecht and Starks, 1995). These in turn impact the drainage identifications and indirectly the drainage divides and network. The DEM for the LWRW is a Level 2 DEM and has been processed for consistency and systematic errors. However, a Level 2 DEM is not hydrographically corrected and problems such as spurious depression and flat areas remain. These must either be rectified, for example through data preprocessing as described above, or accepted as data limitations. For the LWRW project these problem features in the DEM have been rectified.

Spurious depressions are rectified by a procedure of depression breaching/filling (Garbrecht et

al., 1996), and flat surfaces are rectified by imposing two gradients which are a function of the landscape configuration surrounding the flat surface (Garbrecht et al., 1996). Both these rectifications result in an approximated, yet realistic drainage pattern. It was also common to see discrepancies in the position of derived and actual channels. Such discrepancies were expected because a DEM is only an approximation of the true landscape topography, and the derived drainage divides and network represent the drainage features of the approximated topography.

Degree of Watershed Segmentation and Drainage Network Density

The degree of watershed segmentation and drainage network density are a function of the value given to the critical source area parameter (CSA). The CSA is the minimum drainage area that is required to initiate a first-order channel (Strahler, 1957). Any area smaller than the threshold value does not produce enough runoff to form and maintain a channel. The threshold CSA value depends upon, among other things, terrain slope characteristics, soil properties, land use, and climatic conditions. It can be as small as a fraction of a hectare or as large as tens of hectares, depending on the landscape characteristics under consideration.

Often the CSA value is also used to represent different degrees of watershed segmentation and drainage network densities to address scaling issues. At a small scale, one would choose a small CSA value to represent the smallest channels and hill slopes. As a result, a high degree of partitioning, many subcatchments, and a dense drainage network are obtained. In the case of large-scale applications, only the major streams in the watershed may be needed. A large CSA value would result in the desired low degree of watershed segmentation, few subcatchments, and only large streams. This capability to generate GIS coverages of different degrees of watershed segmentation and drainage network densities is important for landscape modeling.

Figure 7.2 (see color section) is an overlay of the basic LWRW DEM coverage and a TOPAZ-generated stream network from the DEM. The relief of the DEM is approximately 190 m. Each color change on the DEM represents a 7 m change in elevation from the neighboring color. In this example, a CSA of 8 hectares was used to generate the stream network, resulting in 1,218 first order, 264 second order, 54 third order, 12 fourth order, 4 fifth order, and 1 sixth order (Strahler number) channels.

DIGITAL SOILS COVERAGE

The LWRW soil coverages were developed from two data sources provided by the Natural Resources Conservation Service (NRCS): (1) county soil survey maps, and (2) the digital State Soil Geographic Database (STATSGO). The STATSGO database contains the soil attributes for the county soil survey maps. From this information a basic soil coverage and derived soil attribute coverages can be developed.

The basic soil coverage for the LWRW consists of the soil mapping units digitized from the county soil survey maps and rasterized to a 30 m pixel cell size. It was readily apparent that the name given to the soil mapping units is influenced by which county the mapping unit falls within (i.e., the county lines are seen in the soils coverage) [Figure 7.3 (see color section)]. This systematic trend is partly related to the different experience and interpretation of the county's soil scientist in charge of soil classification (Arnold et al., 1994). The trend can also be attributed to different dates at which a county's soils were classified. Soil names of an earlier classification in one county may not correspond to an updated soil classification in another county at a later date. However, it is not the difference in name that is important, but that the soil physical properties are similar for both soil names. Therefore, special care was taken to ensure that the attribute data were

correct for all soils, regardless of soil name, before including them in the GIS data base for the LWRW. The consistency was ensured by involvement of NRCS personnel in the review of the soils attribute data, particularly for the soils along the county lines.

The soil attribute data were transferred from the NRCS STATSGO database into a computer worksheet. The data consist of both generalized attributes for the soil mapping units as well as soil profile data for up to six layers within a mapping unit. The soil layer data include surface and subsurface horizons. Tables 7.2 and 7.3 list examples of attribute data for the soil mapping units and profile layers, respectively. Some attributes are given as maximum and minimum values, and it is up to the investigator's discretion as to which value within this range is appropriate for use in a particular application.

Table 7.2. Examples of Attribute Data for Soil Mapping Units

Slope	Surface Soil Texture
Taxonomic classification	Annual flooding frequency
Flood duration class	Depth to water table
Ponding depth of surface water	Depth to bedrock
Hydrologic soil group	

Table 7.3. Examples of Soil Profile Attribute Data

Depth of Soil Layer	Permeability
Soil texture	Clay content
Water holding capacity	Bulk density

A number of soil attribute coverages can be developed from the basic GIS soil coverage and the attribute data contained in the worksheet by matching the soil mapping units codes in the GIS coverages to soil characteristics in the worksheet attribute file and creating a corresponding soil attribute coverage.

LAND COVER

Land cover is a dynamic entity which varies both spatially and temporally. For example, in agricultural areas it is typical for crop canopies to cover a field for part of the year, while at other times that field is fallowed or bare. Also, crop rotation patterns, crop type, and total acreages planted in crops vary from year to year.

A series of land cover coverages was produced to gain a better understanding of the vegetative dynamics for the LWRW. These coverages were derived from Landsat MSS satellite images for the spring, summer, and fall seasons of every even-numbered year from 1972 through 1994. Each seasonal image was subjected to an unsupervised classification on all four wavebands from the satellite. In the unsupervised approach, a cluster analysis was used to examine the reflectance properties of the land surface and to aggregate related reflectance values into a number of classes. These classes were derived by cluster analysis and represent natural groupings of reflectance values (Eastman, 1992; Lillesand and Kiefer, 1994). Finally, ground truthing was used to assign a land cover category to each class. Land cover categories developed from the seasonal data are water, urban, bare soil, woodlands, native rangeland, tame rangeland (planted), and cultivated lands.

The seasonal remotely sensed data were combined to yield a synoptic temporal view of the agricultural landscape. This was achieved by converting the spring, summer, and fall remotely sensed data into "greenness" values using the greenness vegetation index algorithm (Kauth and Thomas, 1976). The greenness index quantifies vegetation presence and vigor. Colors were assigned to crops in accordance with their "greenness value" and in which season they were actively growing. For example, crops growing only in summer were assigned a color of green, with intensity of that color in proportion to the greenness value. By overlaying these three separate seasonal data sets, a new GIS coverage of the temporal dynamics of the agricultural landscape was produced [e.g., Figure 7.4 (see color section)]. Table 7.4 lists the GIS categories for the coverages of the temporal variability of land cover.

Table 7.4. GIS Categories for Temporal Land Cover Variability

Rangeland:	-native and planted
Wheat :	-spring only
	-fall only
	-spring only
Other crops:	-summer
	-spring and summer
Woodlands	
Water:	-also includes urban and bare soil

CONCLUSIONS

The development and use of three categories of GIS coverages for the LWRW were presented. Selected topics addressed the development of hydrographic coverages from a DEM, reliability of soil property data extracted from county soil survey data, and identification and dynamics of land cover derived from remotely sensed data. Hydrographic data sets were discussed with reference to the quality and spatial resolution of the DEM from which the coverages were derived, and also with reference to the degree of watershed segmentation and drainage network density. Development of the soils coverage revealed inconsistencies in the soil mapping units along county boundary lines within the LWRW. Therefore, NRCS personnel were involved in verifying the consistency of the soil attribute data before it was transferred from the STATSGO data files into the LWRW GIS. Two types of land cover information were derived from remotely sensed data. These show the spatial distribution and temporal dynamics of the land cover. Together these topographic, soil and land cover coverages provide a comprehensive GIS database in support of our research program in water resources and watershed modeling.

CHAPTER 8

Regional Characterization of Inland Valley Agroecosystems in West and Central Africa Using High-Resolution Remotely Sensed Data

Prasad S. Thenkabail and Christian Nolte

BACKGROUND

Inland valleys (IVs) (locally also known as fadamas, bas-fonds, and dambos) have the potential to become agroecosystems with a substantial impact on African food production (Izac et al., 1991). These agroecosystems are favorable for rice cultivation and dry season cropping and have the potential to increase acreage and yields in Africa if careful attention is paid to technical, environmental, and socioeconomic constraints (Juo and Lowe, 1986).

Inventorying, mapping and characterizing inland valleys at regional level (meso/semidetailed level, typically mapped on scales of 1:50,000 through 1:250,000) in sample areas of macrolevel agroecological zones (Figure 8.6, color section) is crucial for the selection of representative research sites, which then allows for the development of appropriate technologies that can be reliably tested and transferred to larger regions (regionalization or technology transfer).

Recognition of the importance of inland valley agroecosystems led the International Institute of Tropical Agriculture (IITA) to adopt a new research agenda, as put forth in Izac et al. (1991). This strategy involved a combination of biophysical and socioeconomic research issues to be addressed at three spatial scales:

a. level I (macro or continental or subcontinental, typically mapped in scales of greater than or equal to 1:5,000,000);
b. level II (meso or regional or semidetailed mapped in scales of 1:100,000 to 1:250,000); and
c. level III (micro or research site/watershed related, mapped in scales of less than or equal to 1:50,000).

This was conceived to facilitate the design of appropriate technology, able to sustain the highly varying resource base and at the same time to be acceptable to smallholder farmers in the diverse socioeconomic and ethnic environment of West and Central Africa.

The first step to characterize parameters critical to land use of IVs constituted the (macro) level I map based on secondary agroecological and soil data using a Geographic Information System (see Thenkabail and Nolte, 1995a for details). The objective was to map on a subcontinental

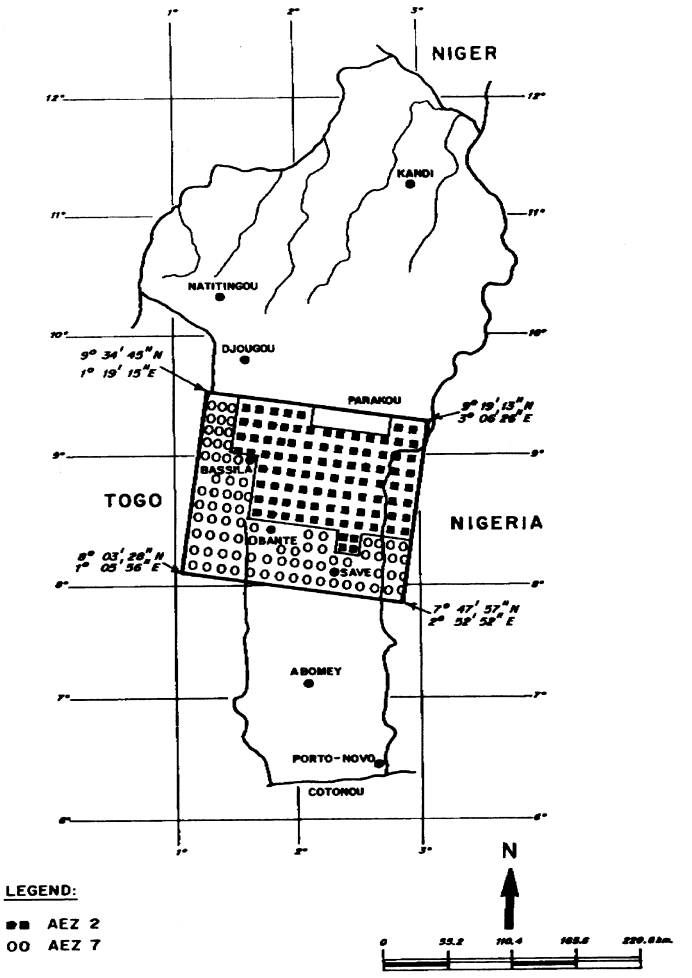

Figure 8.1 Spatial distribution of level 1 agroecological and soil zones (AEZ) in Landsat 192/54. Of a total area about 3.12 Mha, 49% fall into AEZ 2 and 46% into AEZ 7. The remaining 5% area is outside the 18 zones mapped in Figure 8.1.

(macro) scale broad agroecological and soil zones in the mandate area of IITA in West and Central Africa (Figure 8.1b). The level I map was the result of combining two parameters:

a. IITA's agroecological zones; and
b. major soil groupings according to the FAO classification (FAO/UNESCO 1974, 1977).

The five agroecological zones of IITA's map, namely northern Guinea savanna, southern Guinea savanna, derived and coastal savanna, humid forest, and midaltitude savanna, were overlaid with the 23 zones of major soil groupings. This resulted in 18 zones of more than 10 million ha each in West and Central Africa, for a total of 492 million hectares (Figure 8.6, color section).

Regional (or level II) characterization of inland valley agroecosystems were planned within the "windows" of macro (level I) zones. For rapid characterization and mapping at a regional scale of such a large area, which is spread across a subcontinent, it was only feasible using high-resolution

satellite images (Thenkabail and Nolte, 1995a; Thenkabail and Nolte, 1996). The location of the acquired Landsat TM and SPOT HRV satellite images for regional (level II) characterization study in relation to the IITA level I (macroscale) map are displayed in Figure 8.6 in color section.

Four international research centers (IITA, WARDA, CIRAD, Winand Staring Centre and Wageningen Agricultural University) and several national research systems (from Republic of Benin, Burkina Faso, Côte d'Ivoire, Ghana, Mali and Nigeria) acknowledged this holistic research approach to characterization of IVs at a workshop at WARDA headquarters, Bouaké, Côte d'Ivoire, June 1993, since it fit well with the ideas developed by these institutes.

RATIONALE AND JUSTIFICATION

Characterization of the agroecosystems in which IVs occur is available at subcontinental/macrolevel of West and Central Africa (Hekstra et al., 1983; Andriesse and Fresco, 1991; Izac et al., 1991; Windmeijer and Andriesse, 1993). Country/mesolevel studies of inland valley agroecosystems were published for the Republic of Benin by Kilian (1972), for Senegal by Bertrand (1973), for Burkina Faso and Mali by Albergel et al. (1993), and for Côte d'Ivoire by Becker and Diallo (1992). Turner (1985, 1977) gives mesolevel details upon biophysical data of fadamas in Central and Northern Nigeria, which were completed by the studies of Kolawole (1991) on fadama economics and management. Many studies upon dambos and their cultivation pattern have been done in South and Southeastern Africa. For example, Rattray et al. (1953) described vlei cultivation in Rhodesia/Zimbabwe. Other regional studies in this part of sub-Saharan Africa are reviewed by Ingram (1991).

Given the fact that the characteristics of IVs are known to vary dramatically within and across agroecosystems, it is inadequate to characterize only a few IVs as most conventional studies often do. Lack of representativeness of a few study sites in the context of a regional agroecological zone leads to limited extrapolation or regionalization of the results of key sites to other areas within the same agroecological zone.

Lack of an appropriate approach to characterization constitutes a major constraint to research activities in developing technologies that are able to sustain the resource base of large regions and are adoptable by diverse groups of farmers with highly differing socioeconomic and ethnic backgrounds. Therefore, IITA attempted to systematically characterize agroecosystems of IVs in West and Central Africa. This three-tier methodology from macro- to microlevel is intended to lead to the development of technologies at benchmark sites.

OBJECTIVES AND APPROACH

Level-II (regional) characterization work involves establishing detailed characteristics of IV agroecosystems in sample areas of level I. The specific objectives envisaged in level-II characterization fall within the overall objectives of Izac et al. (1991) and were:

1. inventory the area of inland valley systems and their uplands;
2. map the spatial distribution of IVs, and study their spatial variability;
3. study the existing land-use pattern of IVs and uplands, and establish their interactions;
4. explore the potential of IVs for dry-season cropping;
5. determine the existing crop types and cropping pattern in IVs, and on uplands;
6. map the major road systems and significant settlements;
7. establish the cultivation pattern with respect to distance from road network and settlements;
8. study the watershed, and establish morphometric characteristics of IV watersheds;

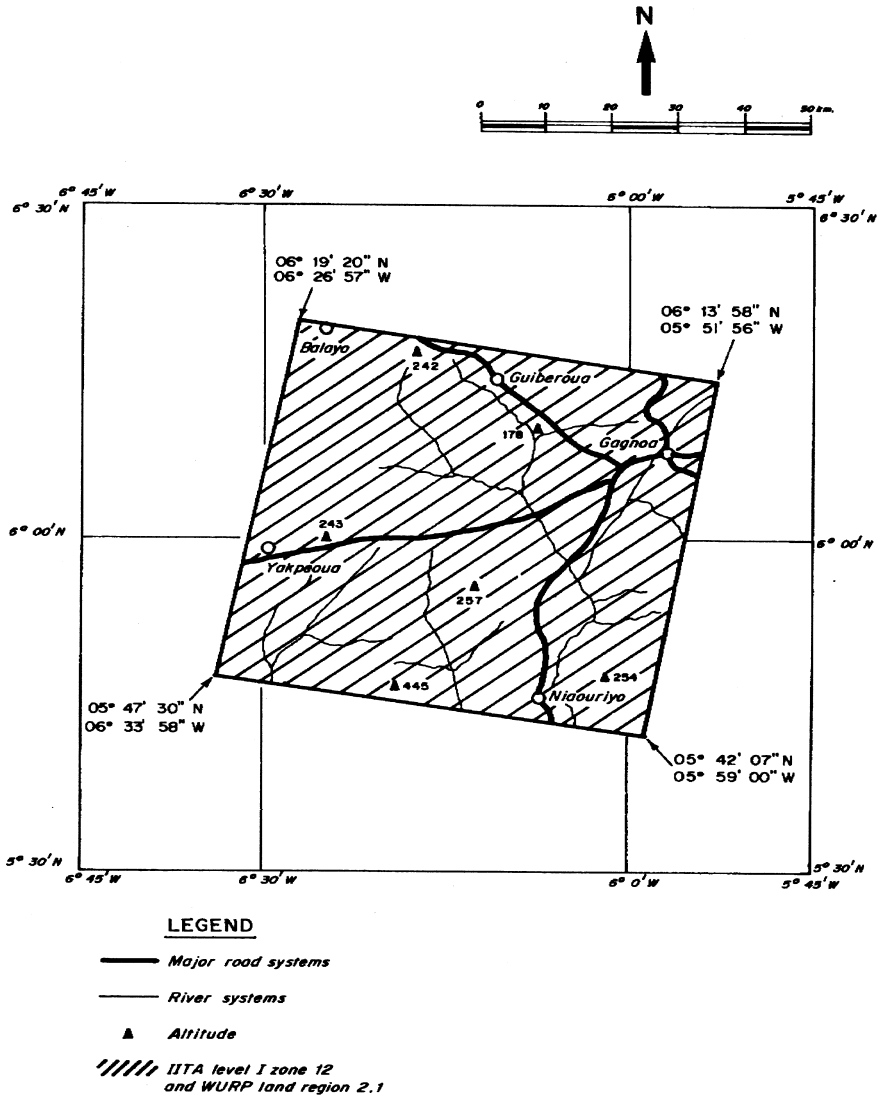

Figure 8.2 Spatial distribution of level 1 agroecological and soil zones in SPOT K:J of 47/338. Of the total area of).49 Mha, the entire 100% are falls in AEZ 16.

9. describe morphological IV characteristics such as shape, size, and slope;
10. make it possible to compare and contrast IVs within and across agroecological and socioeconomic zones in West and Central Africa;
11. rationalize the selection of representative benchmark site/s or benchmark IV watershed/s for the main phase research (i.e., technology development) activity; and
12. reveal the socioeconomic conditions of IV use. (Note that this is not part of the ongoing study).

IITA adopted a specific approach to achieve the above specific level-II objectives through integration of high-resolution satellite data with Global Positioning System (GPS) data, and ground-truth data in a Geographic Information Systems (GIS) framework. A comprehensive methodology

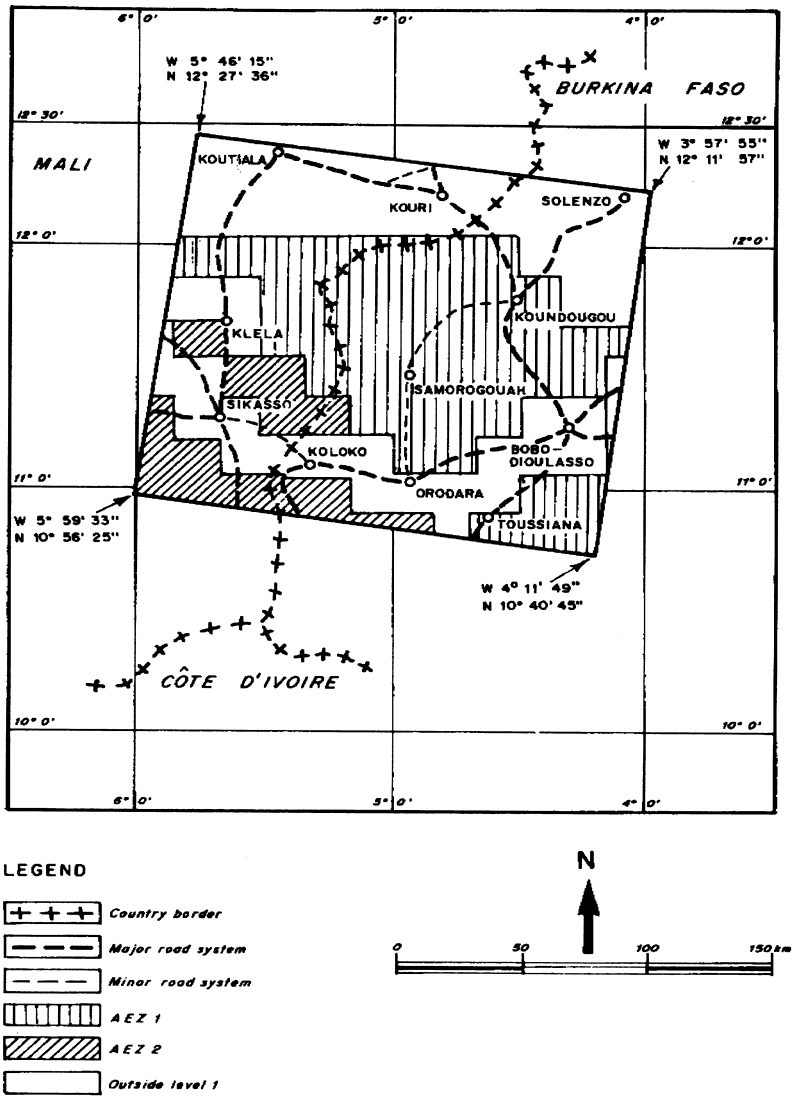

Figure 8.3 Spatial distribution of the level I agroecological and soil zones in Landstat 197/52. Of the total area of about 3.14 Mha., 45% is in AEZ 1 and 12% in AEZ 2. As for the rest of the area, 43% is outside the 18 AEZs mentioned in Figure 8.1.

for rapid characterization and mapping of inland valley systems at regional level using satellite imagery was developed and reported by Thenkabail and Nolte (1996, 1995a).

In this chapter two Landsat TM images (path 192 and row 54 and path 197 and row 52, [(see Figure 8.1and 8.2; and Table 8.1 for details and spatial location)], and one SPOT HRV image (Figure 8.3, 8.6 in the color section and Table 8.1)] were was used for the study. These images were selected, based on a set of criteria that included availability of cloud-free (0% cloud cover) satellite scenes, location of images in different agroecological and socioeconomic zones, most recently available dates of satellite overpasses (images were of early 1990's-see Table 8.1), accessibility of

the region for ground-truthing, and coverage during wet and dry seasons. The images covered four agroecological and soil zones (AEZ) of level I—AEZ 1, 2, 7, and 16.

Inland valleys, their fringes, and uplands distributed in each of the above AEZs were be reported along with their land-uses, cultivation intensities , and their spatial distribution.

The level II work offers :

a. the capability to zoom in on IV agroecosystems from macro- to microlevels ("top-down" approach) leading to the rationalization of benchmark site selection for technology development research activities; and
b. the capability to extrapolate research results to larger regions or the regionalization of research results ("bottom-up" approach) for the transfer of technology.

DEFINITION USED FOR MAPPING INLAND VALLEYS

It is obvious from the various accounts in the literature that there is no single, widely accepted definition of IVs. They (IVs) are one of the many forms of wetlands that are characterized in their bottom by hydromorphic soils. Beyond this, there are significant variations in the definitions and characteristics of IVs even within the same region as perceived by different people (e.g., Savvides, 1981; Raunet, 1982; Hekstra et al., 1983; Acres et al., 1985; Mäckel, 1985; Turner, 1985; Andriesse, 1986; Oosterbaan et al., 1987; Andriesse and Fresco, 1991; Izac et al., 1991; Mokadem, 1992). For example, Mäckel (1985) defines a uniform zonation of dambos in Southeast Africa depending on vegetation, soil type, moisture content, and morphodynamics of the dambo.

Lack of a consistent definition of IVs has been a constraint in comparing or synthesizing different studies. To most researchers, characterization of IVs meant valley bottom characterization. Others included fringes also in their studies. Andriesse and Fresco (1991) proposed a physiohydrographic model of an inland valley.

The working definition adopted in this study will be as follows: Inland valleys (IVs) comprise valley bottoms and valley fringes (Figure 8.5). Valley bottoms are characterized by hydromorphic soils that constitute a relatively flat surface with or without a central stream. Valley fringes refer to areas along the slopes of the valley; rainfall either runs off above the surface of these areas or interflows horizontally on impervious subsurface layers toward the valley bottom and the central stream. Valley fringes, typically, have two distinct characteristic zones (Figure 8.5):

1. the lower part of the valley fringe immediately adjoining the bottoms that may have a high likelihood of a seasonal hydromorphic zone with significant potential for dry-season cropping; and
2. the upper part of the valley fringe with steeper slopes, in zones with less than 1400 mm rainfall (Guinea savanna) characterized predominantly by impervious layers (ironstones or carapaces) from which rainwater quickly runs off to the valley bottom). Soils in these upper portions of valley fringes dry out rapidly once the rains have ceased, and therefore, have no potential for dry-season cropping.

METHODOLOGY

An overview of the methodology has been shown in Figure 8.4 and described in detail in Thenkabail and Nolte (1995) and Thenkabail and Nolte (1996). The methodology permits a rapid characterization of large areas on a regional scale. The methodology includes the description of techniques for:

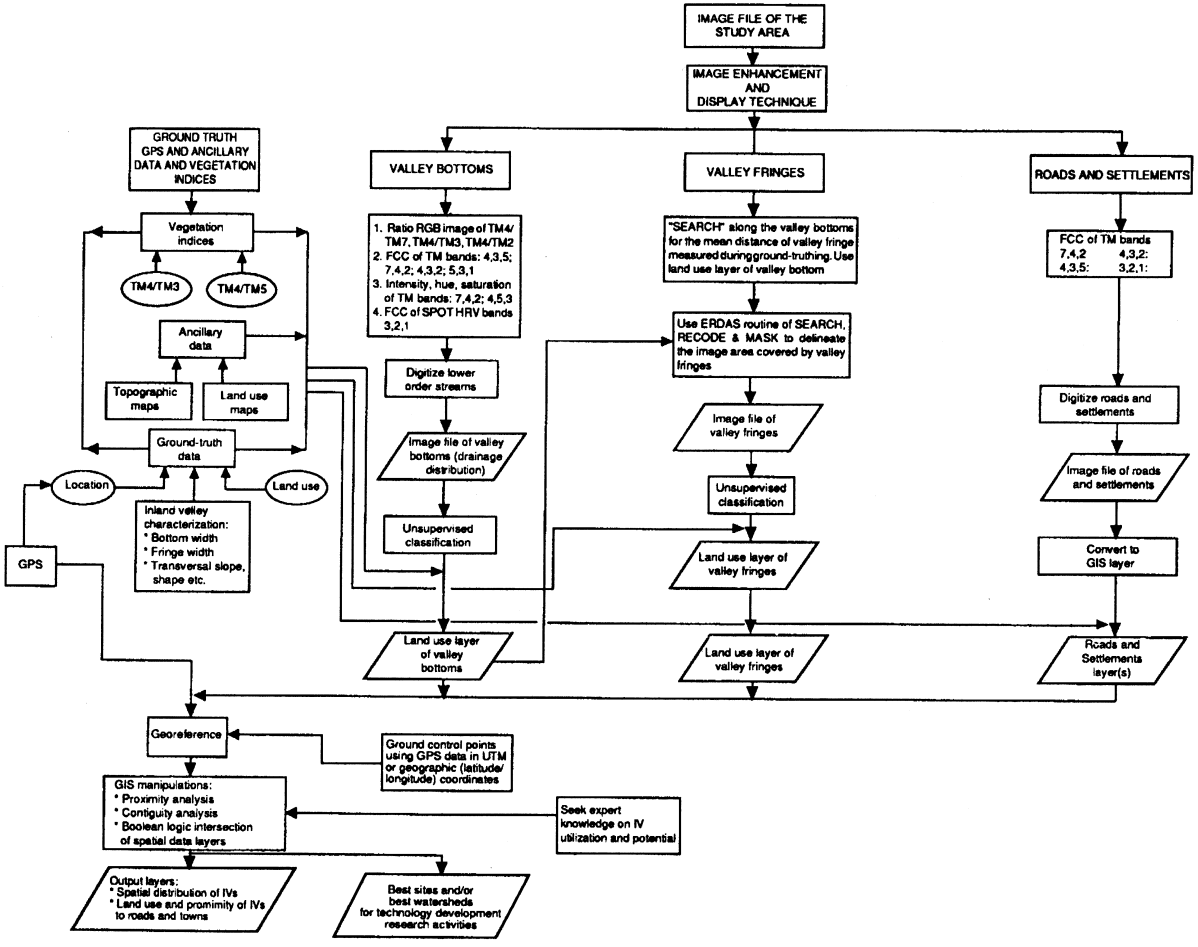

Figure 8.4 Methodology for mapping and characterizing Inland Valley (valley bottoms plus valley fringes) agroecosystems using Remote Sensing, Global Positioning System (GPS), and Ground-Truth Data.

1. valley bottom mapping;
2. valley fringe mapping;
3. mapping roads and settlements;
4. establishing land-use land-cover characteristics across the IV toposequence (uplands, valley fringes, and valley bottoms); and
5. establishing other IV characteristics such as IV stream densities and stream frequencies.

Figures 8.7 to 8.11 in the color section demonstrate the application of the methodology (Figure 8.4) for certain subareas of the study. Using the methodology, valley bottoms were highlighted (Figure 8.7, see color section) and delineated (Figure 8.8, see color section) for a subscene in Landsat TM path and row 192/54 that is part of agroecological and soil zone (AEZ) 7. The fringes adjoining the bottoms were mapped as illustrated in Figure 8.9 in the color section. A similar procedure was used to delineate valley bottoms from a SPOT subscene (Figure 10, see color section) which is in AEZ 16. Figure 8.11 in the color section (in AEZ 2) illustrates the large widths of the valley bottoms that are seasonally flooded and are characteristically dissimilar to valley bottoms in other AEZs. Sixteen land-use classes (Table 8.2) were mapped consistently across each study area based on the percentage distribution of 10 different land-cover types (Table 8.3).

Table 8.1 Parameters Describing the Level I Agroecological and Soil Zones[a]

Level I AEZ[b]	Agroecological zone According to IITA's Definition	LGP[c] (days)	Major FAO Soil Grouping[d]	Area[e] (million ha)

STUDY AREAS AND GROUND-TRUTHING

In this chapter results of the three study areas (each satellite image comprising a study area) have been discussed (Table 8.4 and 8.1; Figures 8.1, 8.2, and 8.3; Figure 8.6, see color section). These study areas cover four distinct agroecological and soil zones (AEZ) in:

1. AEZ 2 (49% of the total area) and AEZ 7 (46%) by Landsat path 192 and row 54 (having an total area of 3.12 million hectares) (Figures 8.1, 8.6, see color section, Table 8.1 and Table 8.4);
2. AEZ 16 (100% of the total area) by SPOT HRV K 47 and J 338 (having an total area of 0.39 million hectares); (Figures 8.2, 8.6, see color section, Table 8.1 and Table 8.4) and
3. AEZ 1 (45% of the total area) and AEZ 2 (12%) by Landsat path 197 and row 52 (having an total area of 3.14 million hectares) (Figure 8.3, 8.6, see color section, Table 8.1 and Table 8.4).

Table 8.4 Attributes of Landsat TM and SPOT HRV Data Acquired for the Level II Characterization of Inland Valley Agroecosystems in West and Central Africa [a]

Landsat TM Path	Landsat TM Row		Center Coordinates		Date of
SPOT HRV K	SPOT HRV J	Region / Country	longitude	latitude	Overpass
192	54	Save / Republic of Benin	02° 06′ E	08° 41′ N	12/29/91
47	338	Gagnoa / Côte d'Ivoire	06° 12′ W	06° 00′ N	12/27/90
197	52	Sikasso / Mali	04° 59′ W	11° 34′ N	09/27/91

[a](See their location in Figure 8.1)

Ground-truthing was conducted to correspond with satellite overpass dates during 1993 and 1994 (Table 8.4). The location of each ground-truth site was determined using a global positioning system (GPS) Garmin 100-SRVY. Locations noted were geographic co-ordinates (latitude/longitude) in degree, minutes and seconds, and universal transverse mercator (UTM) coordinates (x,y) in meters. The accuracy of these GPS readings was within ± 30 m. The GPS was also used to collect ground-control points to georeference the satellite image.

Land-use measurements were made in a 90 m by 90 m plot of the valley bottoms, valley fringes, and uplands. Its location was determined from the center with the GPS. The leaf area index of trees, shrubs, and grasses was measured in the same plot. Each land-use class has varying degrees of land cover types (Table 8.3). A total of 10 land-cover types was recorded at each ground-truth site: water, trees, shrubs, grasses, cultivated farms, barren farms, barren lands, built-up areas or settlements, roads, and others. Different combinations of these landcover types constitute specific land-use categories (Table 8.2).

The measurements (in meters) of valley-bottom and valley-fringe width were taken at a transect covering the 90 m by 90 m plot for land-use measurements. Other characteristics recorded at each inland valley sample site included valley bottom width (in meters), valley fringe width, transversal slope (degree), stream order (number), and qualitative observations of the soil moisture status as well as the level of water management system prevailing in valley-bottom fields.

RESULTS AND DISCUSSIONS

The results of each of the three study areas have been discussed seperately in the subsections below. Data from Landsat and SPOT satellites for the study areas described below were integrated with GPS location data and ground-truth data in a GIS framework. The spatial data layers were georeferenced to Universal Transverse Mercator (UTM) coordinates obtained during ground-truthing using a GPS. Digital georeferenced databases generated include spatial distribution of inland valleys and land-use classes of inland valleys and uplands.

Save (Republic of Benin) study area

The study area [Figures 8.1, 8.6 (see color section), Table 8.1, and 8.4] encompassed two level I (macro or subcontinental) agroecological and soil zones: 1.AEZ 2 (southern Guinea savanna with Luvisols) and AEZ 7 (derived savanna with Luvisols) [see Table 8.1, Figures 8.1, and 8.6 (see

color section)]. AEZ 2 is representative of 18.4 million ha and AEZ 7 of 24.9 million ha in West and Central Africa (see spatial distribution of these zones in Figure 8.6 in the color section and Table 8.1). Both these agroecological and soil zones have Luvisols as major soil grouping. The zones differ in their length of growing period, with AEZ 2 having 181–210 days and AEZ 7 having 211–270 days. The study area is part of a region that gets rainfall varying between 975 mm and 1336 mm per year. Of the total study area 49% falls into AEZ 2 and with 46% into AEZ 7, while the remaining 5% is located outside the level I zones.

A total of 9.0% (281,500 ha) of the entire study area (3.12 million ha) is occupied by valley bottoms (Figure 8.12, see color section and Table 8.5). The corresponding numbers for the subzones were 7.9% in AEZ 2 and 10.2% in AEZ 7. Valley fringes accounted for 18.3% in AEZ 2, 21.8% in AEZ 7, and 19.9% in the entire study area, while uplands represented 73.3% in AEZ 2, 67.1% in AEZ 7, and 70.3% in entire study area. These results indicated a greater percentage of inland valleys in the wetter zone (AEZ 7) compared to the drier zone (AEZ 2).

The cultivation intensity differed only marginally between the AEZs (Table 8.5). A total of 7.9% of the valley bottoms in the entire study area were cultivated with 7.9% in AEZ 2 and 7.7% in AEZ 7. A total of 15.9% of the valley fringes was cultivated in the entire study area with 15.1% in AEZ 2 and 16.6% in AEZ 7. Compared to the valley fringes, less of the upland area was used as farmland, 13.2% across the entire study area, 11.2% in AEZ 2, and 14.3% in AEZ 7. These results indicated a low percentage of cultivation across the toposequence. This was attributed to: (a) a low density of the road network and (b) a low number of settlements, hence low population densities. In addition, socioeconomical issues such as the traditional preference of farmers in cultivating uplands, debilitating diseases in lowlands, lack of appropriate technologies (e.g., low-cost water management techniques), lack of knowledge about lowland agriculture, lack of market access, and lack of governmental support for farmers imply less than optimal utilization of inland valleys for agriculture.

TM data facilitated mapping the shape, size, spatial distribution, density, and frequency of inland valley bottoms occurring in the study area. The spatial distribution of these characteristics is illustrated in Figure 8.12 in the color section. They were also found to be very useful in detecting settlements (usually of sizes of >15 ha) and the motorable road network. This was especially useful in mapping the recent spread of settlements and the road systems in the absence of such information on base maps, such as topographic maps (which were mostly available from the early 1960s). Furthermore, the cultivation pattern of inland valleys with respect to their distance from settlements and the road network could be studied.

There was a high spatial correlation in the cultivation pattern of valley bottoms and valley fringes compared with the cultivation pattern of uplands. Significantly cultivated areas are mainly concentrated along major road networks and near settlements. The degree of cultivation decreased significantly as the distance from settlements or the road network increased. Stream drainage densities (km/km^2) were denser in the wetter zone (AEZ 7: 1.07 to 1.20 km/km^2) compared to the drier zone (AEZ 2: 0.9 to 1.0 km/km^2). The same was true for inland valley stream frequencies (number of streams per km^2): 0.95 to 1.10 streams/km^2 in AEZ 7; and 0.74 to 0.79 streams/km^2 in AEZ 2.

About 90% of the inland valleys were classified as U-shaped. Only about 17% of those surveyed during ground-truthing had some improved water management schemes, such as field leveling and bunding. The valley bottom widths of first- to third-order valleys in AEZ 2 and AEZ 7 varied between 40 m and 81 m and hence provided considerable valley-bottom areas (7.7% to 9.0% of the geographic area). The valley bottoms are flat to near-flat. Most valley bottoms are characterized by grassy vegetation that could be easily cleared for cultivation.

Land-use characteristics were mapped separately for valley bottoms, valley fringes, and up-

Table 8.5. Distribution of Valley Bottoms, Fringes, and Uplands, and Their Cultivation Pattern in the Save (Republic of Benin) Study Area[a]

100	18.0	20.6	40.3	16.9	40.1	15.0

[a]The study area falls entirely into agroecological zone 16 of the level I map (Figure 8.1and Table 8.1).

The entire study area [Figure 8.2, and 8.6 (see color section) Table 8.1, and Table 8.4] falls within a single level I (macro) agroecological and soil zone 16 (AEZ 16): the humid forest zone with Acrisols as the major soil grouping according to the FAO soil map of the World (FAO/-UNESCO, 1977) (see Figure 8.2 and Table 8.1). As a result, the characteristics reported for the entire study area will also be true for the macroscale zones AEZ 16 (Figure 8.2).

The study area comprises 18% valley bottoms (Figure 8.13, see color section), 40.3% valley fringes, 40.1% uplands, and 1.6% others (e.g., roads, settlements) (Table 8.7). The area covered by valley bottoms (18%) was relatively high as a result of large bottom widths with mean values of 89 m (first-order valleys), 164 m (second-order), 173 m (third-order), and 244 m (fourth-order). These measurements showed a high variability across the stream orders. First-order valleys had significantly smaller valley bottoms than higher-order valleys. The inland valley stream density in the study area was determined as 0.97 km/km^2 (medium as per Hekstra et al., 1983) and the stream frequencies were determined to be 0.75 streams per km^2 (coarse as per Hekstra et al., 1983). The mean valley fringe widths were 300 m (first-order valleys), 303 m (second-order), 355 m (third-order), and 436 m (fourth-order).

The 16 land-use classes (Figure 8.16, see color section)– six for uplands, three each for valley fringes and valley bottoms, and four others—were mapped for the entire study area (Table 8.8). The total area covered by humid forest vegetation with insignificant farmlands (land-use classes 5, 6, 9, and 12) was 58.3%, whereas the area with humid forest-cropland mosaic (land-use classes 2, 8, and 11) was 23.0% of the total geographic area. The intensity of cultivation was significantly higher for valley bottoms (20.6%) compared with valley fringes (16.9%), and uplands (15%) (Table 8.7). This was mainly a result of the use of valley bottoms for rice cultivation, as revealed by ground-truthing. In the entire study area of the image, the most significant areas of farmlands were in the lower left corner (southwestern portion) of the image near the settlement of Yakpéoua and around predominant settlements, such as Gagnoa and Guibéroua (Figure 8.4). In significant portions of the image there was a strong relationship in the cultivation of uplands and inland valleys.

As expected in a low population density area that belongs to the humid forest zone (Figure 8.6 in color section), the forest vegetation (classes 5, 6, 9, and 12) dominates the image. In the classification system used in this study, the characteristics of areas with insignificant farmlands at valley fringes (class 9) and in valley bottoms (class 12) are similar to those areas with dense and very dense forest on uplands (classes 5 and 6). The only difference is in the toposequential position of the area under consideration. The vegetation of these classes mostly consists of dense and vigorous evergreen trees, and dense and vigorous shrubs. Grasses were less common and farmlands were insignificant in these classes.

Notes:
[a]The study area falls entirely into agroecological zone 16 of the level I map (Figure 8.1 and Table 8.1)
[b]Class 3 occurs only in Guinea savanna zones.
[c]Spectral characteristic of vegetation in class 9 is similar to that of classes 5, 6, and 12; the difference is mainly in the toposequence position.
[d]Mainly riparian vegetation; spectral characteristics of vegetation similar to classes 5, 6 and 9; the difference is mainly in the toposequence position.

Areas on uplands, at fringes, and in valley bottoms with forest and savanna vegetation and scattered farmlands (classes 2, 8, and 11) have > 10% and < 30% of cultivation and can be termed as forest-cropland mosaic. This mosaic occurs especially in the middle and western portions of the image, covers about two-thirds of the overall image, and is typically to be found around settlements and major road networks (areas around Gagnoa and Guibéroua in Figure 8.4).

The forest-cropland mosaic land-use classes (2, 8, and 11) contain a significantly higher percentage of farmlands (land-cover types 5 and 6) and a lower percentage of trees and shrubs (land-cover types 2 and 3), but they still have a significant amount of forest vegetation. The overall area under forest-cropland mosaic represents 23.0% of the total geographic area.

Ninety-two percent (92%) of the inland valleys (valley bottoms plus valley fringes) were U-shaped. Ninety percent of these valleys were considered suitable for cultivation, which means that the bottom width was reasonably large enough (> 5–10 m wide and more or less flat). Low-level water management systems, such as leveling and bunding of fields were found in 25% of all the valleys. The characteristics of valley bottoms, such as their widths, spatial distribution (density,

frequency, and location), and land-use characteristics, were mapped for the entire study area as displayed in Figure 8.16, see color section.

The characteristics of inland valleys in the region clearly indicate a vast potential for agricultural development (Table 8.7): over 80% of the valley bottoms and valley fringes are currently unexploited, they offer wide bottom widths, adequate water resource, and are relatively easy to clear compared to uplands due to the presence of significantly fewer trees.

All major and minor roads discernible on SPOT data were mapped, providing a road network density of 0.16 km/km^2 which is considered as a good road infrastructure by Manyong et al (in preparation). Ninety-three settlements of varying sizes were also mapped based on SPOT data, constituting a significant portion of the overall settlements in the study area. The relationship between intensity of cultivation and the distance of farmlands from roads and settlements was established. The intensity of cultivation at all the components of the toposequence (valley bottoms, valley fringes, and uplands) was slightly lower at distance zones beyond 4 km compared with distances within 4 km. This was due to the presence of a large number of well connected small road systems, equally well distributed small settlements, and therefore good access to markets. The spatial distribution of these characteristics are illustrated in Thenkabail and Nolte (in press, 1995c).

Sikasso (Mali), Bobo-Dioulasso (Burkina Faso) Study Area

In this study area Landsat–5 Thematic Mapper (TM) Path: 197, Row: 52, with a total area of 3.13 million hectares, (see the exact coordinates in Figure 8.3) was used. The total study area (3.13 million hectares) [Figure 8.3, 8.6 (see color section) Table 8.4] comprised 8.6% valley bottoms, 20.4% valley fringes, and 70.2% uplands (Table 8.9). Water bodies, roads, and settlements comprised the other 0.8% area (Table 8.10). The drainage density of 0.4 km per km^2, and stream frequency of 0.61 number per km^2 obtained in the study area were classified as low (0.3 to 0.6 km/km^2), and coarse (0.5 to 1.0 number/km^2), respectively, by Hekstra, et al. (1983). In spite of the low and coarse drainage densities, and stream frequencies in the study area, the percentage area of inland valleys (valley bottoms plus valley fringes) were significant mainly as a result of large valley bottom and fringe widths of the inland valley streams (first- to fourth-order streams). The mean bottom widths for the first- to third-order stream were about 90 meters, increased dramatically for the fourth-order to about 400 meters. The mean valley fringe (hydromorphic plus nonhydromorphic) widths for the first three inland valley streams were about 200 meters, and for the fourth-order stream about 920 meters. Hence, even though the stream frequencies and stream densities were coarse and low, respectively, the large sizes of the valley bottoms and valley fringes led to their significant percentages.

Due to significant differences in the geographical areas studied (45% of entire study area for AEZ 1, 12% for AEZ 2; Table 8.9) a direct and realistic comparison of results across zones was not feasible. However, it may be noted that the valleys in AEZ 1 had greater bottom widths than valleys in AEZ 2, resulting in higher percentage area of valley bottoms (Figure 8.14, see color section) in AEZ 1 (9.1 %) compared to AEZ 2 (7.7 %). Due to the same reason, the percentage valley bottom area in land region 2.8 (9.1%) exceeded that of land region 3.3 (8.2%).

The study mapped 16 land use classes [Figure 8.17 (see color section) and Table 8.10] in the total study area of 3.13 million hectares and for the subzones [Figure 8.19 (see color section)]. The spatial distribution of these characteristics are illustrated in Thenkabail and Nolte (1995d).

The grassland dominant savannas dominate the study area. The overall savanna percentage areas were 65.5% for AEZ 1, 70.4% for AEZ 2, 67.1% for land region 3.3, 61.6% for land region 2.8, and 65.4% for the entire study area. The forest classes are predominantly trees along the river bank and were about 4% for all level I zones within the study area. This very low percentage of

forest cover was only to be expected in the study area as it falls in the northern guinea savanna and sudan savanna. The study areas in the sudan savanna comprised of maximum barren areas of 6% when compared to other level I zones studied.

The cultivation intensities were nearly the same across the toposequence with 18.4% for valley bottoms, 19.2% for valley fringes, and 21.9% for uplands (Table 8.9). The significant cultivation across the toposequence were mainly attributed to the market-driven conditions. In most cases cultivation intensities were about 3% higher for distance limits within 0–5 km from road network and settlements compared to those areas beyond 5 km.

The valley bottoms in the study area were characterized by flat or near-flat surfaces that have shallow flooding all through the rainy season. Rice cultivation (Figure 8.19, see color section) forms an important component of lowland rainy season cultivation in the entire study area, especially in the valleys surrounding Sikasso, Mali. These broad and flat or near-flat valley bottoms of the study area offer an excellent opportunity for innundated rice cultivation (swamp rice) during rainy season. However, the area of valley bottoms available for cultivation far exceeds their current utilization. A total of 269,006 hectares constitute valley bottoms (Figure 8.14, see color section) in the entire study area, of which only 18.4% (49,497 hectares) was cultivated. Of the cultivated IVs 42% (20,789 hectares) had rice cultivation (Figure 8.19, see color section).

One hundred percent of the inland valleys that were studied were ‘U’ shaped, 74% were fadamas (that is, inland valleys with potential for dry season cropping). At the time of groundtruthing 69% of the inland valleys were wet, 21% were moist, and 10% were dry. A mapping of

biomass levels during summer will show: (a) upland and lowland contrasts in maximum as a result of significant moisture presence in lowlands relative to near dry uplands; (b) biomass variations within valley highlighting moisture availability in the valleys (see an illustration in Figure 8.21, see color section) when upland vegetation is dry. The mean transversal slopes were generally mild with about 1.5 degrees for the first- to third-order inland valley streams, and about 0.5 degrees for the fourth-order inland valley streams.

The study showed a strong relationship between upland cultivation and inland valley cultivation (Table 8.9) proving one of the hypotheses of this study.

SUMMARY

This study used high-resolution satellite images from Landsat TM and SPOT HRV in three separate study areas [Figure 8.1, 8.2, 8.3 and 8.6 (see color section), and Table 8.4) covering four agroecological and soil zones (AEZs; as shown in Figure 8.6 in the color section) of West and Central Africa to characterize and map inland valley agroecosystems. The characteristics studied include: inventorying the areas of inland valleys (valley bottoms plus valley fringes), determining the cultivation intensities of inland valleys and their uplands, and studying the land-use characteristics of inland valley bottoms and fringes, and their uplands.

The paper briefly outlined the holistic three-tier "top-down" approach developed by IITA to rapidly characterize and map inland valley agroecosystems of West and Central Africa at macro (level I), regional (level II), and micro (level III) scales. The focus of the paper was in applying the methodology for regional (level II) characterization and mapping of inland valleys in four major level I agroecological and soil zones (AEZ) using high-resolution satellite imagery from Landsat and SPOT systems (see Figures 8.7–8.11 in the color section for illustration of the methodology along with Figure 8.4). The three study areas were: (1). Save, Republic of Benin (Figure 8.1) covered by a Landsat TM image; (2). Gagnoa, Côte d'Ivoire (Figure 8.2) covered by a SPOT HRV; and (3). Sikasso, Mali/Bobo-Dioulasso, Burkina Faso (Figure 8.3) covered by a Landsat TM image. The three images cover four different agroecological and soil zones [AEZ 1, 2, 7, and 16; see Figures 8.1, 8.2, 8.3, and 8.6 (see color section), and Table 8.4] with a total area of about 6.6 million hectares.

The study made it possible to estimate inland valley (valley bottoms plus valley fringes) areas and their degree of cultivation (Table 8.5, 8.7, and 8.9). Inland valley bottoms (Figures 8.12, 8.13, and 8.14 in the color section) were highest in the humid forest zone (AEZ 16) with 18% (Figure 8.13 in the color section with Figure 2, and Table 7) of the total geographic area of study compared to 9.1% (Figure 8.14 in the color section with Figure 8.3, and Table 8.9) in northern Guinea savanna (AEZ 1), 7.7% (Figure 8.14 in the color section with Figure 8.3, Table 8.9) to 7.9% (Figure 8.12 in the color section with Figure 8.1, and Table 8.5) in southern Guinea savanna (AEZ 2), and 10.2% (Figure 8.12 in the color section with Figure 8.1, and Table 8.5) in the derived savanna (AEZ 7).

Currently, only 8% to 20% inland valley bottoms and 15% to 22% inland valley fringes are exploited for agriculture in AEZ 1, 2, 7, and 16 (Tables 8.5, 8.7, and 8.9). The vast percentage of unexploited inland valleys are rich in soil fertility, have potential for rice cultivation during main cropping season, and significant percentage of valleys have sufficient moisture to sustain upland crops during dry season.

Sixteen similar land-use classes were mapped cutting across the toposequence (uplands, valley fringes, and valley bottoms) for each study area (Tables 8.6, 8.8, and 8.10; and Figures 8.15, 8.16 and 8.17 in the color section). The toposequence oriented land-use mapping has been a unique feature of this study. It is indeed clear from this study that the inland valley bottoms that constituted

7.7% to 18% of geographic area have great economic significance with rich potential for agricultural and ecological exploitation [see an example in Figure 8.19 (see color section) for rice cultivation] and preservation and hence deserve to be mapped as separate land units. The land-use classification resulted in estimates of areas covered by savannas, forests, farmlands, wetlands, and other land-uses (water, settlements, road networks, and barren areas) apart from estimating percentage areas cultivated and the the percentage areas still available for exploitation.

The area of inland valleys was significantly higher in wetter agroecological zones compared to drier zones. For example, valley bottoms in humid forest (AEZ 16) were 18% (Figure 8.13, color section; Table 8.7) and in derived savanna (AEZ 7) were 10.2% (Figure 8.12, color section; Table 8.5) compared to much lower areas in the northern Guinea savanna (AEZ 1) with 9.1% (Figure 8.14, color section; Table 8.9) and southern Guinea savanna (AEZ 2) with 7.7% (Figure 8.14, color section; Table 8.9) and 7.9% (Figure 8.12, color section and Table 8.5). In each study area there was a strong relationship between inland valley and upland cultivation (Tables 5, 7, and 9).

There was no clear relationship between the degree of cultivation and the agroecological zones. One of the hypotheses (Izac et al., 1991) was that drier zones will have a greater degree of valley bottom utilization than the wetter zones as moisture availability in the valley bottoms is more crucial in drier zones than wetter zones. This hypothesis is not a practical reality as other factors play an important role in inland valley utilization. Availability of reliable rainwater supply during wet season, relatively better access to technologies, higher population densities, and higher densities of road networks and socioeconomic factors facilitated utilization of 20.6% (Table 8.7) of valley bottoms, mostly for rice cultivation, in Gagnoa study area. In contrast, the percentage utilization of valley bottoms were, generally, much lesser in drier agroecological zones of Save (Table 8.5) and Sikasso (Table 8.9) due to relative absence of above-mentioned factors.

Digital georeferenced databases generated from the study consisted of the spatial distribution of inland valleys, land-use characteristics of inland valleys and their uplands, and major settlements and road-networks. Other spatial data layers like GPS data, ground-truth data, and expert knowledge databases were integrated with remote sensing derived digital databases into a Geographic Information Systems (GIS) framework. Spatial modeling of these data layers resulted in deriving potential benchmark research areas for technology development research activities (Figure 8.20, color section).

Figure 8.20. Location of potential benchmark research sites for technology development research activities in the study area covered by Landsat TM path: 197 and Row:52 (Sikasso, Mali; Bobo-Dioulasso, Burkina Faso). These locations were selected by integrating remote sensing, GIS, ground-truth, and expert knowledge data in a GIS model.

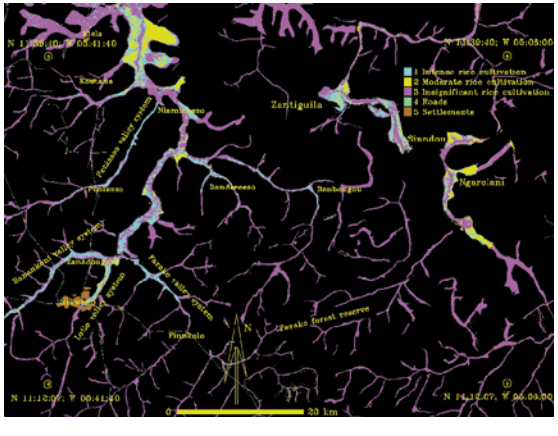

Figure 8.19. Rice cultivation in inland valleys bottoms surrounding Sikasso Mali (AEZ 2). The areas in magenta have either insignificant or no rice cultivation, but have very high potential for exploitation for rice cultivation. The flat and large valley bottoms, which are significantly flooded during rainy season and fertile soils, make these valleys ideal for rice cultivation. Special varieties that can withstand flooding are required.

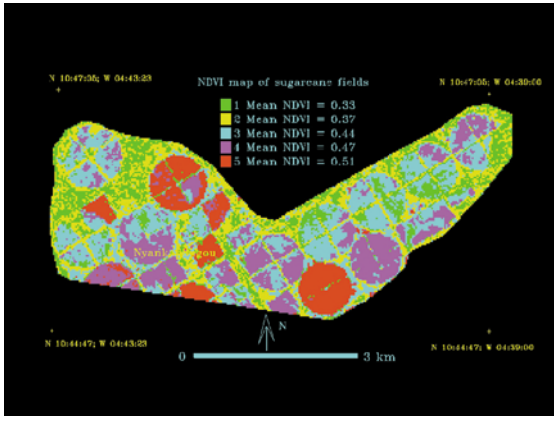

Figure 8.21. Study of biomass levels in the valley bottoms in summer offer a powerful means of assessing potential of valleys for dry season cultivation and in general assessment of moisture levels. The normalized difference vegetation indices (NDVI) has been widely accepted as powerful means of biomass assessment. The above NDVI based biomass levels are for Nyankadougou, South-West of Bobo-Dioulasso, Burkina Faso.

CHAPTER 9

Watershed Characterization by GIS for Low Flow Prediction

Glenn S. Warner, Andrés R. García-Martinó, Frederick N. Scatena, and Daniel L. Civco

INTRODUCTION

A GIS was used to determine watershed characteristics for development of multiple regression equations for prediction of low flow in streams in the eastern part of Puerto Rico. A preliminary selection of 45 gauged watersheds was based on a general Life Zone Map, and vector coverage of precipitation and temperature regions typical of the Caribbean National Forest. The number of watersheds was reduced to 19 by overlaying land use coverage in a GIS and selecting those watersheds having permanent forest cover and available data including digital elevation models (DEMs). A total of 53 initial watershed parameters (grouped into geology, soils, geomorphology, stream network, relief, and climate) were determined by GIS for each of the 19 watersheds. The number of parameters was reduced to 13 through a two-step process using criteria that included correlation among the parameters, correlation with low flows, colinearity, significance of coefficients, and logic. Multiple regression analyses were performed to predict the 7 day–10 yr, 30 day–10 yr, and 7 day–2 yr low flows using combinations of the 13 parameters. Selection of the final regression model for each low flow was based on five statistical tests. Four parameters (drainage density, weighted mean slope, an aspect parameter, and ratio of tributaries to main channel length) were found to be the best predictors, resulting in R^2 from 0.96 to 0.97 for the three low flow variables. A non-GIS model was also developed with easier to measure parameters, but resulted in a higher SE than the GIS-based models.

BACKGROUND

Due to the complexity involved in the generation of low flow in streams, few if any physically based models have been developed for prediction of low flows. Instead, measured low flows are usually regressed against physical parameters that characterize the watersheds involved. Parameters used in low flow studies have varied considerably from one region or study to another, but typically include parameters that reflect basin, climatic, and cultural characteristics (Singh and Stall, 1974) that may play a role in the generation of low flow. Examples of parameters include watershed area, surficial geologic materials, watershed shape, and stream length.

A number of researchers have used GIS for watershed characterization for purposes such as modeling of water quality (Cahill et al., 1993), runoff (Luker et al., 1993), and nonpoint pollution (Robinson and Ragan, 1993). However, GIS application in low flow research is very limited. Low flow studies typically include a large number of watersheds with great differences in drainage areas, topography, geology, and other watershed characteristics. GIS provides not only a format

for more efficient determination of these parameters, but also opportunities for investigation of parameters that are not easily measured by manual means and that therefore have not been used in most low flow studies. The development of automated computer programs for watershed characterization (Martz and Garbrecht, 1993; Eash, 1994) could lead to routine use of GIS in determination of parameter values for multiple regression equations.

The need for low flow prediction and the availability of stream gauge data and GIS coverages for eastern Puerto Rico provides an opportunity to study low flow in streams draining the Caribbean National Forest, also known as the Luquillo Experimental Forest (LEF). The LEF is located in the eastern end of Puerto Rico and covers an area of 11,300 ha. Elevations range from 73 m to 1,075 m above sea level. The LEF is almost completely forested and receives an average of 3864 mm of rainfall annually (García-Martinó, 1996). Water demand by municipalities in the area is putting increased pressure for water withdrawal from streams draining the mountains. The lack of information on low flow for ungauged streams provides a need for better methods of predicting low flows in these streams.

DATA AND METHODS

The GIS database included land use, soils, geology, hydrography (all in vector format), and Digital Elevation Models (DEM). All GIS coverages were obtained as $7.5' \times 7.5'$ quadrangles and georeferenced to the Universal Transverse Mercator (UTM) coordinate system. Soil and geology coverages were digitized from 1:20,000 scale maps from the USDA Soil Surveys (published in the 1970s) and the U.S. Geological Survey (USGS), respectively. Unconsolidated material formations as small as 7,000 m^2 are depicted in the geology coverages. The land use data (produced by the Puerto Rico Dept. of Transportation for 1977) were divided using first degree units based on Anderson et al. (1976) and highly subdivided to specific categories. The stream network was obtained from the USGS as Digital Line Graphs (DLG), showing rivers and major tributaries. The stream network shown in the DLGs was virtually the same as that shown on USGS topographic maps.

We obtained DEMs from the USGS in two different formats: 30 m by 30 m DEMs (USGS, 1987) for the eastern region of the island, specifically for El Yunque, Fajardo, Humacao, Naguabo, Juncos, and Fajardo quadrangles; and a DEM produced by the Defense Mapping Agency (DMA) for the rest of the island. The DEM from the DMA has a resolution of 3×3 arc seconds, which in Puerto Rico is equivalent to an approximate 90 m x 90 m resolution. All DEMs are in UTM coordinates with elevations in meters.

A typical low flow study involves watershed selection, frequency analysis, watersheds characterization, and multiple regression analysis. Since we were interested in the humid montane regions of Puerto Rico, we limited our investigations to watersheds either within the LEF or with rainfall and land use characteristics similar to those of the LEF. The frequency analysis for low flow of the gauged streams and the regression analysis followed standard procedures. The watershed characterization, however, was not limited to commonly used parameters that could be measured by hand, but initially included a large number of potentially important factors that either alone or in combination with other factors might be significant hydrologically. The number and complexity of the parameters considered were only feasible when using GIS, since the effort to evaluate each parameter for each watershed by hand would have been overwhelming.

To select as many representative watersheds as possible, we followed a scheme that first digitized the Life Zones Map for Puerto Rico produced by Ewel and Whitmore (1973) using the Holdridge classification system. We next performed a broad, general selection of USGS stream gauges by a visual inspection of the Life Zones Map and major drainage networks of the island.

We looked first for stations draining the LEF, and second, for stations with temperature and precipitation characteristics similar to those in the LEF. The first GIS analysis consisted of overlaying the watersheds of 45 stations (continuous and partial) with Life Zone and land use coverages. The watershed boundary for each of the 45 stations was drawn on USGS topographic maps with a 1:20,000 scale, and digitized.

We reduced the number of stations to 19 (in three different regions of the island) based on land use and life zone classification, followed by GIS application of the geology, soils, stream network and DEM coverages. We initially chose a large number of parameters based on their potential to influence storm runoff and groundwater dynamics. Many parameters such as soil water-holding capacity, liquid limit, texture, and depth to bedrock did not vary significantly across watersheds and were dropped. A total of 53 parameters (Table 9.1) covering six groups were determined by GIS to vary across the 19 watersheds and were chosen for further analysis. We found that GIS has several advantages over traditional methods: (1) a large number of parameters can be evaluated for numerous watersheds, (2) parameters not easily determined by hand such as percent of area having slopes or aspects less than various thresholds can be calculated, and (3) area-weighted parameters such as the weighted mean elevation within the watershed can be determined easily.

The data for most of the partial stations consist of six or seven low flow measurements taken over a four year period. Some low flow values were obtained from Santiago (1992). Measured low flows for other partial and three continuous stations with short records were correlated with concurrent discharges from nearby watersheds with similar hydrologic characteristics as recommended by Riggs (1972). Daily low flow measurements were randomly selected for each of these stations and correlated with concurrent low flows from nearby continuous stations. All correlations were significant ($\alpha = 0.05$).

We developed two types of regression models: GIS-based models (for 7d–10yr, 30d–10yr, and 7d–2yr low flows) that considered all 13 parameters and a non-GIS model (7d–10yr only) that only considered parameters that could be easily measured without a GIS. A model can be statistically strong, but if the parameters are difficult to measure, then the model may be useless. Although GIS technology is dramatically closing the gap between easy and hard to measure parameters, GIS is not always available. We selected the best models of each type using a number of statistics given by Helsel and Hirsch (1992). Parameters considered in each model and details of the statistical tests are given in García-Martinó (1996).

RESULTS AND DISCUSSION

Four parameters consistently produced the best overall results for the GIS-based models: DD is total length of perennial channels per unit area (m/m^2), SLP is weighted mean slope in the watershed (°), PA90 is percent of total area of watershed with aspects between 0–90°, and CHATRI is ratio of total tributary length to length of main channel. Although watershed area does not appear directly in the equations, it is highly correlated with other parameters. The GIS models (one for each low flow) are:

$$\text{Log7d–10yr} = 1.78 - 1331.61(\text{DD}) - 0.0316(\text{SLP}) + 0.0146(\text{PA90}) + 0.3126(\text{CHATRI}) \qquad R_a^2 = 0.97 \tag{1}$$

$$\text{Log30d–10yr} = 1.60 - 1098.26(\text{DD}) - 0.0301(\text{SLP}) + 0.0160(\text{PA90}) + 0.2957(\text{CHATRI}) \qquad R_a^2 = 0.96 \tag{2}$$

Table 9.1. Definitions of Watershed Parameters Used in Correlation and Regression Analyses

CLIMATE BASED PARAMETERS:

MMYR = mean annual rainfall (mm/yr)
10YRCDNR = number of consecutive days with no rain with recurrence interval of 10 years
M#DNR = average number of days per year with no rain
MMCDNR = maximum consecutive days with no rain

GEOLOGY BASED PARAMETERS:

UNCON and QA = area and % of area of watershed classified as unconsolidated material, respectively
LSEU = length of perennial streams in direct contact with unconsolidated material
INTRU = % of area classified as intrusive igneous rock with low water bearing capacities
STRAT = % of area classified as alluvial deposits and sedimentary formations (sandstone)

SOIL BASED PARAMETERS:

PLASTI = area-weighted mean plasticity index for watershed
PERM = area-weighted mean permeability

STREAM NETWORK BASED PARAMETERS:

PERC = total length of perennial channels (m)
CHAN = total length of main channel (m)
TRIB = total length of tributaries to main channel (m)
DD = total length of perennial channels per unit area (m/m^2)
SD = number of perennial channels per unit area ($\#/m^2$)
TRIPER = ratio of total length of tributaries to total length of perennial channels
CHATRI = ratio of total length of tributaries to total length of main channel
CHANSLP = slope of main channel between 15% and 85% points of main channel (°)
CHSLP = (CHANSLP/CHAN)/100
SINUO = total length of main channel divided by length of watershed

WATERSHED MORPHOLOGY BASED PARAMETERS:

AREA = watershed area (ha)
SLP = area-weighted slope of watershed (°)
PERIM = length of perimeter of watershed boundary (m)
COMP = ratio of PERIM to circumference of a circle with area = AREA
FORM = AREA/(watershed $length^2$)
ELONG = diameter of circle with area = AREA divided by watershed length
AREA4 and A4, AREA7 and A7, AREA10 and 10 = areas and % of AREA with slopes < 4, 7 and 10°
MSLP100, ASLP100, MSLP200, ASLP200 = maximum and mean slope within 100 or 200 m buffers of perennial streams (°)
ASPECT = area-weighted aspect (°)
AREA90 = total area of watershed with aspect between 0 and 90(°)
PA90 = % of AREA with aspects between 0 and 90°
ASP100 and ASP200 = mean area-weighted aspect inside 100 and 200 m buffers along perennial streams

WATERSHED RELIEF BASED PARAMETERS:

EL = area-weighted mean elevation
ELRANGE = maximum minus minimum elevation in watershed (m)
RELIEF = ELRANGE divided by length of watershed
RERA = RELIEF*ELRANGE
SLORAT = CHANSLP/SLP
HYP1 = % change between 0.25 and 0.75 points of hypsometric curve of watershed
HYP2 = HYP1/AREA
HYP3 = HYP1/(% change between 0.50 and 0.75 points of hypsometric curve)

$$\text{Log7d–2yr} = 1.70 - 1157.49(\text{DD}) - 0.0248(\text{SLP}) + 0.0121(\text{PA90}) + 0.3017(\text{CHATRI})$$
$$R_a^2 = 0.97 \quad (3)$$

where R_a^2 is the adjusted R^2 (Velleman, 1992).The best non-GIS model consisted of four parameters that could be relatively easily measured by manual methods for prediction of the 7d–10yr flows:

$$\text{Log7d–10yr} = 0.1827 - 0.0824(\text{CHANSLP}) + 2.24(\text{FORM}) + 0.0012(\text{ELRANGE}) - 882.51(\text{DD})$$
$$R_a^2 = 0.94 \quad (4)$$

where: CHANSLP is slope between 15% and 85% points of main channel, FORM is area divided by square of watershed length, ELRANGE is maximum minus minimum elevation in the watershed, and DD is same as for GIS-based models above.

The error in a model is the product of chance variation and variation from unaccounted differences in watershed characteristics. The objective is to decrease the variation due to the latter. The variation in Y due to each variable (R^2) is very similar in each GIS model (Table 9.2). The strongest variable is DD, contributing over 53% of the variation in Y in each model. The strongest parameter in the non-GIS model was also DD (Table 9.2), which evidently explains a high degree of the subsurface and groundwater dynamics.

The best method of determining the accuracy of the non-GIS model compared to the GIS model is the standard error of the estimate (SE). The SEs varied from 11.5% to 13.8% for the GIS models compared to 19.5% for the non-GIS model (Table 9.2). Values for SE over 100% are common (Riggs, 1973). One of the most accurate low flow models was developed for West Virginia by Chang and Boyer (1977) and had an SE of 31%. Since SE tends to be underestimated for small samples, an adjusted SE (SE_a) as suggested by Ezekiel and Fox (1959) was calculated by the following equation:

$$SE_a = [N/(N - M) * SS_e]^{0.5} \quad (5)$$

where N is the sample size, M is the number of coefficients in the model including the intercept, and SS_e is the sum of squares of the error. The SE_a's for the GIS models shown in Table 9.2 are good, even when compared with the nonadjusted SE more commonly found in low flow research. Although the variation in Y covered by the non-GIS model is relatively high ($R^2 = 0.94$), the SE_a of 82.8% is well above the SE_a of the GIS models. It is still a good model when compared to most low flow research in the U.S. A direct comparison of the GIS model vs. non-GIS model can be made for the 7d-10yr which shows an increase in SE_a from 58.7% (GIS) to 82.8% (non-GIS) that can be attributed to the ability to include additional and more complex parameters by GIS.

The future availability of greater resolution DEMs for areas outside the LEF will significantly improve the analysis. Greater resolutions will permit more detailed and precise watershed characterization, especially when dealing with slopes and aspect. Also, it will be possible to extend the stream network to streams not included in a USGS topographic map. GIS coverages are available for the whole island. These or similar models can be developed and/or adapted to the unique conditions for each region of the island in order to characterize the watersheds and develop better water management plans. On the other hand, the accuracy of the selected models is relatively high, and its application to humid montane regions in Puerto Rico and adjacent areas should provide opportunities for more intensive analysis and greater confidence for low flow predictions.

Table 9.2. Parameters and Comparative Statistics for Selected GIS and Non-GIS Models

GIS Models	Model C-3 (7 day–10 yr)			Model D-4 (30 day–10 yr)			Model E-3 (7 day–2 yr)		
Parameters	R_a^2	SE[1]	SE_a[2]	R_a^2	SE	SE_a	R_a^2	SE	SE_a
DD	0.59	45.68	193.81	0.53	44.67	189.51	0.54	43.19	183.25
DD + CHATRI	0.91	21.84	92.68	0.88	23.41	99.32	0.92	18.11	76.85
DD + CHATRI + PA90	0.96	15.71	66.65	0.95	15.59	66.15	0.96	12.83	54.43
DD + CHATRI + PA90 + SLP	0.97	13.84	58.72	0.96	13.94	59.15	0.97	11.47	48.64

Non-GIS Models	Model P-1 (7 day-10 yr)		
Parameters	R_a^2	SE[1]	SE_a
DD	0.59	45.68	193.81
DD + ELRANGE	0.74	37.55	159.33
DD + ELRANGE + FORM	0.88	26.84	113.88
DD + ELRANGE + FORM + CHANSLP	0.94	19.52	82.81

[1]Standard error.
[2]Adjusted standard error.

SUMMARY AND CONCLUSIONS

The application of GIS for watershed characterization for low flow prediction provides the opportunity to evaluate large numbers of parameters and to evaluate parameters which are difficult to determine by hand methods. Unique and highly qualitative parameters could be readily measured using GIS. The GIS-based models produced better estimates of low flows than use of a non-GIS model developed for gauged watersheds in humid montane regions of Puerto Rico. The adjusted standard error of the estimate (SE_a) of the GIS-based model for the 7d–10yr flow was 58.7% compared to 82.8% for the non-GIS model. These SE_a's are less than the error of most low flow research performed in the U.S. The most significant parameters in the GIS model for each of the three low flows were drainage density (DD), the ratio of the length of the tributaries to the length of the main channel (CHATRI), the percent facing northeast (PA90), and the mean slope in the watershed (SLP).

CHAPTER 10

Evaluation of the Albemarle-Pamlico Estuarine Study Area Utilizing Population and Land Use Information

Robert E. Holman

BACKGROUND

The Albemarle-Pamlico Estuarine Study (APES) has been funding many information acquisition projects over the last five years in the areas of resource critical areas, water quality, fisheries, and human environment (Steel and Scully, 1991). Most of these projects have transferred their data over to the APES's Geographic Information System (GIS) which was created through a subcontract with the North Carolina Center for Geographic Information System (CGIA). GIS has the ability to bring together (enter, display, edit, and manipulate) data based information with digital mapping (locational attributes). At the time of this study, the Center (CGIA) had or was creating all of the needed databases. CGIA was able to combine the data layers in various ways to analyze the relationship among different layers in a visual as well as a statistical manner.

The study area encompasses approximately 23,250 square miles and includes all or portions of 37 counties in eastern North Carolina and 19 counties in Southeastern Virginia. There are six counties along the coastline, 9 counties along the sounds, and 41 cities/counties that lie in the upper drainage basin (Figure 10.1). This study also incorporates all or portions of 6 major river basins including the Chowan, Pasquotank, Lower Roanoke, Tar-Pamlico, Neuse, and White Oak (Figure 10.2). Each basin is divided into subbasins as follows: Chowan, 13; Pasquotank, 8; Lower Roanoke, 3; Tar-Pamlico, 8; Neuse, 14; and White Oak, 5.

METHOD

The analytical method was broken into three phases. Phase One was the creation of county land use maps from the existing Landsat classification scheme. These map products were sent to U.S. Fish and Wildlife and county officials to determine the accuracy of the defined land use classes. The land use maps were also used by the author during flights over the coastal and metropolitan areas to further clarify classification errors. Phase Two was to correct some of the errors in the existing classification. This was carried out by digitizing the corrections to the map products that were returned from Fish and Wildlife and county officials. The map information was also supplemented with other sources of information such as U.S. Fish and Wildlife Service—National Wetland Inventory, U.S. Forest Service—Forest Inventory and Analysis, U.S. Bureau of Census—Census of Agriculture, and U.S. Soil Conservation Service—National Resources Inventory and Hydric Soils in North Carolina counties. Phase Three was identifying correlation between

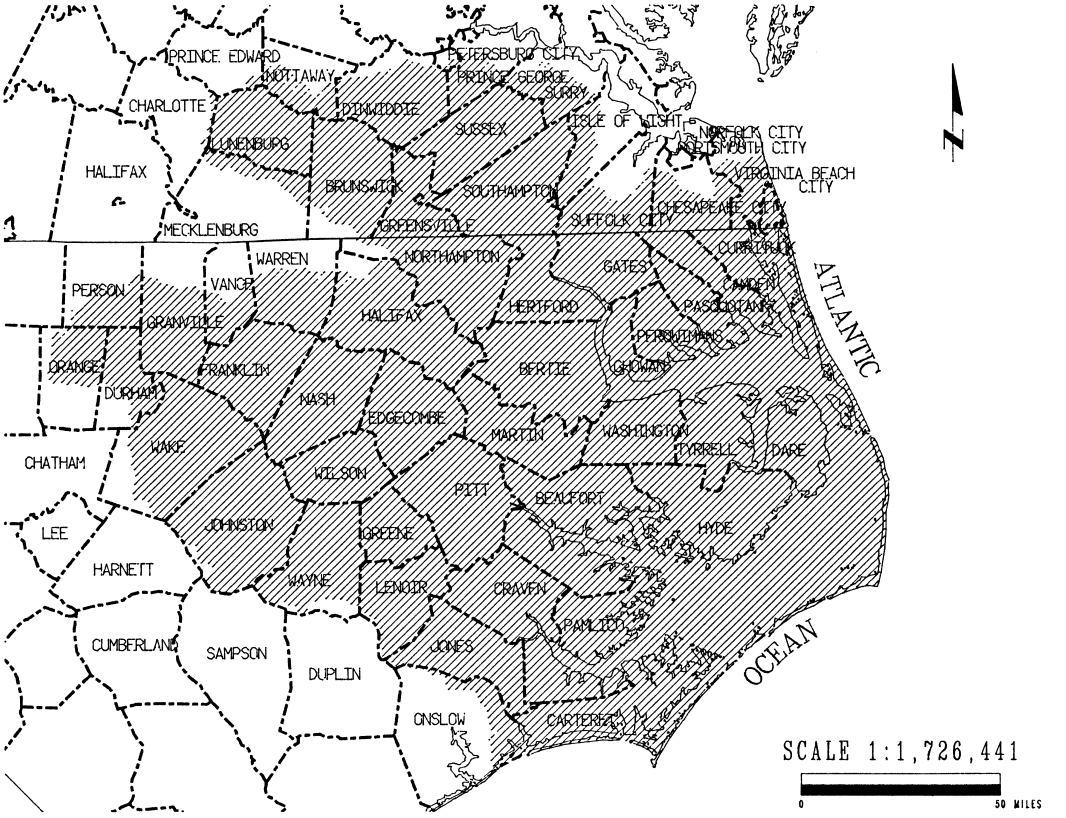

Figure 10.1. Map of study area.

different data sets such as county census population and county acreage of developed land. If a strong correlation was found, then a simple linear regression model was applied in order to predict the relationship between the two parameters. These models were used to correct some of the errors in specific land use categories.

Map Development

There were three tasks in the development of land use and population estimates for the entire APES area: (1) defining the actual drainage area; (2) having all the basin and subbasin boundaries digitized in order to determine the land use and population; and (3) correcting for errors associated with the different land uses.

First, the study area was defined as the entire drainage area of the Albemarle and Pamlico Sound system including Core and Bogue Sounds. The upper Roanoke Basin and a portion of the White Oak Basin were not included because: (1) the upper Roanoke River Basin covers approximately 8,370 square miles in Virginia/North Carolina and stretches over two-thirds the length of North Carolina, and would add one-third more area to the study area; and (2) a decision was made early in APES to have Carteret County as the furthest area south. However, due to the watershed approach in defining the study area in this project, all the subbasins in the White Oak Basin were included except the furthest one southwest that starts at Camp Lejeune. There was no compatible land use data available for this subbasin.

Figure 10.2. The six APES basins and their subbasins.

Second, all North Carolina basins and subbasins were digitized by the Research Triangle Institute and compared closely with the U.S. Geological Survey subbasins for North Carolina. Virginia subbasin information was supplied by Information Support Systems Laboratory within Virginia Polytechnic Institute and State University and was based on Soil Conservation Service (SCS) information. Due to the large number of subbasins identified by SCS in the Virginia portion of the Chowan and Pasquotank Basins, subbasins were combined to create areas of the same size range as subbasins identified in North Carolina. All subbasins were digitized from U.S. Geological Survey's 1:24,000 scale topographic maps. Specific subbasins were identified by a six number code that was broken into two-digit sets. The first two digits identified the regional basin; the second two digits identified the basin; and the third two digits identified the subbasin (Figure 10.2). Codes used in this report were the same ones adopted by the North Carolina Division of Environmental Management.

The third task was to identify the accuracy of the land use data and to develop methods to correct for the errors. Khorram and others (1992) found that with the Landsat data, the urban or built-up land use category was only 46% accurate, and the accuracy of forested wetlands was unknown. In addition, the classification of mixed pixels in the existing land use data set had to be resolved. Mixed pixels are defined as areas that could not be classified because the resolution or pixels were a mixture of many categories. The land use classification from 1987–1988 developed by Khorram will be referred to as the "Landsat" classification in this study.

Accuracy and Errors

The first task was to define which level of land use to utilize. Landsat land use classification defined 18 separate classes that can be generally broken into similar U.S. Geological Survey level I and level II groupings (Anderson and others, 1976). The land use classification was based on Landsat data which Khorram interpreted mostly as land cover (the actual extent of vegetative and other cover) and some land use (interpretation of activities taking place on the land). Interpretation of land use is much more subjective than land cover and is dependent on the knowledge of the individual interpreter.

A level II map with 18 individual classes was provided to officials of two Fish and Wildlife Refuges within the APES area for their evaluation as to land cover accuracy. The Great Dismal Swamp National Wildlife Refuge staff reviewed the Landsat land use map of the refuge. This refuge, located on the border between North Carolina and Virginia just south of Portsmouth, Virginia covers approximately 110,000 acres and is predominantly forested wetland. The staff felt there was good separation among development, agriculture, water, and forest; however, the different forest cover types had serious reliability problems. A major problem was the misclassification of wetter deciduous stands like cypress/gum and maple/gum as pine/hardwood forest. A second land cover map was sent to Mattamuskeet and Swan Quarter National Wildlife Refuges personnel for their review. These two refuges are located entirely in Hyde County, North Carolina, and Swan Quarter is adjacent to the Pamlico Sound. These refuges together cover approximately 65,700 acres and are predominantly water, wetland, and forest. The staff found quite a few areas that were referred to as mixed pixels that were actually open water and irregularly flooded brackish marshes. White Cedar stands were actually marsh impoundment areas around Lake Mattamuskeet, and pine forest was actually mixed pine/hardwood or hardwood/cypress/pine forest. In general, both refuges indicated accuracy problems with the different forest and the mixed pixel classifications.

After indicating they could not evaluate all the classifications in level II land cover maps, officials of counties in the Currituck Sound Basin south of Virginia Beach and adjacent to the Atlantic Ocean were sent, for comment, land cover maps which included the following attributes: USGS level I with 6 categories shown in color; U.S. Census TIGER files that displayed the road network, map scale of 1:100,000; and modified LUDA land use data for the urban or built-up category.

Land Use Data Analysis (LUDA) was an early GIS effort started by U.S. Geological Survey in 1975 to define the land use for the entire United States. All the photographs were manually photointerpreted. The map series consisted of 1:250,000 scale maps of North Carolina defining 37 uses based on the level II classification system. Source imagery was 1:56,000 color infrared photography and 1:80,000 black and white photography dating back to 1970. Resolution was 10 acres for the urban or built-up categories and 40 acres for the remaining classifications (Kleckner, 1981). For comparison, the Khorram classification was based on 1987–1988 Landsat satellite imagery that was semiautomatically interpreted. The county map series was at a scale of 1:100,000 with a final resolution of 1 acre.

In 1991 and 1992, the author flew along the Outer Banks and inland around the estuarine portion of the study area and over portions of Wake, Durham, and Orange Counties to verify the problems with the categories of urban or built-up, wetland, and mixed pixels. The urban or built-up class was underestimated on the 1987–1988 land use maps mainly due to forest crown cover that obscured the true land use on the ground. High spectral reflectance of bare agricultural fields was also a problem because these fields were being classified as developed areas. The problem with fields being identified as developed areas was especially evident in the Landsat scene furthest west that included the Raleigh metropolitan area. This category was a very small percentage (3.3 to

7.9%) of the overall land use of the study area but is critical in that urban or built-up land use can cause the greatest impact on natural resources of the APES area.

Problems associated with the wetland class were found to be interference from forest crown cover. Open marsh and pocosin wetlands were usually accurately defined by the 1987–1988 land use maps but closed forest canopy prevented standing water below the forest to be seen. Therefore these true wetland types were usually defined as forest.

The category of mixed pixels is a grouping the classification scheme could not identify. Flights over the coastal and metropolitan areas verified that in most cases they were a mixture of standing water and wetland vegetation. The only exception to this observation was in Pasquotank County where poorly drained agricultural land was defined as mixed pixels or wetland on the county land use map.

These land use classification problems and others were identified in a workshop the author attended to verify remotely sensed land cover data for the Coastwatch Change Analysis Program of the National Oceanic and Atmospheric Administration (Burgess and others, 1992). The problems fell into four categories: classification error, cover versus land use, categorical resolution, and change detection. Classification errors included "salt and pepper" effect of individual pixels, shadows and bare ground as urban areas, and problems with the degree of wetness during image acquisition. Cover versus land use had the inherent problem with distinguishing land uses and required ancillary data. Categorical resolution was related to the spatial resolution and improper classification. The change detection problem involved the ability to detect a change but not always the nature of the change. From the author's own observations and the results of this workshop, methods were developed to overcome some of the problems associated with remotely sensed land cover data.

Land use information used in this study was analyzed according to the Khorram and others (1992) classification system but condensed from 18 to 7 categories. Certain corrections were incorporated into some classes depending on the observed and documented error associated with each class. The LUDA data set was used to determine "developed land" because the information appeared to be closer to the actual extent and location than the original 1987–1988 Landsat data set. Corrected Landsat built-up areas on the maps returned by county officials were found to have a high degree of correlation (R^2 of 0.9) with the LUDA "developed" category. A linear regression model was used to predict built-up land from the LUDA data. U.S. Fish and Wildlife's National Wetland Inventory (NWI) data were used as a reliable source of wetland acreage for the coastal plains of North Carolina (Wilen, 1990 and Burgess and others, 1992). Wetland acres for twelve of the coastal counties was provided by Kevin Morehead of the Savannah River Ecology Laboratory. The same procedure used to correct built-up areas was used to reconcile the Landsat wetland category with the NWI acreage. A high correlation resulted with a R-squared of 0.9 and a simple linear regression model was used to predict wetland acres from the NWI values. The mixed pixel unidentified category was determined by the U.S. Fish and Wildlife personnel and two overflights of the APES area to be predominantly wetland in nature. The mixed pixel figures were incorporated into the wetland classification.

RESULTS

Land Use

The entire APES area land use classification is based on a modified U.S. Geological Survey's level I classification scheme. One fact to keep in mind is that the water class is not a true *land* use but is a very important classification. There were seven classes with the following percentages: "urban" 4.8%, "agriculture" 28.2%, "forest" 28.4%, "water" 14.6%, "wetland" 20.5%, "shrub

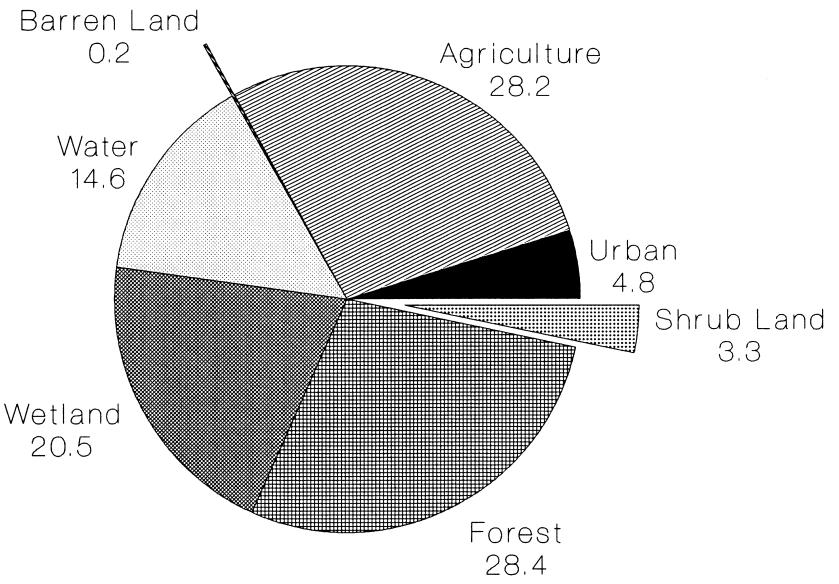

Figure 10.3. APES 1990 land use/land cover.

land" 3.3%, and "barren land" 0.2% (Figure 10.3). In general, the study area is rural in nature with less than 5% of the total area developed. More than 55% of the total APES acreage came from the categories of agriculture and forest.

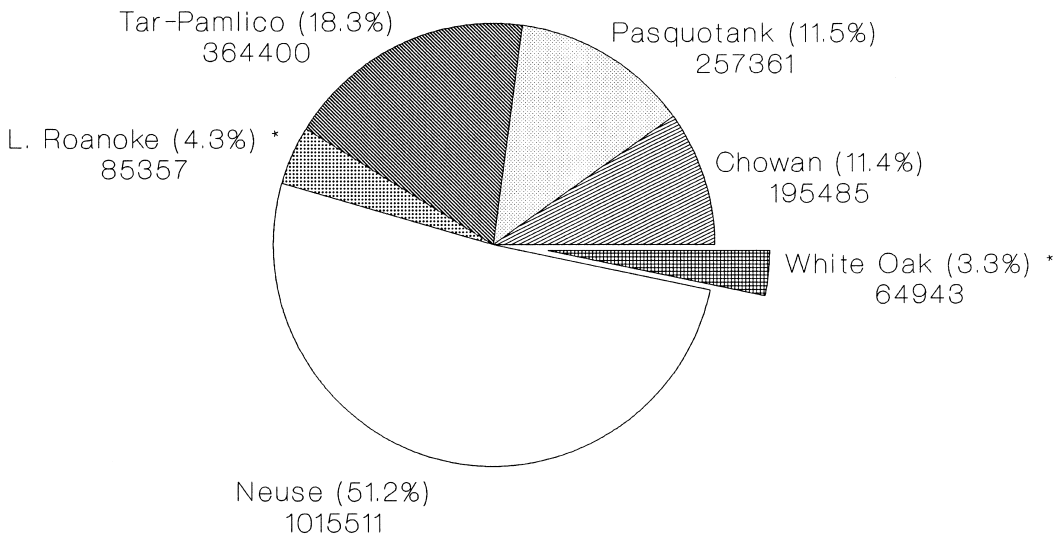
Population

The population of the study area was almost 2 million people (Figure 10.4). About 51.2% reside in the Neuse Basin, which occupies only 26.8% of the land area. Population density for the basins ranged from 163.1 persons/square mile in the Neuse to 39.9 persons/square mile in the Chowan. Since the population density of all but two basins fell below the U.S average of 69 persons/square mile, most of the study area can be characterized as nonmetropolitan (U.S. Bureau of Census 1960, 1970, 1980, 1990).

Population Versus Developed Land

When the subbasins with the highest number of persons/square mile are compared to the subbasins that have the greatest amount of developed land there appears to be a great deal of agreement. If a strong correlation exists between these two parameters then a powerful planning tool can be created to predict the amount of developed land from the existing or projected population for a certain area.

The APES area has only two comprehensive land use databases and one does not correlate well with the category of urban or built-up land. Therefore, another source of long-term land use



*** Only a portion of this basin**

Figure 10.4. APES basin populations in 1990.

data is needed to determine if the relation between population and developed land is statistically sound. Land use data from the State of Maryland has been gathered since 1973 and has been taken as frequently as every five years during the past 15 year period (Maryland State Planning Office, 1991). The acres of total developed land were compared to the closest population census data for each county in Maryland. Three periods (1973, 1981, and 1990) had correlation with a R^2 value of greater than or equal to 0.9. A simple regression model was developed for each correlation and the results were very similar for all three periods. A population of 200,000 people was equated to between 39,000 and 43,000 acres of developed land. Since this relationship held for the Maryland data set, could the same relationship be established with the limited land use data sets in North Carolina? The earlier LUDA data set appeared to correlate well with developed land, but how could the existing Landsat accuracy for developed land be improved? Landsat land use maps of 21 counties in the APES area were sent out to county planners or other county officials for their review. Each county official was to shade in the extent of development that took place in his county during 1990 and change any land use that was not properly classified. The returned maps were digitized and new acreage for developed land was obtained for each county. Both the LUDA and the corrected Landsat land use maps were compared to the population census data in the same manner as the Maryland information. Both correlation had a R^2 value of greater than or equal to 0.8. Again, a simple linear regression model was developed for each correlation and the results were very similar for both 1970 and 1990 (Figures 10.5 and 10.6). A population of 200,000 people was equated to between 45,000 and 60,000 acres of developed land.

A statistical relationship between population census and developed land for the same time frame has been established for land area in Maryland and the APES area. The relationship is not the same for both areas and probably will vary from region to region. Based on this relationship

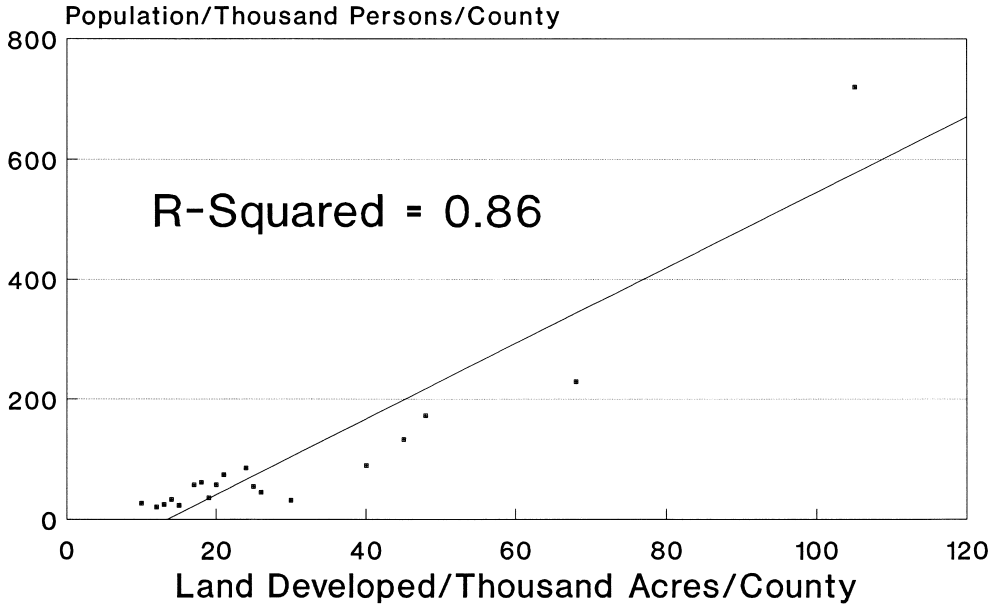


Figure 10.5. 1970 population vs 1972 land use.

the number of acres of developed land for the years 1970, 1980, and 1990 has been estimated for each of the six basins in the APES area. The resulting pattern is similar to that of population, with the Neuse Basin having the largest amount of developed land over the last 30 years. The 1990 figures show the Neuse Basin with approximately 306,000 acres of developed land and the

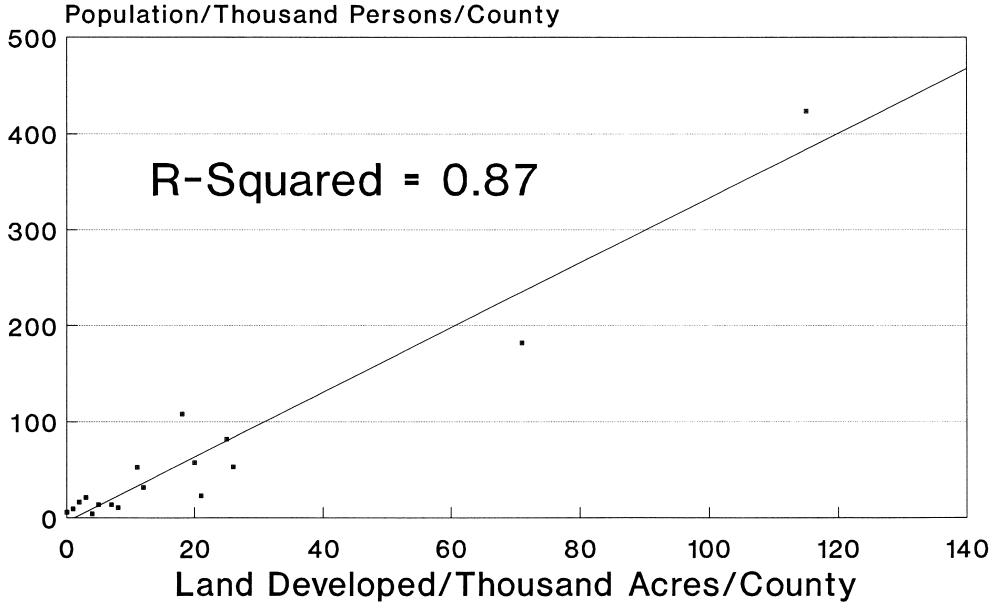

Figure 10.6. 1990 population vs 1990 land use.

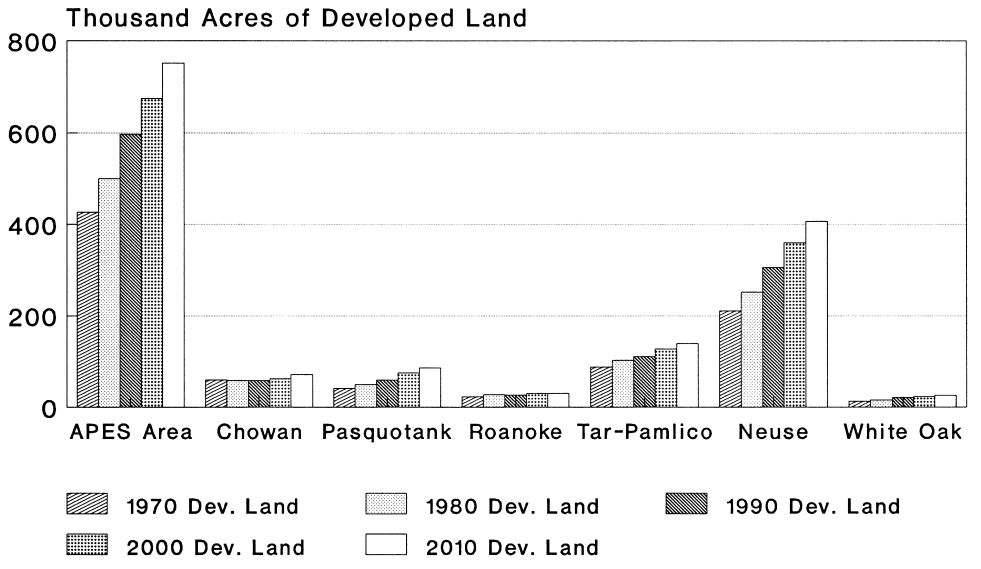

Figure 10.7. Developed land in basins.

White Oak Basin with the least at 65,000 acres of developed land. Developed land for the entire study area for 1990 was approximately 597,000 acres based on this predictive method. Projections for the year 2000 and 2010 (NCDC, 1991; VEC, 1991) have also been estimated and compared to the year 1990. Developed land for the entire study area for the year 2010 is approximately 752,000 acres based on this predictive method. The Neuse River Basin continues to have the most developed land with 407,000 acres and the White-Oak Basin has the least with 26,000 acres (Figure 10.7). The Pasquotank Basin appears to have outpaced the Chowan Basin in the amount of developed land and contains the third largest acreage behind the Neuse and Tar-Pamlico.

CONCLUSIONS

This study found that land use data from Landsat was not adequate by itself to properly identify seven land use classifications. The greatest errors appeared to be associated with the classes of built-up and wetlands. This was due to the forest crown cover obscuring the true land use of rural residential development on the ground and data sources combined with existing data sets in the form of a linear regression appeared to compensate for these two major errors.

A high correlation between population and developed land was found on a county level from Maryland, Virginia, and North Carolina data. Based on this correlation a linear regression model was developed to predict the number of acres of developed land based on the projected population for a particular county. The relation between population and developed land will not be the same for each region but this method can be a powerful tool in predicting where and how development will take place in a particular county.

CHAPTER 11

Application of GIS and Remote Sensing for Watershed Assessment

Lloyd P. Queen, Wayne L. Wold, and Kenneth N. Brooks

INTRODUCTION

Located at the western terminus of Lake Superior, the Nemadji River Watershed covers 670 square kilometers in Minnesota (Figure 11.1). Approximately 40% of the area of the Nemadji Basin occurs in what is termed the Red Clay Area, a band of montmorillonite clays, up to 60 meters in depth. The clays, which are a result of offshore sediment deposits from glacial Lake Duluth, are highly erodible and prone to mass wasting. The high levels of sediment transported by the Nemadji River system adversely affect the designated trout streams in the basin, and deposit an estimated 525,000 metric tons of sediment annually into the Duluth/Superior harbor.

The erosion and sedimentation problems associated with the Nemadji Watershed led to the creation of the multiagency research and demonstration "Red Clay Project." This project concluded that erosion in the red clay area and subsequent transport and sedimentation is a natural process that has been intensified by forest harvesting, road building, and land-use conversions from forest to agriculture and open land (Andrews et al., 1980). Forest removal reduced evapotranspiration rates, resulting in a reduced resistance in soils to shear forces because of increased soil moisture content. In addition, the weaker root systems of replacement vegetation compared to the original white pine forests contribute to soil mass movement. The loss of large woody debris in stream channels also is thought to have reduced stream channel stability. In 1991, the conclusions of the Red Clay Project were reassessed, focusing attention on watershed factors that may be of greatest importance in correcting or mitigating the problem of soil mass wasting in the Nemadji basin. This chapter discusses the results of this reassessment.

SETTING

Soil mass wasting is the process of downslope movement of soil that consists of shear stress and displacement along surfaces that are either visible or that can reasonably be inferred (Huang,1983). Movement is thought to be the result of three contributing factors: (1) the high transportability rate potential of the soils; (2) the high soil moisture content; and (3) the absence of strong root systems to hold the soil in place. The Nemadji River Watershed exhibits excessive amounts of soil mass wasting (hereafter referred to as slumping). Most evident in the watershed are the chiefly rotational slumps that occur on hillslopes in the stream valleys and along the streams themselves. These slumps are suspected as a significant source of sediment to both the tributaries and the main stem of the Nemadji (Andrews et al.,1980).

The purpose of this research was to relate the frequency of slumping to watershed characteris-

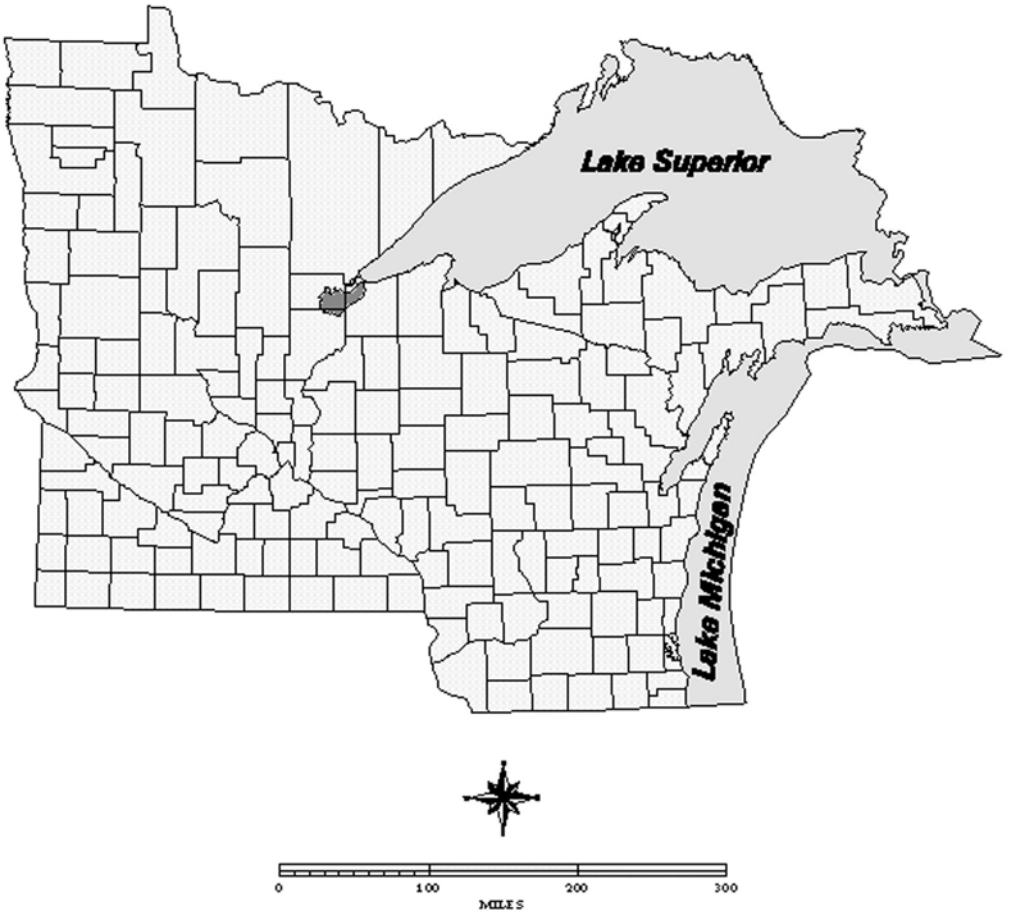

Figure 11.1. Nemadji Basin location map.

tics that potentially have the greatest effect on soil mass wasting. These watershed characteristics were considered independent predictor variables of the dependent variable, frequency of slumping. Secondarily, the research was to determine data requirements for efficient and cost-effective development of a Geographic Information System (GIS) that could be applied for future watershed planning and management.

Based on previous work, this research analyzed the following nine watershed variables thought to affect soil mass wasting: stream channel gradient, time of concentration, stream length, degree of slope, total length of roads in the subwatershed, watershed area, percent coniferous cover, percent deciduous cover, and total forested area. Each of these variables was examined with frequency of slump sites in each of nine subwatersheds (Figure 11.2).

Fortunately, the relationships between forest cover and water yield have been the subject of considerable research. Results from research conducted in humid-temperate regions indicate that, in general, water yield is considerably greater under hardwoods than under conifers due to decreased interception losses and the longer dormant period of deciduous species (Swank and Douglas, 1974).

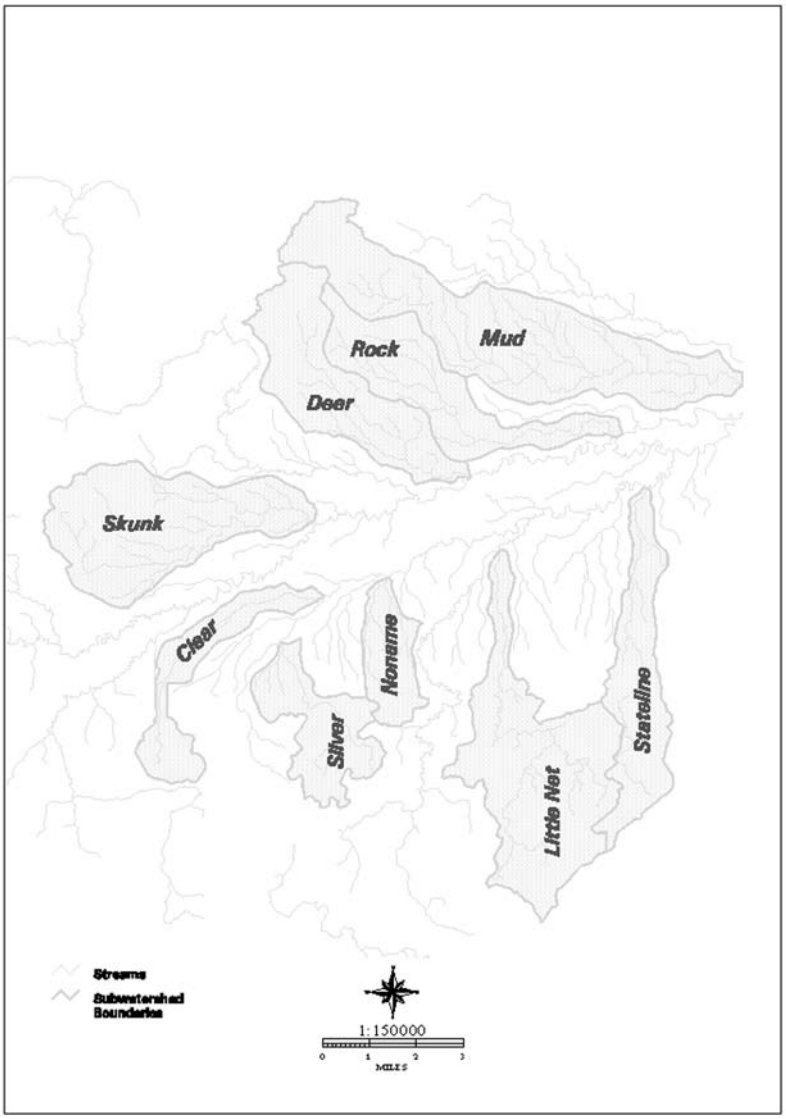

Figure 11.2. Map showing subwatersheds within the Nemadji Basin.

Increased streamflow provides additional energy for streambank degradation. Logging or thinning forests, converting from deep rooted to shallow rooted vegetation, or changing vegetative cover from one with a high interception capacity to one of lower capacity, all have been shown to increase water yield (Brooks et al., 1991).

Studies in Minnesota by Verry (1986) indicate that annual water yield increases and that average annual peak flows can double after cutting upland forests. As the amount of nonforested area in a basin increases, one would expect water yield to increase and with it, higher streamflows with higher velocities and energy. Such conditions could promote the undercutting of slopes and consequently, streambank slumpage. Streambank undercutting, pervasive in the highly erosive red clays, leaves the banks susceptible to slides and slumping. Such effects could be greater following the removal of conifers than hardwoods.

In addition to the role of forest cover type on stream flow, the root strength of different species also can influence soil mass wasting (Sidle, 1985; Abe and Ziemer, 1991). The loss of tree roots diminishes resistance to slumping. On steep slopes bordering streams this combination induces soil creep and slumping. According to the Red Clay Project, high (prefrost) soil moisture levels can be positively correlated with the rate of spring soil mass soil wasting along stream banks (Andrews et al.,1980). Conifers, which transpire later into the fall and retain their interception capacity year-round, should reduce soil moisture during this critical period.

The dependent variable, slump frequency, was determined by tabulating areas where the mineral soil was exposed due to slumping; these sites were identified and mapped from high-resolution low-altitude aerial photographs. Frequency of slumps served as the primary indicator of the relative rate of erosion in each subbasin. In this application, slump frequency was evaluated for both entire subwatersheds and for a series of five discrete buffer zones surrounding each of the streams in those subwatersheds.

APPROACH

Pronounced differences in stream sediment concentrations and related turbidity exist among streams in the Nemadji Basin. To encompass the range of sediment-turbidity conditions, three subwatersheds were selected from each of three turbidity classes, low, moderate, and highly turbid. Classifications based on turbidity were verified using suspended sediment samples and discharge data collected during April and October 1993 and April 1994 (Table 11.1). Suspended sediment, turbidity, and streamflow discharge were measured for both upstream and downstream locations from each of the nine streams (USGS, 1977) at the locations shown in Figure 11.3 (see color section).

Each of the nine predictor variables and maps of slump sites were compiled for each of the nine subbasins in a vector-based GIS. A vector model was chosen for data development and analysis because these systems provide an excellent platform for development and mapping of point (e.g., slump sites), line (e.g., streams), and polygon (e.g., forest stands) data as well as for spatial data analysis. Additionally, local and regional management organizations had previously adopted vector GIS for in-house use. Design criteria for the Nemadji GIS data are map themes at a scale of 1:24,000, with Universal Transverse Mercator (UTM) Zone 15 coordinates applied to all spatial entities, built using conic projections. Base maps for the GIS were derived from existing USGS 7.5 minute quadrangle maps. Quad maps also served as source data for topographic (slope) data, stream locations, and stream gradient estimates. The generation of data themes, the crux of most GIS efforts, is described in the next two sections.

The three primary hydrologic themes are stream gradient, time of concentration, and watershed area. All blue-line (perennial and intermittent) streams were digitized from the USGS 1:24,000 quadrangle maps (Figure 11.4, see color section). The change in elevation from the headwaters to the mouth was taken directly from the quadrangle maps and divided by the length of the stream to determine gradient. Time of concentration was estimated using the Kirpich formula as reported by Gray (1970).

The primary terrestrial variables are slope, stream length, road length, and land cover; and the dependent variable, slump sites. Slope maps were interpolated from a series of contour lines digitized as points from the USGS quads, and a triangulated irregular network (TIN) algorithm was used to create an interpolated slope coverage for all basins. Mean slope was then calculated for each basin (Figure 11.4). The roads theme was acquired in digital vector format from the Minnesota Department of Transportation.

Stereo pairs of conventional color photographs, acquired in May 1992, were used to identify

and map slump sites. Photos were acquired from a helicopter platform using a 35 mm format camera. Negatives were printed at a nominal scale of 1:5,000, and interpreted using a 3-power mirror stereoscope. Land cover was mapped from stereo-pairs of 1:24,000 NHAP photographs into four land cover classes: (1) agricultural/open land; (2) coniferous forest; (3) deciduous forest; and (4) open water. NHAP prints were manually interpreted under magnification using a 0.5 hectare minimum mapping unit. Digital files of land cover were plotted and visually field-checked for accuracy of the cover typing (Figure 11.5, color section).

Slump sites were located on the 1:5,000 scale photos using a magnifying stereoscope. After intensive field checks (using a 75% sample) for accuracy and completeness, sites were entered into the GIS. Large-scale photos were required for accurate interpretation and each slump site could only be represented as a point location. However, due to differences in scale between the photos and the base map, it was difficult to locate the slumps precisely on the base map. Manual editing was employed to reposition the sites in some cases; as a result slump sites were estimated to be located to within 60 meters of their true location at a scale of 1:24,000 (Figure 11.6, color section).

The end result of data compilation was a 1:24,000 scale GIS for all of the nine subwatersheds. Values of land cover class area, ratio measures of percent cover, and lengths and values for the other variables as calculated within the GIS are reported in Table 11.1. The final data preprocessing step was to create data on buffer strips to examine the role of proximity of forest cover to stream channel as a covariate for the independent variables. To assess this effect, five buffer zones were defined along each stream channel, representing buffer strips of 10, 20, 40, 80, and 300 meters on each side of the stream.

Finally, a series of linear regressions were performed based on the frequency counts of soil mass movement sites in each basin and the measurements of the independent variables from the GIS.

RESULTS

The pattern of discharge follows the expected annual trend of highest flows occurring in April, with decreasing flows from August to October. The highest discharge gauged was just over 382 liters per second, measured in April on Skunk Creek. Although the low sample size prevents derivation of sediment rating curves and the use of statistical tests, there is no apparent difference in the observed discharges between the three classes that were grouped on the basis of stream turbidity. Overall, the more highly turbid streams (e.g., Mud, Rock, and Deer Creeks) not only had higher suspended sediment values, but they also exhibited more load variability over the sampling period.

Stream gradients are not higher in the more turbid streams (Table 11.1), and mean slope values are scarcely higher (but not statistically significant) for the more turbid streams. Total subwatershed areas vary from 3,889 hectares for Mud Creek to 750 hectares for Noname Creek; stream length and time of concentration are proportional to the total subwatershed areas for all of the basins. Mud, Rock, and Skunk Creeks have the highest values for total lengths of roads, and all are classified as having high to moderate turbidity. However, it is possible that road building may have its greatest effect at specific road cuts and bridge locations where slope stability was reduced.

Stream gradient was not significantly correlated to the number of slump sites and was relatively constant along the profiles. In a similar fashion, stream length did not exhibit a geographic pattern of variability, nor was it correlated to slump frequency. Time of concentration, conceptually, is an indication of the time it takes for water to travel from the hydraulically most distant point of a watershed to the mouth of the primary stream. The less the amount of time required, the faster a

given stream will flow and thus the greater the energy potential for streamflow through the stream channel. No significant linear relationship was found between time of concentration and the number of observed slumps. However, there is little difference in time of concentration values among the different subwatersheds (Table 11.1).

The relative proportions of land-cover types varies considerably for the subwatersheds. The northern-most subwatersheds (Mud, Rock, and Deer Creeks) generally have lower forest cover area and higher suspended sediment concentrations (Table 11.1) than those subwatersheds to the south. Deciduous forest was the dominant forest type in all of the subwatersheds, with a maximum in the Little Net subwatershed of 77% and a minimum of 33% in Rock Creek basin. There was no strong geographic pattern of differences in the distribution of coniferous forest from one subwatershed to another.

As the width of the buffer zones increases, generally we see a reduction in the proportion of conifer cover to deciduous cover as a percentage of the area of the buffer. Across all nine subwatersheds it appeared that conifer cover types tended to occur most frequently in near-stream locations. When 300 meter widths were considered, the buffer strip usually extended to the ridgetop. This in part explains the increasing proportion of nonforested (agricultural and open) land at the 300 meter width.

The regression analysis of watershed characteristics and slump frequency yielded only one significant linear relationship. When the regressions were repeated for all of the buffer strip widths for all independent variables, again only one relationship was significant. In both cases forest cover percent was the significant variable. Note that the highest turbidity streams tend to have the most slump sites and a smaller relative proportion of forested land. Yet, low turbidity and high turbidity streams occur in watersheds with about the same percentage of conifer cover. The need to consider interactions of other variables and the distribution of the conifer cover in the basin is clear.

The percent slope of hillsides is generally assumed to be a significant covariate when examining causes of soil mass wasting. As percent slope increases, the effects of other contributing factors are amplified. These data show that as the mean slope of a subwatershed increases, there is a tendency for the number of slumps to increase as well. Although mean basin slope was not a significant predictor variable, it was noted that slope effects may be site specific, and when averaged over a large area, this effect was not apparent. Percent slope at each slump site, or the configuration of the hillslope associated with each slump site, could provide a different result.

The relationship between the total length of roads within each subwatershed and the number of slumps within that subwatershed was not significant. The larger the watershed, the greater the road length contained within it. Thus, the length of roads within a subwatershed was correlated with the size of the subwatersheds and not with the number of slumps. Results show the lack of a significant linear relationship of area to the dependent variables. As with slope percent, we suspect that roads need to be investigated on a site specific basis. The effect of roads most likely enhances slump occurrence at or very near the road cut itself. Because they were not mapped in this study, the impact of logging roads and skid trails remains untested.

On a subwatershed level, the occurrence of slumps generally did not diminish with increasing percent of conifer cover. There is a significant inverse relationship between the amount of total forest cover in a subwatershed and the number of slumps observed. As the amount of total forested area in a subwatershed increases the number of observed slumps decreases. However, when the buffer zones were analyzed this relationship did not persist. In fact, the only significant relationship found when repeating all regressions for all variables and all five buffer zone widths was the percent of coniferous cover within 80 meters of the stream channel. This might suggest that the percentage of the total watershed area in open/agricultural land affects the number of slumps, but

the effect of location, or distribution, of the nonforested area in proximity to stream channels could not be tested at the scale and resolution of this study.

Study Implications

The GIS created for the basin contains maps of slump locations, land cover conditions, slope, and other characteristics for portions of the Nemadji River Watershed. In addition to serving as a data management tool, the GIS was used as the basis for data development and analysis. As a result of building GIS capability, several relationships between physical watershed characteristics could be examined systematically and efficiently.

Land cover was disproportionately distributed between the four land cover classes. Deciduous forest cover was more abundant in the upper reaches of the subwatersheds than in the lower reaches. In all subwatersheds, there is more deciduous cover than coniferous cover. Progressing downstream, the amount of conifer cover increased, especially within the stream valleys themselves. Much of the conifer cover was balsam fir (*Abies balsamea*) and spruce (*Picea* sp.) rather than the larger and deeper rooted white pine (*Pinus strobus*) that was the dominant conifer at the turn of the century. Conversely, the amount of open/agricultural area decreased from the upper to lower reaches of the stream. When large open areas occurred from the ridgetop leading down to a stream, there was generally a higher frequency of slumps in association with the open area.

Slope was identified as a significant covariate with slump locations from the Red Clay Project and other sources. Although our results did not show a significant linear correlation between percent slope and slope failure in the subwatersheds, there were plausible explanations. The mean slope and the number of slumps tended to increase closer to the mouth of the stream. Coincidentally, the percentage of conifer cover increased in lower areas as well. While the reason for the increase in conifer cover downstream was not known, it was possible that it would be more difficult to harvest on steep slopes.

Furthermore, the type of coniferous species present, which was not quantified from the aerial photographs, can influence slope stability through differences in root strength and rates of transpiration (for example, balsam fir is shallow-rooted and would not have the same slope stability effects of white pine or red pine). These two effects, among others, greatly complicate the analysis of cover type by slope class.

CUMULATIVE EFFECTS

The occurrence of soil mass wasting in the Nemadji Basin most likely was an expression of the cumulative effects of land use activities that have taken place over the past century. The removal of white pine forests at the turn of the century, the accompanying expansion of agricultural development, road construction, and the conversion from white pine to aspen-dominated forests all affected processes that would be expected to reduce slope and channel stability. The GIS approach allowed the consideration of individual variables as they might affect slumpage; however, the cumulative effects of all these activities over the watershed was not easily quantified and may be a situation of the total being "greater than the sum of the individual parts."

The removal of white pine and the subsequent replacement by either farmland or aspen forests would be expected to reduce slope strength because of loss of root strength on slopes. Overall reductions in evapotranspiration, leading to wetter soils, would increase soil stress. The loss of large woody debris in the channels would be expected to reduce channel stability, which coupled with increased water yield and stormflow volumes and peaks, would promote greater channel scour and streambank erosion. Road construction in the basin adds to these problems. Such processes occur-

ring at the toe of the slope in these deeply incised channels would enhance soil slumps. After nearly 100 years, this watershed system still expresses, through excessive channel erosion, slumpage, and the resulting sediment loading, the cumulative effects of land use change. If we intend to develop models that help explain the cause-and-effect relationships of these systems, a better overall assessment of these cumulative effects is needed.

Because the percent of forested area was inversely related to a greater frequency of soil slumps, management should logically be aimed at increasing and maintaining forest cover in the watershed. Although these results could not identify preferred species for controlling slumps, the literature suggests that certain species such as white pine would be expected to provide more slope stability than other species such as aspen or birch. A more detailed look at species suitable for slope stability is warranted.

The results from this study underscore the need for future research into hillslope hydrology and fluvial processes in the Nemadji Watershed. This study points to certain factors that appear to be related to soil mass wasting and suspended sediment relationships in the Nemadji. Yet no definitive results exist to specifically address the actual relationships of water flow and subsequent soil mass wasting processes. More extensive streamflow data are needed in concert with hillslope process studies. Rainfall and snowmelt events over a range of magnitudes need to be studied so that we can better understand temporal relationships. In fact, the role that large rainfall events play in erosion is as yet unresearched in the Nemadji. Given these results and the availability of the GIS database, a process has been developed that enables managers to continue to examine watershed features and to monitor and track cumulative effects across this critical watershed.

CHAPTER 12

Development of a Database for Lake Ecosystem Studies: Linking GIS with RDBMS

Weihe Guan, Leslie J. Turner, and Sergio L. Lostal

INTRODUCTION

A comprehensive data management system is essential for any ecosystem study. In the Okeechobee Systems Research Division, Ecosystem Restoration Department, South Florida Water Management District (SFWMD), large amounts of spatial data have been accumulated by years of Lake Okeechobee ecosystem studies. This chapter introduces the development of a database in support of the division's lake ecosystem studies. This database links a geographic information system (GIS) with a relational database management system (RDBMS) to best facilitate data use.

Developing and maintaining an integrated GIS-RDBMS database involves the following steps: (1) the establishment of a data server system conveniently accessible to all users; (2) the selection of appropriate RDBMS/GIS software for both attribute data and geographic data; (3) the development of a general data format and database structure; (4) the formalization of data management procedures, including input, update, conversion, QA/QC, and backup; and (5) the implementation of data query and retrieval utilities for end users to search, display, print, or plot information. This chapter documents the major steps in developing a Lake Okeechobee GIS-RDBMS database. The process focuses on the Lake Okeechobee ecosystem studies. Hardware and software availability impacted significantly the entire development approach. The chapter introduces a concept for modeling fuzzy geographic features, which addresses special needs in ecosystem studies. Also introduced in the chapter is the approach for establishing a virtual data server system through a computer network.

BACKGROUND

Lake Okeechobee (Figure 12.1) is the central feature of the Kissimmee River / Lake Okeechobee / Everglades hydrologic ecosystem in south Florida. The lake is a large (approximately 700 square miles), shallow (average depth about 10 feet), subtropical lake which provides water, flood protection, and recreational benefits for a population exceeding 3.5 million people. The lake is also an important biological habitat for economically important fish and wildlife, including several threatened and endangered species (Aumen, 1995).

Various factors have contributed to the deterioration of the Lake Okeechobee ecosystem. Among these factors is excessive nutrient loading from agricultural activities in the watershed, which has caused increased blue-green algal blooms. These blooms, characterized by surface

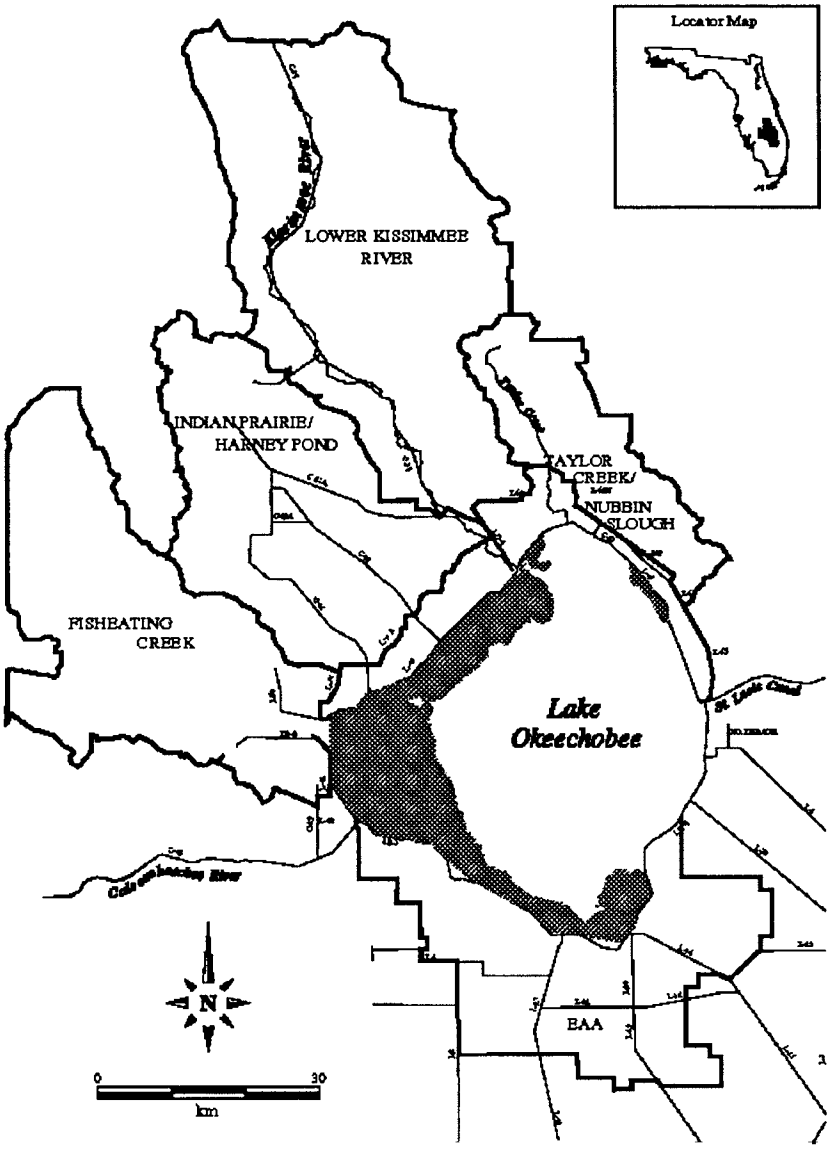

Figure 12.1. Lake Okeechobee and associated ecosystem studies.

scums and unpleasant tastes and odors, raised concerns about declining water quality (Aumen, 1995). Several interdisciplinary, multiyear research efforts were initiated in the late 1980s in response to the algal blooms, including a lake ecosystem study.

The Lake Okeechobee Ecosystem Study (LOES), conducted by the University of Florida under a contract with the South Florida Water Management District (SFWMD), was unique in that it looked beyond excessive nutrient loading to other components of the ecosystem. Research topics include water level effects, water quality, fish and wading bird populations, and wildlife habitat. The study's objective was to provide an ecological baseline against which future ecosystem trends can be compared, and to assess the general health of the ecosystem. The database structure that will be described in this chapter is based on the results of this LOES.

Data Related to Lake Okeechobee Ecosystem Study

The Lake Okeechobee Ecosystem Study addressed the following issues (University of Florida, 1991): (1) data synthesis, modeling, and database management; (2) water chemistry and physical parameters; (3) community and ecosystem ecology of emergent macrophytes; (4) phytoplankton, bacteria, epiphytes, submerged plants, macroinvertebrates, and zooplankton; (5) distribution and abundance patterns and the reproductivity and foraging ecology of wading birds; and (6) larval and juvenile fish. The project involved extensive field data collection and analysis. Data related to the study were archived on floppy disks using Lotus 1–2–3 spreadsheets, WordPerfect documents, ASCII text files, and ERDAS raster files. Data were categorized as follows: (1) plankton—bacteria, bioassays, nitrogen fixation, phytoplankton, and zooplankton; (2) plants—emergent, nutrients, seeds, soils, and submergent; (3) water quality—chlorophyll, nutrients, physical chemistry, and suspended solids; (4) wildlife—birds and fish; (5) hydrology—Lake Okeechobee hydrological data; (6) spatial data—GIS coverages, images, and locational files; and (7) documentation—various text files for clarification, identification, and explanation.

Importance of GIS

Most of the data collected in LOES have locational records. Location is recorded either by x-y coordinates or by verbal descriptions. The geographic information system (GIS) was identified as an important tool for the lake ecosystem study. As stated in a LOES annual report (University of Florida, 1991), the objective of LOES was to use an ecosystems approach to develop a set of tools (models and GIS databases) that integrate the data from various tasks in the project and other projects to provide predictive capabilities with which the SFWMD can evaluate the consequences of various water management options on the marsh littoral zone of Lake Okeechobee and its interaction with the pelagic zone of the lake. Critical concerns include impacts on the fish and wildlife resources, the role of the marsh in nutrient dynamics and exchange with the lake, and estimates of the total flux of nutrients to and from the lake under different water regimes. The following areas of focus were suggested by the LOES review panel (University of Florida, 1991): (1) impact of lake stage on biotic communities; (2) impact of nutrient concentrations on biotic communities and trophic relationships; (3) direct and indirect effects of plant community structure on critical habitat and energy flow to wading birds and fishes; (4) role of littoral zone in the lake's ecology; (5) effects of water pumping from canals on lake communities and productivity; and (6) role of exotics in lake ecology. These focus areas outlined user database requirements.

The LOES review panel (University of Florida, 1991) suggested that a spatially based predictive model utilizing a GIS approach be developed, capable of predicting the responses of fish and wildlife resources to management options such as lake stage manipulation, nutrient loading increases or decreases, or the long-term effects of maintaining the present regimes of stage, nutrients and flows. The model was envisioned to be sufficient to provide indications of the magnitude of the changes in the system and the spatial location of such changes utilizing the GIS information layers and model parameters derived from the various tasks of LOES and other projects.

To effectively use information collected by LOES and other studies, a functional database linking GIS with a relational database management system (RDBMS) was needed. An RDBMS can efficiently manage the large amount of information while a GIS can present data spatially. The effort of developing this database included establishing a data server system, designing an integrated database structure, developing a database management procedure, and implementing a data query and retrieval user interface.

DATA SERVER SYSTEM

A data server system is a computing platform that hosts databases. It may include computers, operating systems, networks, database management systems, geographic information systems, and other hardware and software necessary to input, store, manage, query, and output data (Cowen et al., 1995). Ideally, a data server system should be selected according to the conceptual design of the database to be developed. In reality, many constraints, especially financial, limit available options for the selection of a data server system.

In this study, the computing environment consists of ORACLE as the RDBMS software on a VAX minicomputer, and ARC/INFO and Arcview as the GIS software on SUN SPARC workstations. Some workstations use SUN OS and others use Solaris as the operating system. All computers were networked. Desktop workstations (SPARC 2, 10, 20, or Ultra) and personal computers were available to end users of the GIS-RDBMS database.

The GIS database was a special component of a relational database hosting the information collected by LOES. The GIS database had two components: ARC/INFO coverages for geographic features and unique feature IDs, and ORACLE tables for attribute items with the feature ID as a unique key. The connection between the two was built on the Database Integrator in ARC/INFO and ArcView.

Due to software and storage space limitations, the database cannot be loaded onto a single computer. Several networked computers were needed. Tabular data are stored in ORACLE tables on the VAX, and spatial data were stored in ARC/INFO coverage format on several workstations. One workstation, a SUN SPARC 20, was designated as the "virtual" data server. The graphic user interface for data query and retrieval was installed on this workstation, with the directory structure for all ARC/INFO coverages. Symbolic links in subdirectories point to the actual locations of the coverages on other workstations. When users query on spatial features from a workstation, an ARC-ORACLE interface links to the ORACLE database on VAX and returns appropriate tables and records (Figure 12.2).

This design provides users with a seemingly holistic database on the virtual data server. Users need not know the real storage locations of the database components, nor do they need to interact with any computer platform other than the virtual data server. On the other hand, the group of networked computers collectively provides the required storage and computing capacity necessary for the database, which does not exist in any single computer. When the database grows, more computers may be brought into the group with minimum impact on existing server components.

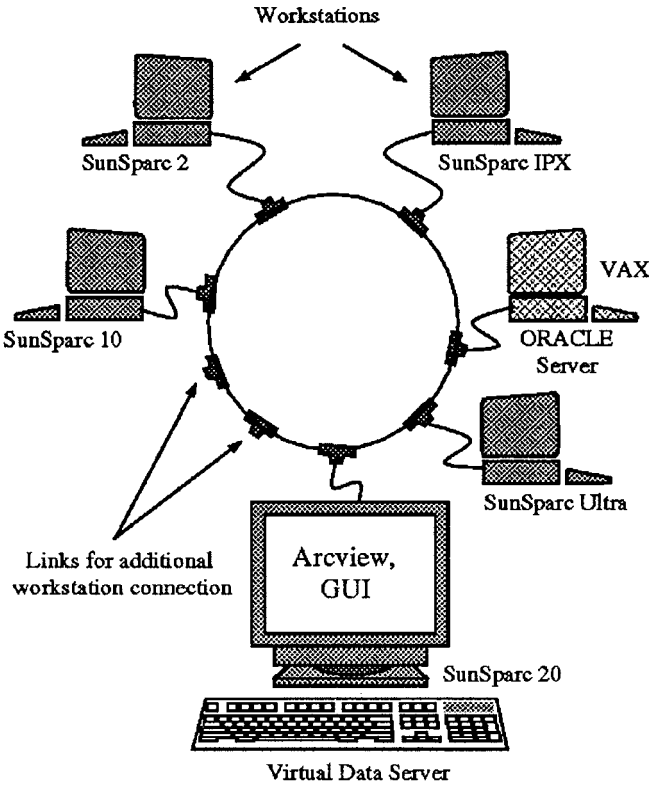

Figure 12.2. The networked data server system.

The disadvantage of this data server structure is its reliance on the network and each computer in the structure. If one data-hosting computer goes off the network, the database will not function properly. Moreover, the database manager must have access to all database computers for maintenance purposes. Because most of the involved workstations are routinely used by SFWMD staff as desktop computers, special effort is needed to coordinate their use for the database.

THE DATABASE MODEL

A model can be thought of as a real-world abstraction where only essential details are kept. Database models are created to understand the data organization before the database and support programs are built. The LOES database model was created using the Object-Oriented Modeling Technique (OMT) (Rumbaugh et al., 1991). Subsequently, the LOES database model was mapped as a relational database and built on a VAX minicomputer using an ORACLE RDBMS.

Originally, LOES data were organized in spreadsheets with different record formats. After data collection was completed, scientists developed a database model from which data could be extracted in convenient formats. The resulting database model has five modules (Lostal, 1996): (1) Locational, (2) Ecological Variable, (3) Biological Species, (4) Time Series, and (5) Organizational.

Locational, Ecological Variable, Biological Species, and Organizational modules have separate, well-defined purposes. The Locational module deals with the measurement site or station. The Ecological Variable module handles information about the type of data (i.e., sample method, parameter, and unit) measured. The Biological Species module describes scientific and common names of measured species. The Organizational module addresses who (i.e., agency, observer) produced the data and why (i.e., project, study, task) the data were produced.

Time Series, the last module, depends on the other modules. Time series are determined by stations, ecological variables, and biological species; they contain summary information and a data point set. Summary information includes items such as period of record, number of observations, average or sum, standard deviation, and maximum and minimum values. The data point set is formed by all data points observed. Each data point encompasses a time series identifier, time stamp, measured or described ecological value, quality indicator information, and organizational code.

The database's architecture allows spatial queries about ecological data. For example, whenever a user selects a location in a map coverage, the GIS client program sends the request to a utility program that chooses the station closest to that location. The program queries the database using the selected station and the database returns a list with all the time series summaries stored for that station. The user reviews the list, selects an appropriate time series, and submits the request. The program queries the database, receives the information, and displays the data point set. As the example shows, the ORACLE database and the GIS client interface initially through locational information.

The Locational Module

The LOES database was modeled using object-oriented methods. As its name suggests, the object-oriented approach organizes real-world concepts as objects. Objects are things or abstractions with boundaries and meaning in the real world. Objects with similar properties are grouped into classes. A database model shows the classes that compose a database, and how these classes associate with each other. The Locational module deals with the classes that represent the measure-

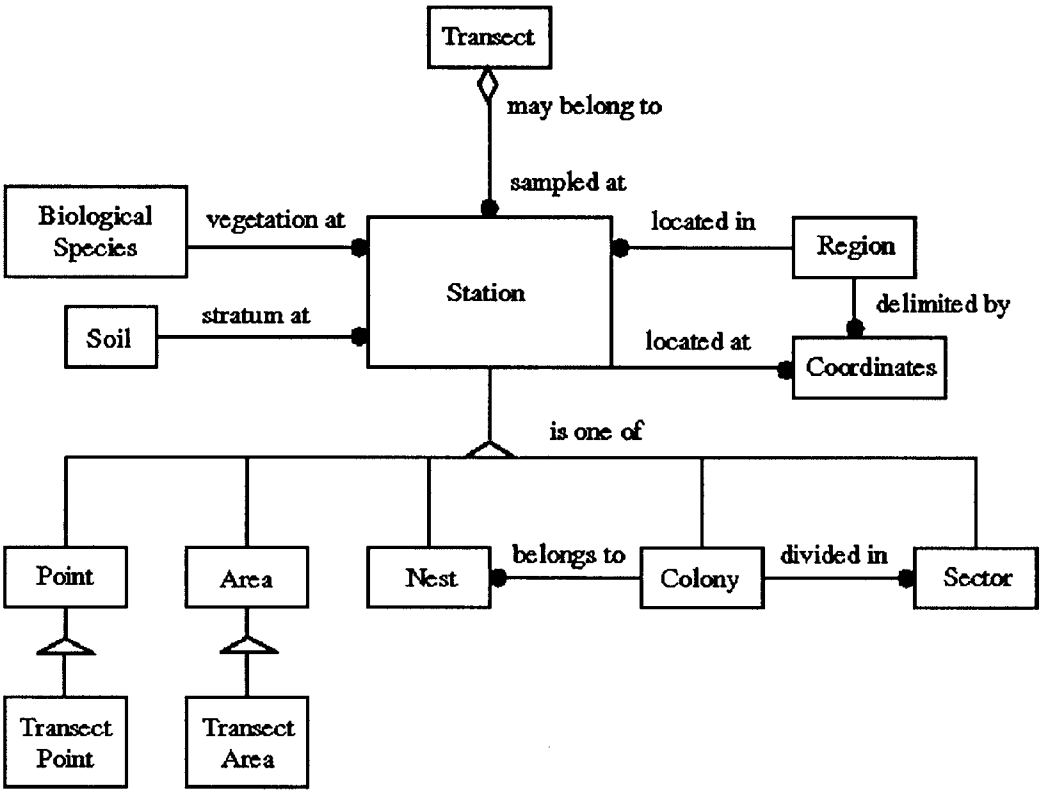

Figure 12.3. Locational module object model.

ment site and their associations. The GIS client is interested particularly in this module, because any information displayed on a map coverage is attached to a measurement site.

Figure 12.3 shows the database model for the Locational module. The measurement site, depicted by the Station class (classes are represented as rectangles in the diagram) is the fundamental component of this module. All classes included in this module associate with the Station class (associations are represented by lines in the diagram). Some classes are specific location types, other classes associate spatially with the Station class, and the rest provide complementary information to the Station class.

Ecological data were collected at a variety of places such as water quality monitoring points, fishing sites, and bird colonies. The Station class was an abstraction that represents any location type. This special association, called a generalization (represented by a triangle in the diagram), was used to classify related classes. As the figure shows, the Station class was a generalization of five location types used to collect data: (1) Point, (2) Area, (3) Bird Colony, (4) Colony Sector, and (5) Bird Nest. Points are sites identified by one pair of x-y coordinates. Areas refer to locations specified by more than one pair of x-y coordinates (two points define a rectangle). Other station types describe bird information. Bird colonies were sites where birds live and procreate. Both colony and point positions were given by one pair of x-y coordinates. However, colonies were classified separately from points because they also associate with other station types such as nests and colony sectors. The use of labels helps to interpret associations. For example, the association between the Nest class and the Colony class indicates that many nests (the filled circle means many) belong to a colony.

Spatially, the Station class associates with regions and transects. Regions are large areas where

stations were located. The diagram indicates that many stations were located in a region. Transects are station aggregates sampled along a transect path. This is a "whole-part" association or aggregation represented as a diamond in the diagram. The transect is the total assembly and the stations are its elements. Of the five station types, only point and area stations may belong to transects. This aspect is shown on the figure by representing Transect Point and Transect Area as separated classes.

The Coordinates classes were related to both Region and Station classes. The Region-Coordinates association shows that a region was delimited (specified) by many coordinates. The association between the Station class and the Coordinates class was more general. The figure indicates solely that a station is located at many coordinates. This association considers all location types explained above. First, a station refers to a location type indicated by one set of x-y coordinates. Second, the station was an area determined by more than one set of x-y coordinates. Third, a station position may be reported without using coordinates values; instead, a descriptive method was used (See Soft Points and Soft Polygons section).

The last two classes in the figure, Biological Species and Soil, serve as "catalogs" for the Station class. For example, the Biological Species class contains all information about vegetation including scientific classification and common name. However, instead of duplicating all the information, the Station class contains solely abbreviated descriptions. When a full description is required, the Biological Species and the Soil classes supply the information that is not stored in the Station class.

Soft Points and Soft Polygons

Due to the biological and ecological nature of the data sets, the LOES database developers needed to process spatial data with uncertain locational coordinates. To address this issue, we introduced the concept of soft points and soft polygons. A soft point is a point without a definite x-y location, and a soft polygon is a polygon without a definite boundary. In ecosystem studies, researchers often have to deal with soft points and polygons when historical and field survey data are involved. Before GIS was implemented, many field observations were made with a verbal description of location, not explicit x-y coordinates. Even with well-established GIS concepts, some ecological features were difficult to describe at a definite x-y location or within a distinct boundary. For example, a given fish species was observed in a certain area of a water body at a certain time. That "certain area" of the water body does not have a clear boundary. Such observations may apply to animals on land, plankton in water, or a floating plant mass in a wetland.

In the soft feature model, the geographic location of a soft point was described by its probability distribution in space. A soft point may appear at any known location with a certain probability. That known location was usually contained in a polygon. When the probability equals one at a known point, the soft point becomes a hard point. Where the probability equals zero, the soft point never appears. The line between none-zero and zero probability areas was the boundary of the probability distribution zone. One soft point may have multiple probability distribution polygons (Figure 12.4).

The geographic location of a soft polygon was more difficult to describe than that of a soft point. Three parameters were required to define a polygon: size, shape, and the location of the gravity center. When any of these parameters is uncertain, the polygon becomes a soft polygon. In theory, this leads to seven types of soft polygons (Table 12.1). In this study, two types of soft polygons are discussed (Types 1 and 5 in Table 12.1), which are most common to ecological studies.

For soft polygons with uncertain size, shape and location, the probability distribution patterns were similar to those of soft points. The probability polygons were stored as an ARC/INFO cover-

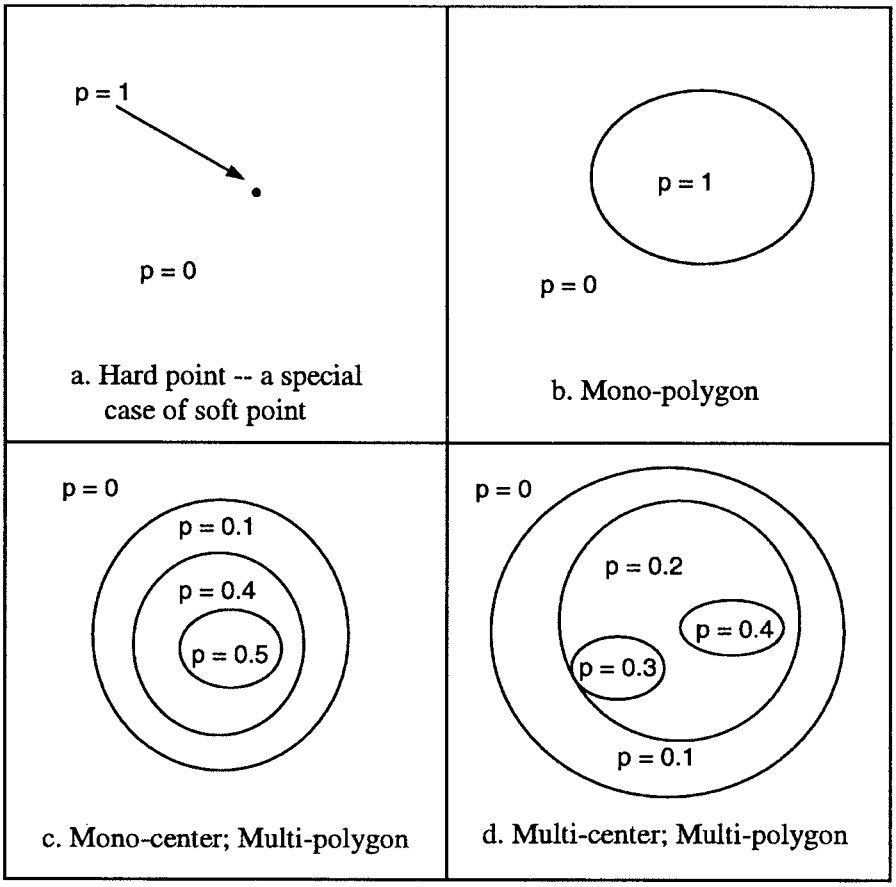

Figure 12.4. Probability distribution patterns of soft points.

age, each with an attribute value indicating the probability of any point in the probability polygon belonging to the soft polygon.

For soft polygons with known size and shape, the only uncertainty was location. The polygon's gravity center may be derived from its size and shape. The probability distribution of the center determines the probability distribution of the polygon. The soft point model discussed above also applies to the center of this soft polygon type. The size and shape of the polygon can be preserved

Table 12.1. Types of Soft Polygons, sort by size, then by shape, then by center location

Type	Size	Shape	Center Location	Note
1	uncertain	uncertain	uncertain	common
2	certain	uncertain	uncertain	uncommon
3	uncertain	certain	uncertain	rare
4	uncertain	uncertain	certain	uncommon
5	certain	certain	uncertain	common
6	certain	uncertain	certain	uncommon
7	uncertain	certain	certain	rare
8	certain	certain	certain	hard polygon, a special case of soft polygon

in a separate coverage or incorporated into the polygon coverage for probability distribution through an appropriate algorithm.

DATABASE IMPLEMENTATION AND MANAGEMENT

Initial database implementation included the following: (1) specifying a directory structure; (2) determining a directory and file-naming convention; (3) specifying read/write permissions and work group arrangements; (4) selecting precision and projection systems for coverages; (5) setting up a standard template for attribute files; and (6) establishing metadata standards.

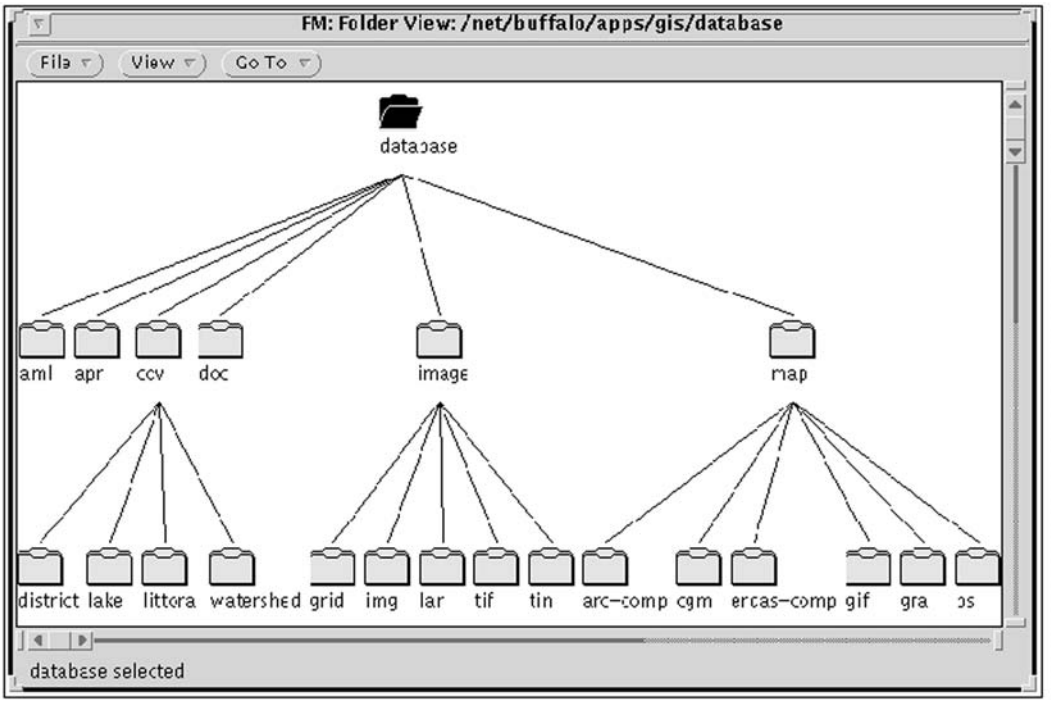

Figure 12.5. The directory structure and naming convention for LOES GIS Database.

The GIS database directory structure was set up on the virtual server. It includes subdirectories for ARC/INFO coverages, ArcView project files, images, map files, programming codes, and documentation files. A naming convention was developed to indicate the subject and format of each subdirectory and file (Figure 12.5).

Access permissions were assigned according to whether an individual was a database developer or user. Developers include database managers, system administrators, and data editors. Database managers have full read/write access to the database and are responsible for managing both the GIS database and the data server system. The system administrators, who also have full read/write access, solve system problems, maintain system security, and perform periodic backups by saving data on external media. Data editors have partial write access to input, update, and/or convert data for the database as well as utilizing metadata standards to document information about the database. End users are an integral part of GIS database management as they provide valuable feedback for database improvement. All end users have read-only access to the database.

Single precision (seven significant digits) and double precision (15 significant digits) are the

only alternatives for storing coverage coordinates in ARC/INFO. Double precision coverages, which provide a more precise geographic location, require more storage space. Due to the large study area (hundreds of square miles) and the variation of parameters within a short distance (inches or feet) in the Lake Okeechobee ecosystem, double precision was used for most coverages.

The projection system was based on the current GIS standard of the SFWMD, which is State Plane zone 3601 (Florida East Zone). The datum for the database was NAD27 (1927 North American Datum). When the SFWMD GIS database migrates to NAD83 (1983 North American Datum), all coverages and images in the Lake Okeechobee database will be transformed accordingly. The transformation will, most likely, use the ARC/INFO PROJECT function.

Minimal attribute data were stored with the coverages in the GIS database. Most ecological data reside in ORACLE tables and are linked to geographic features in the coverages by a unique ID. This ID often is the only external (user specified) attribute in the coverages. The user-specified attribute item (UNIQUE-ID) is indexed to decrease process time across the Arc-Oracle link.

In order to standardize metadata format for the GIS databases, METAMENU, a menu-driven metadata editing user interface was developed. METAMENU provides a convenient tool for users to document GIS data following a predefined standard. It automatically extracts any existing metadata information from GIS files, provides multiple choices whenever applicable, and prompts users to enter required information. The interface also checks for completion of user input, reorganizes entries into a standard metadata format, and saves information at a logical location using a standard naming convention. With this interface, users may define one metadata format for a group of similar coverages, or copy the metadata of one coverage into another and selectively edit some items to document differences.

One major difference between METAMENU and the DOCUMENT command in Arc/Info ver.7 is the metadata file format. DOCUMENT saves metadata in INFO, while the METAMENU interface saves metadata as an ASCII text file. ASCII files can be viewed without an Arc/Info license. Moreover, METAMENU generates metadata more specific to the LOES database users' needs, while DOCUMENT is more general and was designed for a broad range of ARC/INFO users. An example of metadata generated using METAMENU is in Appendix 12.1.

Database Management

The management of a GIS database, similar to that of other databases, involves data development, QA/QC, and backup. Data development includes data input, update, conversion, and construction of metadata. QA/QC, which stands for quality assurance and quality control, is a process following data development. Backup safeguards data from damage.

The unique aspect of GIS data management is the coordination between geographic and attribute data. Geographic data require special techniques and procedures for input, update, conversion, QA/QC, and backup; corresponding attribute data can be managed as regular tabular data. The geographic features and tabular attributes are linked together through a unique ID, which requires special attention when either side of the database is modified.

Data development, QA/QC, and backup of GIS data become more difficult to manage in a multiuser environment. A GIS data management guideline was a necessary tool which assists both database managers and users in systematically handling such transactions. The Lake Okeechobee database management utilized the GIS Data Management Guidelines. These guidelines detail the responsibilities of the database managers, the system administrators, the data editors, and the end users. They also specify the procedures for data QA/QC (SFWMD, 1997).

After data development was completed, data were verified by manual QA/QC procedures. Criteria for assessing data quality were specified for both geographic features and their attributes. Ac-

cording to Montgomery and Schuch (1993), graphic and attribute data "have similar data quality components, such as completeness, correctness, timeliness, and coverage, but the graphic features also are subject to cartographic quality considerations . . . (such as) relative accuracy, absolute accuracy, and graphic quality." The QA/QC procedures for Lake Okeechobee database incorporated these considerations in the data verification process.

An integral part of database management includes database backup. Backup saves database contents on external media as a safeguard against corruption. Three kinds of backup procedures were outlined in the management guidelines for the Lake Okeechobee database: (1) routine backups, which are consistently done at a designated time, regardless of changes in data; (2) nonemergency backups, which are done after changes in data; and (3) emergency backups, which take place preceding the possibility of a natural disaster (e.g., hurricane), power failure, maintenance on critical hard/software, and as otherwise deemed necessary.

DATA QUERY AND RETRIEVAL

The GIS database is accessible to all SFWMD staff for data query and retrieval. A generic user interface is being developed to support users with minimum GIS training to search, display, print or plot data from the database. Thus, the interface must be tailored to user needs.

The first step in interface development was to interview end users and identify their needs for data display, query, and retrieval (Montgomery and Schuch, 1993). Considering the internal structure of the database, user demand, and facilities available, ArcView was selected as the interface platform. Avenue, the object-oriented scripting language for ArcView, was used to communicate with the ORACLE database, customize the display environment, structure query statements, and standardize output formats. A prototype of the interface has been developed, presenting the interface look-and-feel. Development was based on user comments. The interface will be modified based on further input from users.

SUMMARY

This chapter documents the major steps in developing a Lake Okeechobee GIS-RDBMS database. The entire process involved the following components: (1) data server setup; (2) data model design; (3) database implementation; (4) data management standardization; and (5) user interface development. Database development focused on the Lake Okeechobee Ecosystem Study. The approaches adopted in database development were largely determined by hardware and software availability as well as special characteristics of ecological data. Introduced in the chapter is a method for modeling soft geographic features. The chapter also describes the approach for establishing a virtual data server through the network.

Database development is a constant trade-off between "what it should be" and "what it could be." Instead of a "perfect database," the final product of this project is a "functional database," developed under various constraints. Database optimization is a long-term task. By having a functional database first, and improving it constantly, the database will incrementally approach an ideal design that best serves its users.

ACKNOWLEDGMENT

This chapter incorporated review comments from Todd Tisdale, Al Steinman, Chris Carlson, Benjamin Lewis, and Nancy Lin. The metadata editing user interface used a set of AML scripts from a command-drive metadata input program originally developed by Timothy Liebermann. The

data query and retrieval graphic user interface was developed on an ArcView 2.0 data viewing project initially built by Chris Carlson. The authors wish to thank the above-mentioned colleagues—all are staff of the South Florida Water Management District—for their valuable contributions to this study.

CHAPTER 13

Historical Aerial Photographs and a Geographic Information System (GIS) to Determine Effects of Long-Term Water Level Fluctuations on Wetlands along the St. Marys River, Michigan, USA

Donald C. Williams and John G. Lyon

INTRODUCTION

Water levels of the Laurentian Great Lakes and their connecting channels rise and fall in predictable annual patterns related to the seasonal patterns of precipitation, runoff, and evaporation. Variations of winter low levels to summer high levels average from 0.37 meters on Lake Superior to 0.6 meters on Lake Ontario (U.S. Army Corps of Engineers, 1985). Lake levels also rise and decline in unpredictable multiyear patterns following long-term fluctuations of climatic conditions in and around the Great Lakes basin. Historically, the ranges of Great Lake annual water level averages have been from ± 0.6 to 0.9 meters from their respective historic means (U.S. Army Corps of Engineers, 1985).

The Great Lakes long-term water level fluctuations have recurred about every two to three decades. These fluctuations have broad influences on the areas of the wetlands situated along the lake and connecting channel shores (Jaworski et al., 1979; Harris et al., 1981; Enslin and McIntosh, 1982; Lyon and Drobney, 1984; Busch and Lewis, 1984; Quinlan, 1985; Greene 1987; Bukata et al., 1988; Williams, 1995). The subject of this chapter is the use of a Geographic Information System (GIS) to study the influences of long-term water level fluctuations on the wetland areas of the St. Marys River. The St. Marys River is a connecting channel between Lakes Superior and Huron that borders on the U.S. and Canada. The river water levels are largely controlled by the levels of Lake Huron (Williams, 1995), such that wetland areas along the St. Marys undergo fluctuations corresponding to those of Great Lakes wetlands. A GIS was used to measure area changes in five different St. Marys River coastal wetland classes. These area change data were used to characterize wetland class responses to water level changes, to estimate response times, and to examine how wetland class transfers were affected by water levels.

Geographic Information Systems (GIS) offer excellent capabilities as tools for analysis of wetland changes caused by long-term lake level fluctuations. When accurate historical information on wetland areas and wetland characteristics is available in digital form, it would appear that GIS change detection algorithms could be employed to rapidly provide information on changes in wet-

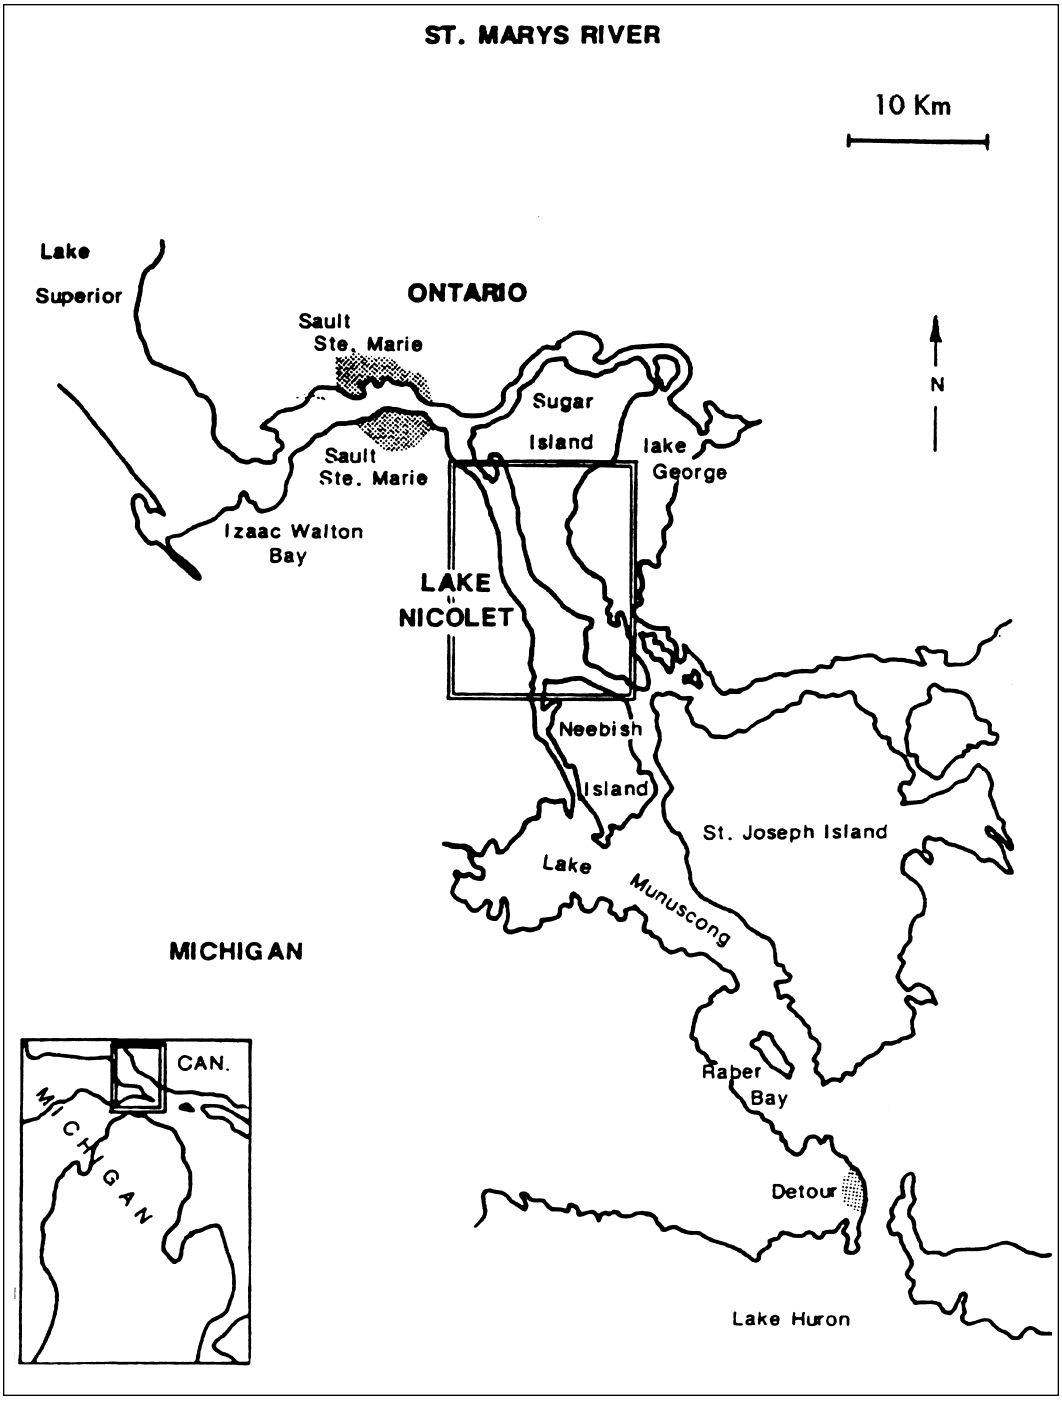

Figure 13.1. Location of St. Marys River study area.

land area and changes in wetland vegetation class associated with water level fluctuations. The following analysis demonstrates the application of such methods to analyze wetland changes due to long-term Great Lakes water level fluctuations. This analysis was conducted on a U.S. Fish and Wildlife Service (USFWS) National Wetland Inventory digital data set on the wetlands of the St. Marys River. This analysis used ERDAS GIS software. Other GIS systems containing similar analytic software would provide similar results.

The St. Marys River connects Whitefish Bay, Lake Superior, with Detour Passage in northern Lake Huron. The wetland study area was directly south of Sault Ste. Marie, Michigan, from Little Rapids Cut at the northern end of Sugar Island, south along both sides of Lake Nicolet, and along the east side of Neebish Island into northern Lake Munuscong (Figure 13.1). The study area is covered by five United States Geological Survey (USGS) 1:24,000 (7 1/2 minute) quadrangle maps.

The wetland types found in the study area are characterized as Unconsolidated Bottom, Emergent Wetland, Unconsolidated Shore, Scrub-Shrub Wetland, and Forested Wetland, using the USFWS Classification System (Cowardin et al., 1979). These wetlands classes are commonly described in nontechnical terms as river bottom, marsh, beach, scrub-shrub, and swamp.

METHODS

Wetland classes and areas in the St. Marys River were determined by interpretation of aerial photos from the summer seasons of 1939, 1953, 1964, 1978, 1982, 1984, and 1985 (Table 13.1). The film types included black and white, black and white infrared, color, and color infrared. The photo scales ranged from 1:12,000 to 1:58,000 (Table 13.1).

The aerial photos were acquired at seven different St. Marys River water levels (Table 13.1). These levels represented a broad sample of the wide range of water levels to which Great Lakes coastal wetlands are subjected. The August 1953 level, 177.52 m, was within 20 cm of the all-time monthly high of 177.64 m August ’52 at the U.S. Slip gauge. The July 1964 level, 176.09, was within 25 cm of the all-time low of 175.86 m (Dec. ’63). These aerial photos recorded the St. Marys wetlands at water levels that varied over a range of 1.43 meters (176.09 to 177.52 m, above the International Great Lakes Datum 1955). This range allowed an analysis of the influence of water levels on the wetlands over a large part of their historic range.

Wetland areas were quantified for each year of aerial photographs by the USFWS National Wetland Inventory contractor (St. Petersburg, FL) experienced with photo interpretation and identification of wetlands. The study area was also visited by the USFWS contractor. Initial interpretations were completed with an analog stereo plotter using the 1984 images. The plotter established

Table 13.1. Dates, Scales, Emulsions and Monthly Average Water Level Elevations of Aerial Photographs

Month	Year	Scale	Emulsion	Monthly Level (m)	Annual Level (m)
July	1939	1:20,000	black & white	177.01	176.62
August	1953	1:16,000	black & white Infrared	177.52	177.19
July	1964	1:16,000	black & white	176.09	176.16
June	1978	1:12,000	black & white	176.74	176.84
October	1982	1:58,500	color infrared	176.82	176.67
September	1984	1:12,000	color infrared	177.18	177.00
October	1985	1:24,000	natural color	177.43	177.20

geometric control and was used to correct any spatial inaccuracies found in the aerial photos. The interpreter viewed stereo pairs of photos, and outlined the wetland boundaries. The other dates of photography were compared to the 1984 maps and boundary adjustments made with a Zoom Transfer Scope. The boundaries were plotted on USGS 7½ minute maps of the study area.

Wetlands up to 800 meters inland from the river shore were included in the analysis to incorporate wetlands that could be influenced by changing water levels. This determination was based on USGS map elevations and mapped marsh areas. The photo interpreter assigned each wetland area to a type or class following the USFWS Classification System (Cowardin et al., 1979; U.S. Fish and Wildlife Service, 1987). Data were summarized in wetland maps and tables of wetland areas reported by the USFWS Wetland Analytical Mapping System (WAMS). The USFWS used its GIS system to create GIS files of the wetland polygons in ELAS format, which could be read by ERDAS software (U.S. Fish and Wildlife Service, 1988; Williams and Lyon, 1991).

The National Wetland Inventory provided maps and WAMS-derived tabular summaries. These were appropriate for completing some analyses. Further GIS analysis using the digital files, however, offered several advantages. First, the numerous wetland classes identified by National Wetland Inventory could readily be aggregated to simplify the analyses and to employ wetland classes used in comparable wetland studies on the Great Lakes. This was effective because of the large number of wetlands found on five USGS quadrangles and the aggregation was accomplished rapidly using the ERDAS software program RECODE. Other data sources on the St. Marys wetlands indicated that the Unconsolidated Bottom class included larger areas with submergent vegetation cover than the USFWS definition of Unconsolidated Bottom (less that 30%). Much of the bottom of the St. Marys is vegetated (Liston et al., 1986), hence the Unconsolidated Bottom class included Aquatic Bed Wetland (Cowardin et al., 1979).

Because the tabular National Wetland Inventory summaries were completed on individual quadrangles, without a GIS it was necessary to sum changes in five separate quadrangles to determine change across the entire study area. Consequently, the GIS was used to combine the quadrangle areas into a single digital file to reduce the number of analyses. Six digital files (one quadrangle was divided into two digital files) from each year were combined into one mosaic. This provided seven mosaics of the study area corresponding to the seven years of historical aerial photographic coverage: 1939, 1953, 1964, 1978, 1982, 1984, and 1985. The mosaics were created using the ERDAS GIS software program SUBSET.

There were also slight discrepancies in the total study area measured in both the tabular data and the individual digital files. Small areas were included in some years that were not in others. The GIS was used to establish an exact common area for each year so that year to year changes in wetland class and area could be determined more accurately. A GIS modeling package (GISMO) was used to create a mask, a sum of areas that were not common to each of the seven files, that was applied to each mosaic so the study area was precisely the same for each of the seven years. Data on the areal extent of each wetland class for each year were then obtained from the corrected mosaics (ERDAS BSTATS). This corrected discrepancies in total area between the seven data sets of up to 1%. Discrepancies in the ranges of the five wetland classes were reduced by as much as 3.8%. Rather than National Wetland Inventory tabular data, these quantities were then used in further analysis (Table 13.2).

The GIS analysis also allowed for the spatial location of changes in wetlands. Analysis of tabular or other data did not allow such identification. Locating exactly where a change occurred was important to identifying other possible causative factors for area changes such as vessel traffic in adjacent commercial navigation channels.

Locational information can also be used with GIS cross-tabulation algorithms to examine the nature of wetland class changes. A transition matrix for the St. Marys River study is shown as

Table 13.2. Quantities of Wetland Classes Calculated by GIS from Mosaics (Hectares). Note: Mask included Upland

Year	Unconsolidated Bottom	Emergent Wetland	Unconsolidated Shore	Scrub Shrub	Forested Wetland
1939	5097.4	1248.7	348.7	352.5	178.7
1953	5586.7	924.7	3.1	321.1	272.3
1964	5100.5	1326.5	99.2	384.3	250.3
1978	5611.2	899.8	9.2	341.4	281.2
1982	5554.5	950.5	7.9	333.1	283.2
1984	5601.1	909.3	1.6	339.9	281.7
1985	5600.8	913.5	1.5	341.7	282.2

Table 13.4. The matrix shows the net area changes that took place between wetland classes from one wetland state to the next. For example, the upper left cell in Table 13.4 indicates that 174.6 ha of Unconsolidated Bottom were gained in 1953 that had been Emergent Wetland in 1939. This matrix was used to examine some of the wetland class dynamics caused by fluctuations in the levels of the St. Marys River.

Class by Class Analysis of Area Changes Due to Long-Term Water Level Changes

The class areas calculated from the six-quadrangle mosaics of the study areas were used for analysis of the effects of water level fluctuations on the wetland class areas. Regressions of class areas on water level were run for the wetland classes Unconsolidated Bottom, Emergent Wetland, Unconsolidated Shore, Scrub-Shrub Wetland, and Forested Wetland. Initially, monthly mean water level from the U.S. Slip gauge was used as the independent variable. Because wetlands do not respond immediately to water level change, and area changes due to water level fluctuations may take months or years to be completed, another set of regressions was run using mean annual water level. Variations in the independent variable, average annual water level, for 1925 through 1985 from the U.S. Slip gauge below the locks at Sault Ste. Marie are shown in Figure 13.2.

Accounting for Lag Times in Wetland Area Changes

Many observations on Great Lakes coastal wetlands (e.g., Jaworski et al., 1979; Busch and Lewis, 1984; Painter et al., 1988) have shown that wetland changes due to the rise or fall of water level may take several years to be completed. To gain some insight into how rapidly wetland areas might have adjusted to water levels, a series of regressions was run using moving average water levels instead of monthly or annual average levels. These regressions were weighted average water levels consisting of the annual water levels of the years of the aerial photographs and annual levels from years prior to the photographs. The levels of the year the wetlands were photographed was given the greatest weight and the preceding years less and less weight. For a two year average the weights were 0.2, 0.1; for a three year average 0.3, 0.2, 0.1, etc.

The standard linear regression equation used for annual mean water levels was:

$$Y = a + b\ (X_{ave}) \tag{1}$$

where Y = wetland area and X_{ave} = average annual water level.

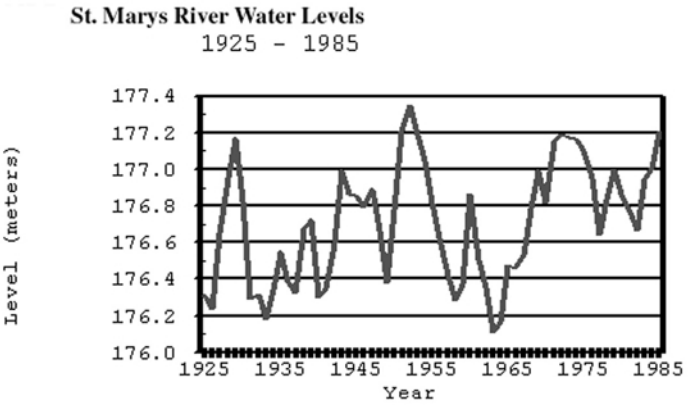

Figure 13.2. Mean annual water levels from the U.S. Slip gauge near the study area (meters above ILGD '55).

For weighted average water levels the regression equation was

$$A = a + b\ (c_1{*}X_t{+}c_2{*}X_t{-}1{+}...{+}c_n{*}X_{t\text{-}n}) \quad (2)$$

where c_1, c_2...c_n were weighting factors for the average annual water levels of the year of photography, the year before the photography, etc., and the weighting factors were 0.2 and 0.1 for a two year regression, 0.3, 0.2, and 0.1 for a three year regression, etc.

The coefficient of determination (R^2) of the regression equation was maximized by adding yearly increments into the linear combination of levels. An optimal combination of water levels was selected for each wetland class based on the maximized R^2. This optimum fit provided an estimate of the number of years that might have been relevant to the adjustment of each wetland class in the St. Marys River to the water level changes, and therefore the importance of the water levels in the years preceding the measured growing season.

RESULTS

Emergent Wetlands

For Emergent Wetland within the study area there was a 426 ha difference between the year with the largest area, 1964, and the year with the least area, 1978. This represented a 32% change, hence Emergent Wetland area varied by about one-third (Table 13.3). The linear regression of Emergent Wetland area on monthly average water level was not significant. The regression of area on average annual level was significant (* $P < 0.05$). This provided strong evidence of a relationship between water level and area of Emergent Wetland areas between 1939 and 1985. As water levels rose, Emergent Wetland area decreased, and as water levels fell, Emergent Wetland area increased. A number of other studies on Great Lakes emergent wetlands have shown this result (Jaworski et al., 1979; Harris et al., 1981; Enslin and McIntosh, 1982; Lyon and Drobney, 1984; Busch and Lewis, 1984; Greene, 1987; Bukata et al., 1988; Payne et al., 1985; Quinlan, 1985). The fact that the regression of area on monthly average level was not significant and the regression of area on annual average level was significant (** $P < 0.05$, $R^2 = 0.64$) suggested that the effect of water level on Emergent Wetland area took a growing season or longer to complete.

Table 13.3. Direction, Rate, and Magnitude of Wetland Class Changes

Wetland Class	Regression Results			Area Change	
	±	P <	Yr. Lag	Hectares	Percent
Emergent	–	0.001	14	426	32
Unconsolidated Bottom	+	0.001	15	514	9
Unconsolidated Shore	–	0.05	22	347	99
Scrub-Shrub	–	0.01	5	63	16
Forested	+	0.01	22	104	37

There is a tendency for the water levels to be higher in the years of photography taken later in the growing season (Table 13.1). This cannot account for the differences in wetland area, however, because the dominant St. Marys emergent plants reach their maximum heights by July, and plants of maximum height are still present in September and generally October (Liston et al., 1986). *Scirpus acutus* Bigelow shoots persist through the winter and are clearly visible protruding through the ice.

Regressions were run for weighted annual water level averages incorporating water levels from 2 to 30 years previous to the years of the area measurement. The regression fit (R^2) increased for each additional year accumulated through the fourteenth year. The analysis thus suggested that water levels in any given year influenced Emergent Wetland area for up to 14 years, or conversely, that Emergent Wetland area was influenced by water levels of multiple years before its occurrence. At 14 years, the regression accounted for 99% of the variability ($R^2 = 0.991$), and was statistically significant (*** $P < 0.001$).

The question of response time for changes in Emergent Wetland has had less attention. Several investigators have postulated that it takes around five years for Emergent Wetlands to adjust to water level changes. Busch and Lewis (1984) used a five-year weighted moving average to explain changes in a marsh in eastern Lake Ontario marsh, and Painter et al. (1988) used a similar method to explain changes in Cootes Paradise on the western end of the same lake. The increase in R^2s for regression using moving averages up to 14 years suggest that the Emergent Wetlands in the St. Marys River might take even longer to adjust to water levels. There is some rationale for supporting the hypothesis that these wetlands may on average take five years or more to complete adjustments to major water level fluctuations. It was clear from the seven sets of aerial photographs that distribution patterns of *Scirpus acutus* Bigelow were very stable. Some areas appeared not to have changed significantly from 1939 to 1985. Although they are not woody plants, many of the emergents in the St. Marys (e.g., *Eleocharis smallii* Britton, *Sparganium eurycarpum* Engelm., *S. chlorocarpum* Rydb., and *Scirpus americanus* Pers.) are long-lived perennials. Storage effects from low levels can occur as gains in colonized areas and increases in robustness and storage products in rhizomes. Substrate (Lyon et al. 1986) and topographic changes brought about by the water level changes may also take some time to complete.

The regressions took into account both gains and losses, and it is common sense to assume that losses of Emergent Wetland could occur quite rapidly in response to high water levels, certainly less than 14 years. Nonetheless, observations of cattail (*Typha* sp.) responses to water level increases at Horicon Marsh in the state of Wisconsin, USA by Mathiak (1971) indicated that maximum die-off occurred in the fourth and fifth years after exposure to high water levels. Given that some perennial marsh species are resistant to flooding, and that the resistance is likely to vary from species to species, it is probable that responses to increased levels will vary from marsh to

marsh depending upon species composition. There appears to be some evidence for this variation (Williams, 1995).

The transition matrix shows some of the interclass transfers that took place between Emergent Wetland and other classes as levels changed. There were large changes from Unconsolidated Bottom to Emergent Wetland associated with the drops in water level from 1953 to 1964 and 1978 to 1982. There were also large transfers from Emergent Wetland to Unconsolidated Bottom during the level increase from 1939 to 1953 and 1982 to 1984. There were fairly large losses of Emergent Wetland in the 1939 to 1953 transitions to Scrub-Shrub, Forested Wetland, and Upland. These would not be expected from water level changes and were probably due to succession that occurred in spite of the level increases.

Unconsolidated Bottom

There was a 514 hectare change in area of Unconsolidated Bottom between the year with the largest area, 1978, and the year with the smallest area, 1964. This amounted to a 9% change in area (Table 13.3). Unconsolidated Bottom area responded in a manner opposite to that of Emergent Wetland. Unconsolidated Bottom expanded during high water levels and contracted during low water levels; as water levels increased, Unconsolidated Bottom area increased. The regression of Unconsolidated Bottom area on monthly water levels was not statistically significant. The regression of area on annual average level was significant (** $P < 0.05$, $R^2 = 0.55$) and suggested that the effect of water level on Unconsolidated Bottom area also took a growing season or more to complete.

A series of regressions was run for weighted average water levels for 2 to 30 years previous to the years of area measurement. The regression R^2 increased for each additional year up to 15 years. The analysis thus suggested that it takes several years before the effects of water levels on Unconsolidated Bottom are complete. At 15 years, the regression (Table 13.3) accounted for 99% of the variability ($R^2 = 0.995$), and was statistically significant (*** $P < 0.001$). The similarity in lag time (15 vs. 14 years) and the opposite response suggested a reciprocal connection between Unconsolidated Bottom and Emergent Wetlands. As water levels increased, many of the losses in Emergent Wetland area were probably attributable to gains in Unconsolidated Bottom and as water levels decreased, the opposite exchanges probably occurred. This was supported by the information in the transition matrix in Table 13.4 discussed above.

Unconsolidated Shore

Unconsolidated Shore is by definition wetland with less than 30% coverage by vegetation and a hydrologic regime varying from intermittently flooded to intermittently exposed. The area of Unconsolidated Shore changed by 347 ha between its minimum and maximum. It varied by 99% of its maximum value (Table 13.3). There was a general decreasing trend until it nearly disappeared in 1984 and 1985. The data suggest that there was gradual colonization of areas that were nearly bare in 1939, possibly because of some disturbance. Regressions of area of Unconsolidated Shore on both monthly and mean annual water level were not significant.

As the regressions on weighted annual mean levels included more and more years prior to the dates of the photographs, the regressions became significant. The results suggested that water levels as early as 22 years prior to the date of the wetland area measurements may have had an influence on the amount of Unconsolidated Shore wetland. The R^2 of the regression reached a maximum of 0.75 with a weighted average that included 22 years of average annual levels prior to

[a] Changes in Hectares

the area measurements (* $P < 0.05$). Like Emergent Wetland and Scrub-Shrub wetland, Unconsolidated Shore decreased with increasing water levels and increased with decreasing water levels.

The transition matrix (Table 13.4) shows that 288 ha of the dramatic loss in area in 1939 went to Unconsolidated Bottom in 1953. This occurred simply because the water levels went up; no vegetation change was necessary. There was also a large loss to Unconsolidated Bottom with the level increase from 1964 to 1978. Table 13.4 also shows significant losses of Unconsolidated Shore to Emergent, Scrub-Shrub, and Upland in the 1939 to 1953 transition. These suggested changes due to succession rather than water level.

Because the largest interchanges were between Unconsolidated Shore and Unconsolidated Bottom, which occurred instantaneously with water level changes, the long lag period shown in the regression analysis does not appear reasonable. The regression correctly shows a reciprocal relationship between area and water level, but succession evidently played a significant role and complicated the water level—area relationship.

Shrub-Scrub Wetland

Scrub-Shrub Wetland area varied by 63 ha, about 16% of its maximum area (Table 13.3). The changes in Scrub-Shrub Wetland were clearly influenced by water level as the regressions of both monthly and annual average water levels on area of Scrub-Shrub were significant (* $P < 0.05$). Scrub-Shrub wetland area, like Emergent and Unconsolidated Shore areas, decreased during higher water levels and increased during lower water levels.

Changes in Scrub-Shrub Wetland area appeared to develop rapidly in response to water level changes. The R^2 reached a maximum with the regression that included only five years of weighted average water levels ($R^2 = 0.86$). The relationship was statistically significant (** $P < 0.01$; Table 13.3). This suggested that it took several years for the St. Marys River Scrub-Shrub Wetland vegetation to complete its expansions and contractions in response to water level changes, possibly not as long as Unconsolidated Bottom or Emergent Wetland.

The transition matrix shows that there were losses to Unconsolidated Bottom during the 1939 to 1953, and 1964 to 1978 water level increases. There were also changes attributable to succession: the 59.3 ha loss to Forested Wetland, the 29.8 ha loss to Upland, and the 64.4 ha gain from Emergent Wetland. The same pattern of losses to Forested Wetland and Upland and gains from Emergent Wetland is found in the 1964 to 1978 transition. Successional processes apparently have a significant effect in the Scrub-Shrub changes.

Forested Wetland

Forested Wetland varied by 104 ha from maximum to minimum area, a change of 37%. The regressions of area on monthly and annual average water levels were not significant.

The R^2s of the regressions using Forested Wetland area on weighted average water levels increased (to 0.64) as yearly average levels were added through 22 years prior to the date of the area measurements. With this lag, the regression was significant (** $P < 0.01$). This suggested that water levels in any given year appeared to have had an effect on area of Forested Wetlands for as many as 22 years after they occurred. The regression was positive, i.e., Forested Wetlands appeared to increase during periods of high water levels.

The latter outcome was not expected because woody vegetation is generally thought to be less tolerant to flooding than herbaceous vegetation (Keddy and Reznicek, 1985). Wetland trees are more tolerant than Upland trees, however. An increase in water levels can indeed result in an increase in the quantity of Forested Wetlands. While standing water or saturated soil will often kill upland trees, many of the facultative wetland plants will, according to their classification, grow in the presence or absence of standing water or saturated soils. Higher water over time will influence the presence of facultative wetland trees, and allow their increased growth as compared to facultative upland trees. The species found near the St. Marys River are typically facultative wetland species. Moreover there is evidence for this from the 8.3 ha change from Upland to Forested Wetland in the 1964 to 1978 transition. It is notable that Forested Wetland areas remained consistent despite higher water levels in 1984 and 1985.

The gains during low to high transitions can also in part be explained by succession. Table 13.4 indicates that the largest gain in the 1939 to 1953 transition is from Scrub-Shrub (59.3 ha), followed by Emergent Wetland (48.9). The same pattern of gains is found in the 1964 to 1978 “high to low” transition; gains are mostly from Scrub-Shrub (11.2 ha) and Emergent Wetland (10.5 ha).

The Forested Wetland changes from 1953 to 1964 were puzzling, however. Indeed, 13.1 ha of 1953 Forested Wetland area came from Upland, and 29.1 ha were lost to Emergent Wetland, the opposite of succession. An explanation may be found in the timing of the large water level

increase in that it was affecting the 1953 wetlands. Figure 13.2 shows that St. Marys River levels were in the third year of a high level spike that lasted four years. That spike could have caused some areas of Upland to change to Forested Wetland and also caused the ultimate loss of some Forested Wetland area to Emergent Wetland and Scrub-Shrub, but not so rapidly as to be visible in the 1953 photographs. The loss may have been either not evident , i.e., the trees were dead but still standing, or the loss may have occurred in the next few years. The successional changes did not show up until after 1953, however.

The regression data for Forested Wetland is at best ambivalent. The transition matrix indicates that Forested Wetland increases occur during transitions from low to high levels as successional processes, i.e., conversion of Emergent Wetland and Scrub-Shrub to Forested Wetland. These are not driven by high water levels, hence the association of larger Forested Wetland areas with higher levels shown in the regression is probably an artifact of the timing of successional processes. Large areas of Emergent Wetland and Scrub-Shrub Wetland were evidently caused by the long period of low water in the 1930s (Figure 13.2). These in part "succeeded" to Forested Wetland despite the high levels in the early 1950s.

DISCUSSION

Because a GIS is a convenient tool for manipulation of mapped data, it simplified development of data sets that could be used in data analysis. Of particular interest in this context was the use of a transition matrix derived from a GIS cross tabulation. The matrix showed interclass transfers from wetland state to wetland state. In this study, the transitions matrix was particularly useful in helping to identify successional effects and distinguish them from water level effects.

If the R-Squares of the regressions were taken as a measure of how much variability in the data is due to the regression, the R-Squares then provided a measure of how much of the variability in each wetland class area was due to changes in water levels. This suggested that virtually most of the variability ($R^2 = 0.99$) in the areas of both Unconsolidated Bottom and Emergent Wetland was due to water level fluctuations. A significant part of the variability in Scrub-Shrub Wetland was also due to level fluctuations in the St. Marys ($R^2 = 0.86$). By statistical measures, there were apparently other important factors affecting Unconsolidated Shore ($R^2 = 0.74$) and Forested Wetland ($R^2 = 0.78$).

The transition matrix was useful in identifying strong evidence of successional trends in these wetland classes by allowing quantification of interclass transfers. The matrix also provided a basis for suggesting that the association found in regression between high water levels and increased Forested Wetland was probably anomalous.

There are several factors that could not be accounted for in this study that may have affected conclusions concerning the wetland class area changes. Accuracy of photo interpretation by the USFWS contractor may have affected data accuracy. There may also have been human influences on area changes. Some of these shores may at one time have been farmed; Forested Wetlands may have regrown in areas previously cut down for agriculture. Filling in some areas was visible from changes in the photographs between 1953 and 1978, causing losses of wetland not due to level fluctuations.

CONCLUSION

Use of GIS and Historical Aerial Photography

Using a GIS for a wetland change detection study proved to have several advantages over manual methods for use of historical photographs, such as mapping and measuring areas with a plane

planimeter and use of overlays. Some of the data in this study could have been derived from the tabular data supplied by the National Wetland Inventory. The tabular data was in effect a National Wetland Inventory GIS product however, and would have been produced from the authors' GIS, had the mapping and digitization not been completed by the National Wetland Inventory.

GIS use allowed creation of mosaics of all study USGS quadrangles, greatly reducing the number of necessary analytic operations. It provided a means of quickly establishing an accurate common area of study for each year of wetland mapping. It provided a means of rapidly aggregating wetland types to convenient wetland classes. It provided an efficient method of measuring historical wetland class changes based on archived aerial photographs. The change measurements could then be used in conjunction with the historical water level data to understand how water level changes affected wetland class changes between 1939 and 1985.

Finally, GIS use allowed rapid development of locational information. Digital maps of areas in which Emergent Wetlands were lost provided information on potential losses besides water levels, such as the proximity of commercial navigation channels. Cross tabulation provided the capability to develop a transition matrix that allowed quantification of class to class changes between wetland states in 1939, 1953, 1964, 1978, 1984, and 1985. These data were particularly useful in confirming expected change patterns and in explaining changes that were not intuitive. Hence this study indicates that GIS and historical aerial photography can be used effectively in tandem to study how water level changes affect wetland class areas. These properties of Great Lakes wetlands are important to know, not only because they provide a better understanding of wetland processes, but also in view of the prospect of Great Lakes water level regulation changes, or the adoption of more extensive regulation of the levels of the Great Lakes and connecting channels.

CHAPTER 14

Watershed-Based Evaluation of Salmon Habitat

Ross S. Lunetta, Brian L. Cosentino, David R. Montgomery,
Eric M. Beamer, and Timothy J. Beechie

INTRODUCTION

Dramatic declines in Pacific Northwest (PNW) salmon stocks have been associated with land-use induced freshwater habitat losses (Nehlsen et al., 1991). Substantial resources are being directed toward the restoration of stream habitats in efforts to maintain and/or restore wild salmon stocks in the PNW, yet there is no common scientific framework for guiding the prioritization of where and how salmon habitat preservation and restoration activities should occur. GIS-based analysis can provide a systematic tool for targeting restoration opportunities by rapidly characterizing potential salmon habitat over large geographic regions and by providing baseline data for development of habitat restoration strategies. When integrated, data on stream channels, riparian habitat, and watershed characteristics provide a powerful tool for the development of watershed restoration and management strategies (Delong and Brusven, 1991).

Previous efforts to prioritize salmon habitat preservation and restoration opportunities on state and federal lands in Oregon (Bradbury et al., 1995) and Washington (Oman and Palensky, 1995) have met with some success, but problems associated with data availability over large geographic regions have limited applications. The objectives of this study were to: (a) develop a rapid, cost-effective, and objective analytical tool to support prioritization of specific subbasins and watersheds for salmon habitat preservation and restoration opportunities; (b) investigate the correspondence between forest seral stage and large woody debris (LWD) recruitment and associated pool-riffle stream bed morphologies; (c) illustrate the creation of integrated baseline data to support watershed analyses and the development of preservation and restoration strategies; and (d) explore the use of such data to facilitate the communication of scientific information to decision-makers and the public.

APPROACH

Classification schemes impose order on a system for some particular purpose. Stream channel classifications, for example, provide a means to evaluate and assess the current condition and potential response of channel systems to disturbance (natural and anthropogenic). Identification of functionally distinct channel types can also target fieldwork on stream reaches of particular interest and provide a reference frame for communication between multidisciplinary groups evaluating habitat conditions. No channel classification is ideal for all purposes, and the approach adopted should reflect the goals to which a classification will be applied. Our project needed to identify the likely location and quality of salmon habitat from existing regional data. Numerous channel classification

systems rely on the integration of physical variables such as channel slope, channel morphology, and channel pattern (Paustian et al., 1992; Montgomery and Buffington, 1993; Rosgen, 1994).

Several existing channel classifications can be applied to PNW streams. Paustian et al. (1992), for example, broadly classify stream channels according to fluvial process groups (i.e., estuarine, palustrine, alluvial fan, etc.). Rosgen (1994) combined channel slope, cross-section morphology, and plan view morphologic attributes to classify stream reaches into general categories. Rosgen (1994) then included channel entrenchment, width to depth ratio, sinuosity, slope, and bed material to further refine stream type categories. Of these attributes only channel slope is readily determined from typical digital data available over broad regions. Moreover, neither approach allows modification of channel type due to the influence of large woody debris contributed from streamside forests, which can be a primary influence on the morphology of stream channels in the Pacific Northwest (Swanson and Lienkaemper, 1978; Keller and Swanson, 1979; Montgomery et al., 1995; Abbe and Montgomery, 1996).

For this study we selected the classification system of Montgomery and Buffington (1993) which broadly stratifies channel morphology and allows for adjustment of channel type due to morphologic influences of LWD, and can be applied over large areas on the basis of correlations with reach average slope. At the reach level of classification, channel morphology is controlled by hydraulic discharge, sediment supply, and external influences such as LWD. The classification identifies distinct alluvial bed morphologies (e.g., pool-riffle, plane-bed, step-pool), and the influence of large woody debris on "forcing" stream morphology is designated by modifiers added to a particular reach label (e.g., forced pool-riffle). These specific channel morphologies can be generalized into source, transport, and response reaches (Montgomery and Buffington, 1993). In mountain drainage basins, source reaches tend to be debris-flow-prone colluvial channels that function as headwater sources of sediment to downstream reaches. Transport reaches tend to be step-pool and cascade morphology reaches that rapidly convey increased sediment loads to lower-gradient downstream channels. Response reaches are pool-riffle and plane-bed channels that can exhibit dramatic morphologic response to increased sediment loads. Channel reach slope (S) generally correlates with reach morphology, particularly at the coarse level distinctions of source ($S \geq 0.20$), transport ($0.04 \leq S < 0.20$), and response reaches ($S < 0.04$).

Among response reaches, several morphologic types may occur. Channels with slopes between 0.001 and 0.01 typically exhibit pool-riffle morphology regardless of LWD loading levels, whereas channels with slopes between 0.01 and 0.02 are LWD dependent: at low LWD loading, these reaches typically have either a pool-riffle or plane-bed (i.e., riffle-dominated) morphology, whereas at higher LWD loading, LWD pieces and LWD jams force the formation of pools, hence the name forced pool-riffle channel. Channels in the 0.02 to 0.04 slope range typically exhibit plane-bed or forced pool-riffle morphologies, depending upon LWD loading (Montgomery and Buffington, 1997). Channels with slopes above 0.04 typically exhibit step-pool or cascade morphologies. Of these channel types, salmonid species appear to strongly prefer pool-riffle and forced pool-riffle channels.

Identification of response reaches provides a simple method for identification of potential salmon habitat, as the zone of anadromous fish use typically is restricted to these low-gradient reaches in Pacific Northwest watersheds (Montgomery, 1994). Also, the age class of streamside forests can indicate the potential for a source of abundant large woody debris to stream channels. Channel slope can be readily determined from digital elevation models. We coupled this coarse slope-based classification of channel types with remote sensing data on the associated seral-stage of the streamside forest to generate a regional GIS-driven classification of potential salmonid habitat locations and quality. This approach, however, simply provides an indication of the likely channel type and a general sense of the likely woody debris loading. Channel slopes determined from digi-

tal elevation models (DEMs) and wood loadings derived from forest seral stage correlations can be misleading due to: (a) poor topographic representation in the DEM at the scale of channels; (b) the natural overlap and range in slope for different channel types; (c) variations in channel type due to local controls; and (d) differences between in-channel LWD loading and riparian forest conditions due to removal of LWD from channels flowing through mid- to late-seral stage forests or clear-cutting of streamside forests without removal of in-channel LWD. In spite of these caveats, the simple classification based on general channel type and riparian forest seral stage provides a direct screening tool for identifying likely sites of low- and high-quality salmon habitat.

We infer that pool abundance correlates with overall habitat quality, and that LWD loading is an important factor in determining habitat quality in response reaches. Assuming that riparian forest conditions correlate with increased LWD loading, it follows that the condition of the adjacent riparian forest would correlate with channel type over the slope range of approximately 0.01 to 0.04, with older forests having higher potential for LWD loading and a higher probability of being forced pool-riffle reaches (high quality habitat). Conversely, reaches with young forests or no forest along the channel have a higher probability of being a plane-bed reach (poor quality habitat).

Application of our results to prioritize specific subbasins and watersheds for salmon habitat protection and restoration efforts is based on three major assumptions: (1) salmon stocks are adapted to local environmental conditions; (2) preservation of "natural" conditions will benefit multiple salmonid species; and (3) a general categorization of channels adequately describes key habitat elements for multiple salmonid species. The first two assumptions are more completely explained by Peterson et al. (1992) and Beechie et al. (1996). The third assumption is supported by limited data showing that several species and life history stages select the same two channel types over others (E. Beamer, unpublished data). These preferences appear to be related to factors such as pool area and depth, cover complexity, and the quality of spawning gravels.

METHODS

Watershed screening was performed at both the subbasin (>450 km^2) and watershed (<260 km^2) scales to identify probable high quality and degraded locations in western Washington State. For the purposes of this study, subbasins correspond to Washington Department of Natural Resources (WDNR) Water Resource Inventory Areas (WRIAs) and watersheds correspond to WDNR Watershed Administrative Units (WAUs). The multiple analytical scales provide comparative evaluations of potential salmon habitat across large geographic regions (e.g., western Washington State) or for evaluations across watersheds within an individual subbasin. Data outputs were summarized by WAU, which typically comprise 120 to 260 km^2. WAUs are subunits within larger subbasins (WRIA) that range from 450 to 6,500 km^2 in western Washington State. The GIS-based predictions of potential habitat locations serve to extend the spatial extent of field observations across the entire study area.

Data Sources

Ideally, all spatial data sources should be derived and used at a scale commensurate with the ecological processes of interest. For this project the appropriate source data scale for watershed analysis and management activities across the western Washington project area is 1:24,000 and larger, to accurately resolve the location of salmonid stream habitat. However, large-scale digital data sets such as vegetation cover and land ownership were not available over the project area. At the expense of spatial resolution, some coarser resolution data sets were used (Table 14.1).

Two sources of digital hydrographic data were available: (1) the U.S. Environmental Protection

Table 14.1. Study Data Sets and Corresponding Scale, Formats, and Source Description

Data	Scale	Format	Description
DEM	1:24,000	raster	7.5-minute; 30-meter cell; Levels 1 & 2.
Hydrography	1:24,000	vector	Compiled from USGS 7.5-minute quads & aerial photography.
Transportation	1:24,000	vector	Compiled from USGS 7.5-minute quads & aerial photography.
WAU Boundaries	1:100,000	vector	Variable accuracy due to multiple regional mapping efforts.
WRIA Boundaries	1:24,000 1:62,500	vector	Boundaries developed by state natural resource agencies in cooperation with the USGS.
Forest Vegetation Seral Stage	~1:100,000	vector/ raster	Landsat Thematic Mapper (TM)-derived forest cover.
Land Use/Land Cover	1:250,000	raster	Non-forested lands (ag./urban/etc.) from USGS Land Use/Land Cover.
Validation Data	1:24,000 1:12,000	Hard copy map/pt. data and tabular data.	Field observations.
Land Ownership	1:100,000	vector	Public land ownership.
Landsat TM	~1:100,000	raster	Terrain-corrected imagery ± 15 meters.

Agency's (EPA's) 1:100,000 scale "river reach files"; and (2) 1:24,000 scale hydrography provided by the WDNR. The river reach files have the advantage of unique identifiers for all stream reach locations. Nonetheless, superior mapping resolution associated with the 1:24,000 scale hydrography data was considered a better match for the needs of this study because most field observations and stream habitat measurements were recorded at scales of 1:24,000 and larger, and absolute stream orientation was critical for subsequent spatial data analyses across multiple thematic data layers.

The only available data source for hydrologic unit delineations at both the subbasin and watershed scales for western Washington State was the WRIA and WAU coverages. WRIA boundaries were compiled from 1:24,000 to 1:62,500 scale maps and WAUs were generally compiled at 1:100,000 scale (WDNR, 1988, 1993). Incongruities between the WAU boundary delineations and the larger scale hydrography were common. For example, along wide river main stems, WAU boundaries were not always in agreement with river main stems, especially as river shape became more sinuous in the 1:24,000 scale hydrography data.

Total road length and road density were important attributes used in the assessment of potential habitat quality at the WAU scale of analysis. Transportation data were available for the project area at 1:100,000 and 1:24,000 scales. The 1:24,000 scale data provided the most complete depiction of primary, secondary, and logging roads.

Available source scales for digital elevation data of western Washington were the 1-degree or three arc-second (~85 meter) data and the 7.5 minute (30 meter) DEM data constructed from 1:24,000 scale maps. Given the need to assess channel slope as accurately as possible for this project, the larger scale data provided the best estimate of stream slope over relatively short stream reaches. The slopes of stream arcs were measured over an arc distance of 150 meters. For this purpose, the 30-meter cell size of the 1:24,000 scale elevation models provided superior topographic resolution.

Table 14.2. Study Land Cover Categories Derived from Landsat 5 Thematic Mapper (TM) Data (PMR, 1993; WDNR, 1994)

Class 1
Late Seral Stage
Coniferous crown cover greater than 70%.
More than 10% crown cover in trees greater than or equal to 21 inches diameter breast height (dbh).
Class 2
Mid-Seral Stage
Coniferous crown cover greater than 70%.
Less than 10% crown cover in trees greater than or equal to 21 inches dbh.
Class 3
Early Seral Stage
Coniferous crown cover greater than or equal to 10% and less than 70%.
Less than 75% of total crown cover in hardwood tree/shrub cover.
Class 4
Other Lands in Forested Areas
Less than 10% coniferous crown cover (can contain hardwood tree/shrub cover; cleared forest land, etc.).
Class 5
Surface Water
Lakes, large rivers, and other water bodies.
Class 15
Nonforest Lands
Urban, agriculture, rangeland, barren, glaciers.

Note:
(1) Forest cover derived from Landsat Thematic Mapper™ satellite imagery.
(2) Class 5 derived from Landsat™ and 1:250,000-scale USGS Land Use/Land Cover data.
(3) Class 15 derived from 1:250,000-scale USGS Land Use/Land Cover data.

Forest cover data were originally derived from 1988 Landsat 5 TM data (PMR, 1993) and updated with 1991 and 1993 TM data using image differencing followed by level slicing to identify new clear-cuts (Collins, 1996). The nominal data resolution of 30 meters was interpolated to 25 meters during the terrain correction process. Standard digital image interpretation techniques were then applied to generate the forest cover data (PMR, 1993). Forest cover was broadly categorized into four classes based on forest type and age class (Table 14.2). The overall thematic accuracy of the 1988 TM-based land cover categorization was 92% (PMR, 1993).

The nonforest land cover and most surface water features were derived from 1:250,000 scale U.S. Geological Survey land cover/use data. The data were overlaid on the forest cover classification to discriminate nonforest lands, such as agriculture and urban areas, from forest lands (PMR, 1993). Thus, the final land cover layer contained a mixture of source scales ranging from approximately 1:100,000 to 1:250,000.

Field data used to validate stream channel type prediction were provided as part of an ongoing salmon habitat inventory and management effort. Inventory efforts focused primarily on streams with relatively low channel slopes (<4.0%) and were compiled on 1:12,000 scale orthophotos. Channel slope data were collected using either transit, hand level, or clinometer measurements.

Data Quality and Error Propagation

Errors associated with remote sensing and GIS data acquisition, processing, analysis, data conversion(s), and final data presentation can significantly impact the confidence associated with resultant products and thus influence their utility in the decision-making process. It was not feasible within the scope of this project to explicitly measure discrete error sources and calculate an error propagation budget. Thus, channel type prediction was the only accuracy assessment performed. Channel type accuracy reflects key input data limitations and processing errors. The final GIS data products may give the appearance of uniform thematic accuracy; however, there may be significant variability across specific geographic locations based on the least accurate input data source (Lunetta et al., 1991).

Spatial Data Preprocessing

Data Format Conversions

Data conversion from vector to raster can cause undesirable shifts of objects in the output raster data as well as changes in area and shape (Congalton and Schallert, 1992). This error source was minimized as much as possible by maintaining data in their native format and thus performing limited data conversions. Raster to vector conversions were not performed as part of the project; however, the forest cover data, originally processed from Landsat TM digital imagery were converted to a vector representation prior to processing (PMR, 1993). Also, all single line hydrographic arcs underwent vector to raster conversion to optimize stream buffer calculations (see Stream Buffer Vegetation Tabulation).

Data Generalization

With the exception of the land cover layer, most data sources were not generalized. The Nonforest (class 15) and Surface Water (class 5) classes listed in Table 14.2 were originally compiled under USGS mapping guidelines. The land use and land cover data were interpreted from aerial photography at a scale of 1:60,000 or larger and compiled on 1:250,000 scale topographic maps (USDI, 1993). The guidelines specify a 4.0 hectare minimum mapping unit for urban/built-up lands, surface water, and some agricultural areas. The minimum mapping unit for cropland, pasture, and barren lands is 16.2 hectares. As noted above, the nonforest and surface water data were overlaid on the seral stage coverage to create a combined land cover layer. This layer was subsequently converted to vector format.

Prior to conversion of the land cover data to vector format, a filtering procedure was performed on the raster data coverage to merge polygons smaller than nine pixels into adjacent polygons using a simple majority rule decision criteria. Subsequently, vector polygons smaller than the minimum mapping unit size of 2.0 or 4.0 hectares (depending on adjacent land cover type) were removed (PMR, 1993). Thus, stream bank forest land cover was not accurately represented for patch sizes of less than 4.0 hectares.

Geometric Rectification

GIS processing of multiple data layers requires that all layers reside in a common map projection. A common projection was determined prior to processing based upon possible error sources and processing efficiency. Because project outputs were assumed to be most sensitive to elevation errors, the DEM data were maintained in their native Universal Transverse Mercator (UTM) projection. Changing their projection would have introduced additional error and increased data pro-

cessing time due to interpolation of cell values as both the DEM and vector land cover data existed in UTM space. Therefore all input data not in UTM space were projected to the UTM space of the DEMs and land cover data.

DEM Processing

ARC/GRID analytical routines were used to mosaic 7.5-minute DEMs for each WRIA. Once a grid was created for a WRIA, it was next processed to remove "sinks" (sinks are cells with an undefined flow direction). The processed DEM was then used in stream channel slope calculations. Additional DEM processing was performed to create a slope grid for each WRIA for use in summary statistics compilation. The slope grid was then recoded into three landscape slope classes: (a) Class 1, 0–29%; (b) Class 2, 30–65%; and (c) Class 3, greater than 65%.

Preparation of Hydrography

The 1:24,000 scale hydrography data, originally tiled by township, were appended and clipped to the respective WRIA boundary. Stream direction was set to point upstream. Stream percent slope was then computed from DEM values for each arc. Start and end elevation and slope were written to the hydrography coverage arc attribute table.

Forest Seral Stage

This coverage was checked for positional errors and logical consistency by overlaying it with the ancillary geocoded TM data to serve as a base map. The absolute positional accuracy of the TM base map was plus or minus 15 meters (Table 14.1). If positional errors were found, then a simple x,y shift was performed to improve geometric fidelity. Thematic inconsistencies between the vegetation layer and the TM data were not reviewed. Ideally, obvious errors, such as urban encroachment on forest lands, would have been corrected through editing procedures using the TM data as a validation data source. However, resource limitations precluded the inclusion of such editing.

Spatial Data Analysis

Each WRIA was processed individually using identical protocols. The first step was to compile all data inputs for processing, followed by creation of summary data statistics, hard copy maps, and graphics. Summary statistics and data graphics were generated for both the WRIA and WAU hydrographic units. Additionally, validation procedures were performed using data from nine WAUs (Bacon Creek, Illabot, Jackman, Nookachamps, Finney, Hansen Creek, Gilligan, Mt. Baker, and Alder) located within the Upper and Lower Skagit River WRIAs. The categorization of stream channel types was accomplished using an automated procedure to calculate slope for individual stream reaches.

The sampling procedure was initiated at the low elevation end of the arc, and measured upstream the specified sampling distance of 150 meters. If a slope less than 4% was found over the sample distance, then the arc ID number and UTM coordinate at the end of the sample distance were stored in a file. Upon locating a slope less than four percent, the procedure then moved upstream along the arc another sample distance and measures the slope. The process was repeated if a slope less than 4% was found, otherwise the remainder of the current arc was abandoned and the next one is sampled. Stream segments listed in the output file were then split at the specified UTM coordinates using an automated editing procedure. After the editing procedure, the updated slope and elevation values were written to the edited hydrography coverage.

Stream Buffer Vegetation Tabulation

A 30-meter raster stream buffer was generated along both sides of single-arc streams in the hydrographic data layer. The actual cell size implemented to model stream buffers was six meters; thus, the width of each buffer was modeled with five six-meter cells. Each raster buffer was indexed to the vector hydrography line coverage and the percentage of each land cover category (Table 14.2) was written to its respective arc in the arc attribute table. Raster procedures were incorporated to speed up the buffer processing time through the use of rapid cross tabulation procedures between the buffer areas and the raster vegetation layer. For wider streams and rivers which are depicted with double arcs, buffers were extended from each bank, and vector processing procedures were used to summarize vegetation within each stream buffer. Statistics were then generated from the buffer summary tables for each arc.

Summary Reports

WRIA summary reports were organized by WAU and list attributes for streams, vegetation, roads, slope, and land ownership (Table 14.3). Map and bar chart plot files produced from WRIA coverages and summary table attributes were used to plot graphical aids for watershed assessment teams. WRIA maps can be generated on a large format plotter to depict the following themes: (a) response, transport, and source channel types; (b) vegetation classes; (c) transportation networks; (d) slopes; (e) land ownership; and (f) WRIA and WAU boundaries.

Validation of Stream Channel Type Predictions

Validation was performed by comparing field observations with GIS-generated channel type predictions (Lunetta et al., 2001). Field assessment data were provided to the project for the nine Lower and Upper Skagit River WAUs previously listed. The length of the sample reaches generally ranged from 100 to 300 meters, and the midpoint of each reach was delineated on a topographic map. The comparison was accomplished through creation of an error matrix for each WAU (Story and Congalton, 1986). A Kappa coefficient was calculated using discrete multivariate statistical techniques as a measure of the overall agreement between the stream channel type predictions and field observations (indicated as the major diagonal) versus agreement that is contributed by chance (Congalton et al., 1983). The Kappa coefficient was calculated based on the formula given by Hudson and Ramm (1987).

RESULTS

Of the 164,083 km of stream reaches analyzed, 23.2% (38,002 km) were categorized as response reaches (≤4.0% slope), of which, 8.7% (3,302 km) were associated with late seral and 20.7%(7,867 km) with mid-seral stage forest stream vegetation.

Table 14.3. WRIA Summary Report Attributes, Extent, and Description

Attribute	Extent	Description
Streams	WRIA/WAU	Total kilometers and stream density. Stream density and percent by predicted channel reach type.
Seral Stage	WRIA/WAU/Stream buffer	Hectares and percents.
Slope	WRIA/WAU	Hectares and percent of landscape slope in three classes.
Roads	WRIA/WAU	Total kilometers and road density.

Hydrographic Data Scale

Figure 14.1 (a,b, see color section), clearly illustrates the deficiencies of the 1:100,000 scale hydrography stream network (compared to the 1:24,000 scale product) for depicting the actual stream channel network. In the Finney Creek WAU, a total of 490.1 km of stream length are contained in the 1:24,000 scale hydrography compared to 94.8 km in the 1:100,000 scale product. More importantly, the results of the response reach analyses indicate a significant underestimate of response reaches associated with 1:100,000 scale coverage compared to the 1:24,000 scale (43.0 km and 64.9 km, respectively). The smaller scale EPA hydrographic data in addition to lacking resolution in the number of streams, was also deficient in absolute stream orientation detail.

Stream Slope Sampling

Results of the stream slope sampling procedure are presented in Figure 14.2. The optimal sample length corresponds to the maximum stream arc sampling distance that provides the maximum response reach length. Seven sample distances (100, 125, 150, 175, 200, 225, and 300 meters) were evaluated for each of three WRIAs (Figure 14.2) which represented a broad range of physiographic conditions present throughout western Washington State (Lower Skagit, Willapa River, and Lyre-Hoko). The objective was to determine the maximum effective distance to minimize computational requirements, where 100 meters is the minimum feasible sampling length. Sample length must be sufficiently long to capture the inherent variation of the DEM. Short sample distances are ineffective because the elevation change over the sample length is often very low or zero, and exceedingly long sample lengths tend to mask slope changes.

The stream slope sampling procedure enhanced the detection of response reaches located between stream confluences and the base of steep mountain slopes and identified additional response

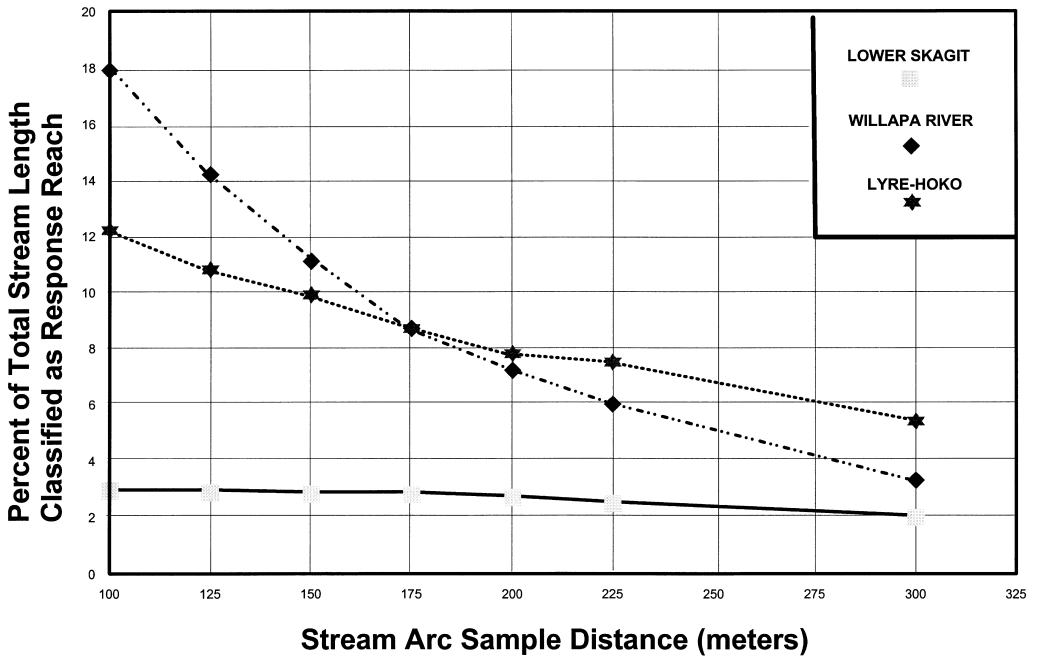

Figure 14.2. Plot of length of predicted response reaches versus sample arc distance as calculated for the Lower Skagit, Willapa River, and Lyre-Hoko WRIAs.

reaches within relatively long stream lengths in moderate terrain. Evaluation of the sample distances indicates that a distance of 100 meters, the shortest distance tested, generated the greatest response length for all WRIAs. As shown for the Willapa WAU (Figure 14.2), the total length of predicted response reaches tends to decrease rapidly as sample length increases from 100 meters to 175 meters, then declines more gradually to 300 meters. The Lyre-Hoko's decline was more gradual than the Willapa, whereas the Lower Skagit was only slightly sensitive to sampling distance. Variations in sampling distance appear to have the greatest effect in locations with moderate to steep terrain. For example, 81% of the landscape of the Lower Skagit WRIA had a slope less than 30 percent; the percentage of area within the Willapa and Lyre-Hoka WRIAs with a landscape slope less than 30% was 75 and 57%, respectively. It appears that hydrologic units with moderate to steep terrain experience the greatest relative increase in response length with decreased sampling distance. Although a l00-meter sample distance maximizes the length of response reaches, a sample distance of 150 meters was applied to minimize errors of commission, and simultaneously reduce processing time and data volume.

Stream Bed Morphology

Field observation data were collected from a total of 120 response reach stream segments in both the Lower and Upper Skagit WRIAs to examine the association between stream buffer zone vegetative land cover and stream bed morphology (Table 14.4). Results indicate that late seral stage forests are associated with forced pool-riffle stream bed morphology. However, the small number of samples (n=8), precludes the drawing of any final conclusions. Response reach buffer zones containing any type of forested land cover had a 77% correspondence to forced pool-riffle stream bed morphology. Nonforested buffer zones were associated with forced pool-riffle morphologies in 35% of the field observations.

Habitat Evaluation

Results applicable to the evaluation of salmon habitat in western Washington State are illustrated in Figure 14.3 (a,b, see color section). The summary bar chart generated for each WRIA and WAU provides a means of comparing potential salmon habitat conditions across WRIAs and to support intra-WRIA assessments. The summary table data for an entire WRIA and individual WAUs include the following information categories: (a) vegetation percent by class; (b) vegetation percent by class within response channel buffers; (c) response, transport, and source channel density; (d) road density; and (e) landscape slope. Summary graphics include drainage density by

Table 14.4. Correspondence between Response Reach Land Cover Categories versus Stream Bed Morphology

Response Reach Land Cover Categories[a]	Percent Reaches Classified as Forced Pool-Riffle
Late Seral Stage	100% (n = 8)
Mid-Seral Stage	78% (n = 18)
Early Seral Stage Other Forest	74% (n = 68)
Non-Forest	35% (n = 26)

[a] observations made along 30m buffers along each bank

channel type and forest seral stage coverage expressed as a percent of total watershed and percent area within buffers around response reaches. These data can facilitate the rapid inference of general streamside conditions and potential for LWD recruitment. In addition, road density and slope data provide some insight to the potential for sedimentation impacts within a given hydrologic unit.

In western Washington more than one-fourth of WRIAs have no late seral stage forest bordering response reaches, and 73% of WRIAs have late seral stage forests along 10% or less of the total response reach length (Figures 14.4 and 14.5). These areas tend to be associated with urban, agricultural or commercial forest land use. Only three WRIAs have more than 20% of their response reach length bordered by late seral stage forests. And these lie partially within national parks or wilderness areas. Overall, only 8.7% of response reaches flow through late seral stage forests. This provides the first quantitative regional characterization of the extent of habitat modifications that accompanied urbanization, agricultural development, and industrial forestry.

Within the Upper Skagit River basin, approximately one-tenth of WAUs had late seral stage forests bordering 10% or less of the total response reach length (Figures 14.6 and 14.7). However, 43% of WAUs had late seral stage forests along 50% or greater of the total response reach length. Of the 20 WAUs identified with late seral stage forests along 25% or greater of total response reach length (highest quality WAUs), eight (40%) were above major dams (Figure 14.7). As in the province scale assessment, land uses in the WAUs with low percent late seral stage tend to be dominated by agricultural and urban development, although some of these WAUs were predominantly industrial forests. WAUs with high percent late seral stage tended to be largely within the boundaries of national parks, national recreation or wilderness areas.

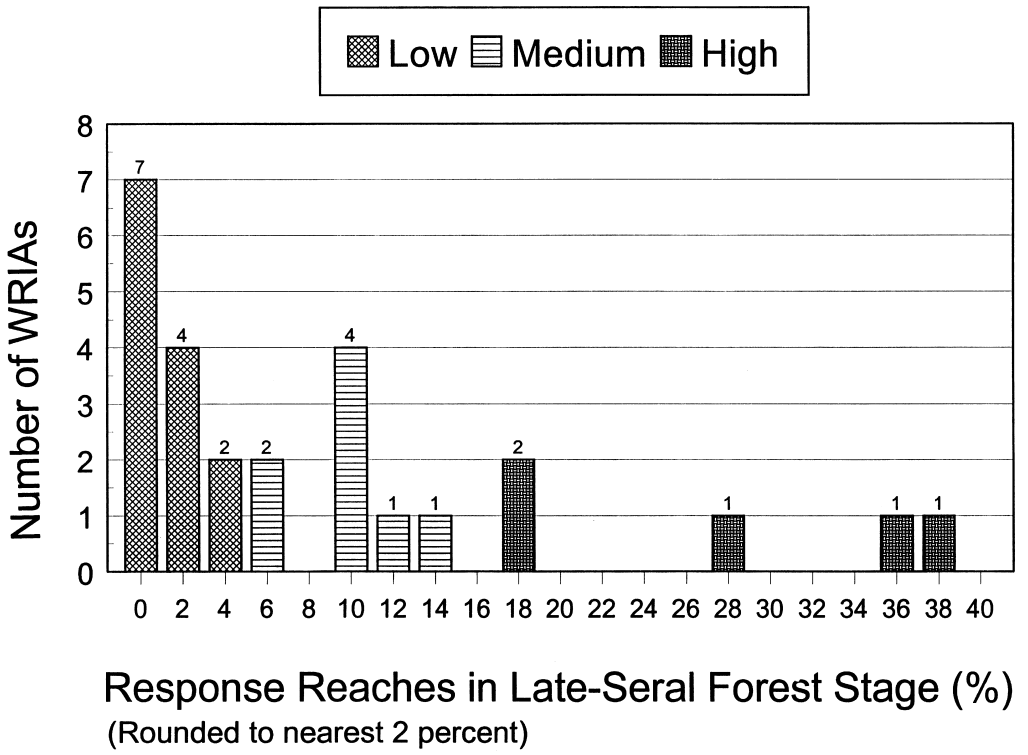

Figure 14.4. Frequency distribution of percent WRIA response reaches in late seral forest stages for western Washington State.

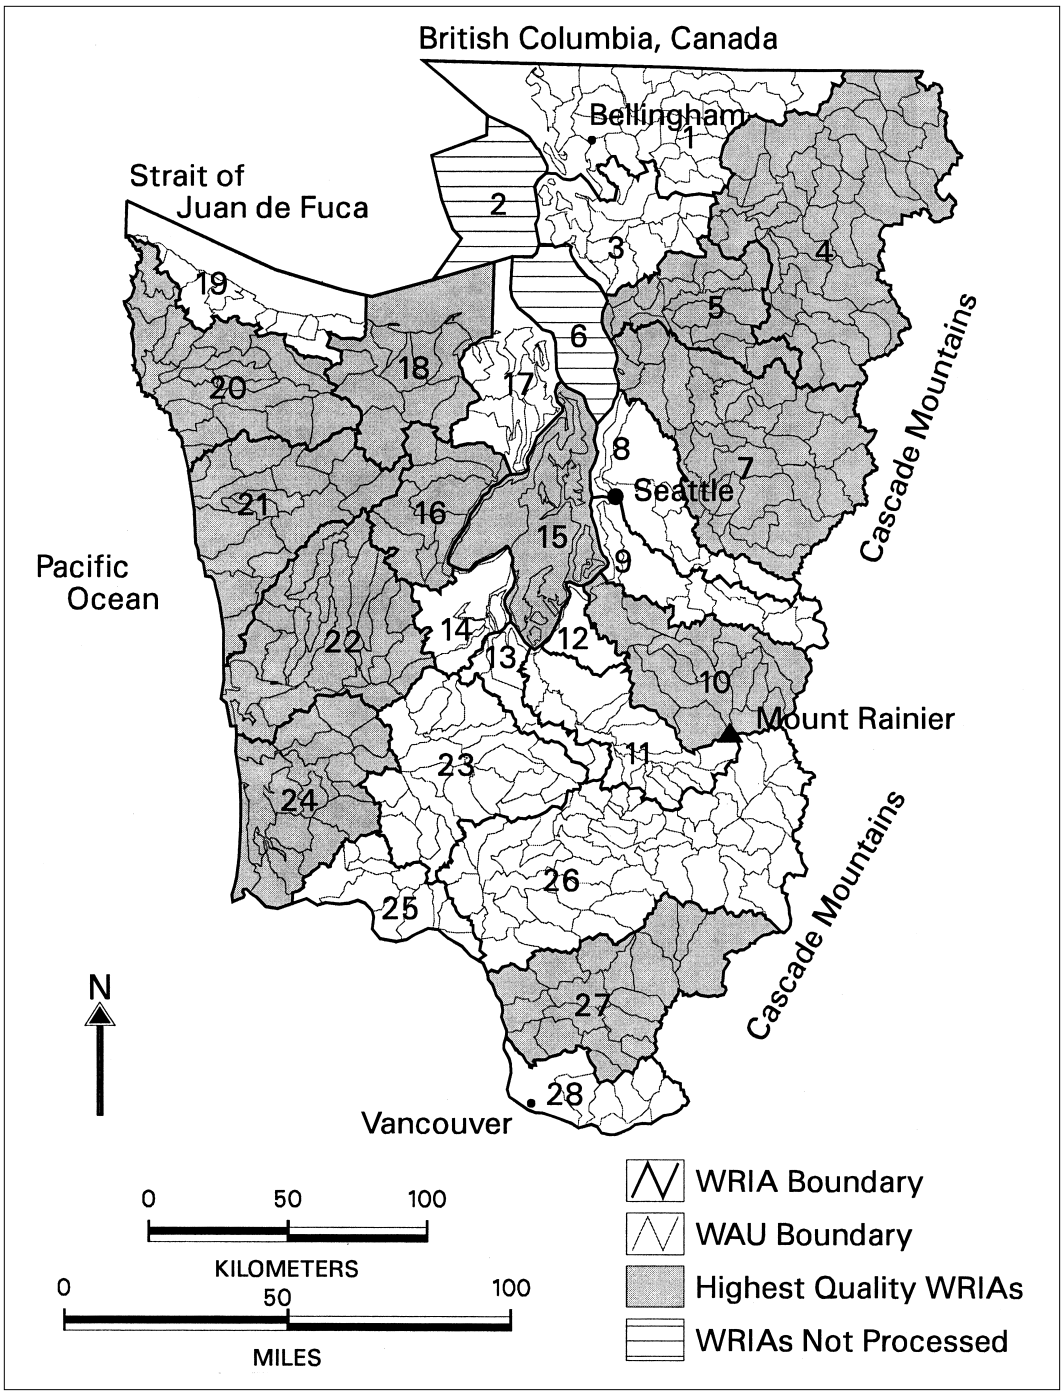

Figure 14.5. Identification and location of the highest quality WRIAs in western Washington State. Note that WRIAs 2 and 6 were not processed because they contain only islands.

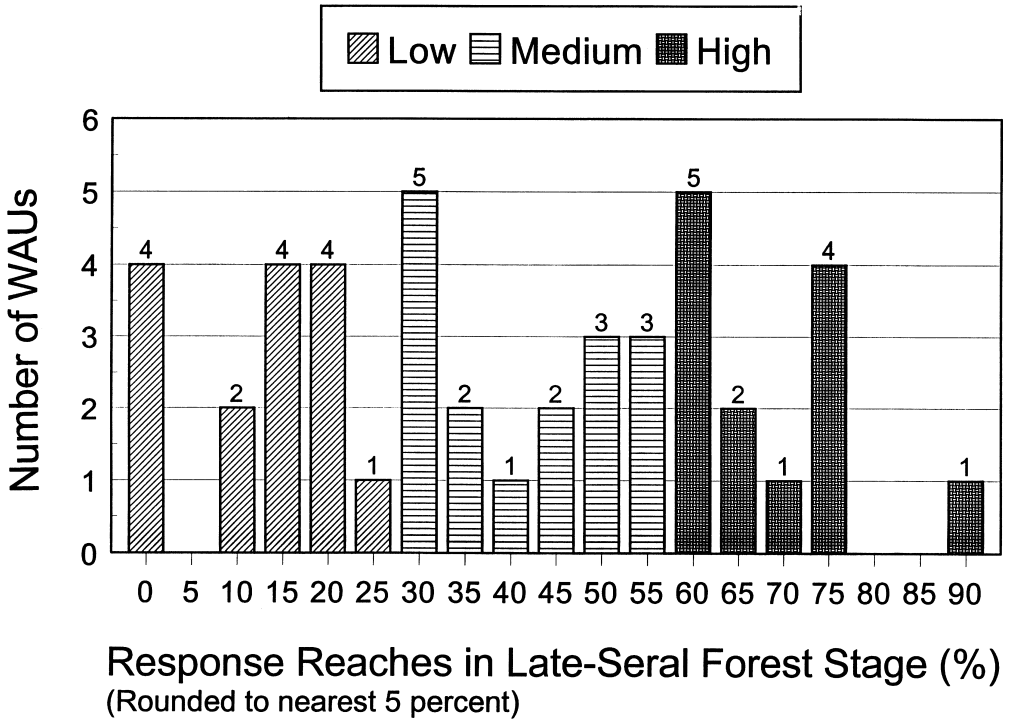

Figure 14.6. Frequency distribution of percent Upper Skagit WAU response reaches in late seral forest stage.

Accuracy Assessment

Although validation was limited to nine WAUs, the basic relationships between physical processes and stream habitat are thought to be consistent across the study area, and the validation for those nine watersheds should be representative for western Washington State. The results of the validation are presented in an error matrix (Table 14.5). The identification of response reaches was 96% accurate, and the overall accuracy of all channel type predictions was 79%, Kappa statistic = 0.64 (n=158). Errors of omission and commission associated with predicted response reaches were 24.0% and 4.0%, respectively. As mentioned above, the use of the 150-meter arc sampling distance tended to minimize commission errors while increasing errors of omission between response and transport channel types. In theory these omission errors could be reduced by using a 100 meter arc sampling distance, but commission errors would likely increase. However, the ultimate limiting factor is the resolution and quality of the DEM data.

DISCUSSION

The intent of this effort was to produce a regionally consistent information base that federal agencies could use for planning or prioritizing salmonid habitat restoration opportunities in the PNW. Our analyses were based on simple concepts that are consistent with our understanding of habitat-forming processes in western Washington State. These are: (a) channel slope largely determines the range of potential channel morphologies; (b) large woody debris abundance modifies within channel type morphology; and (c) salmonid habitat utilization increases with increased

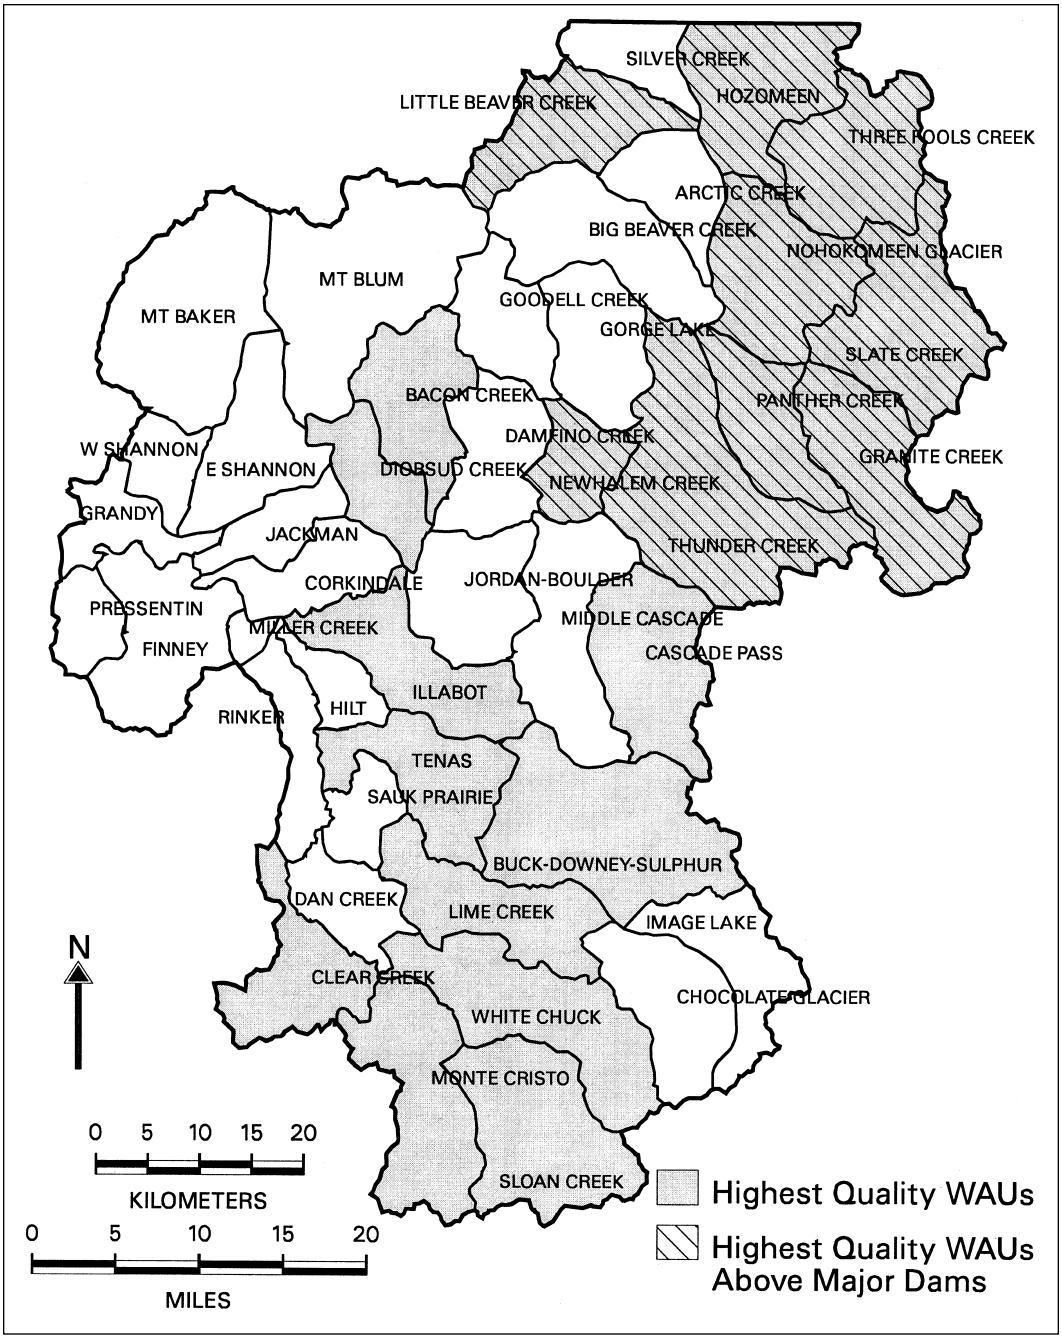

Figure 14.7. Identification and location of the highest quality WAUs in the Upper Skagit WRIA.

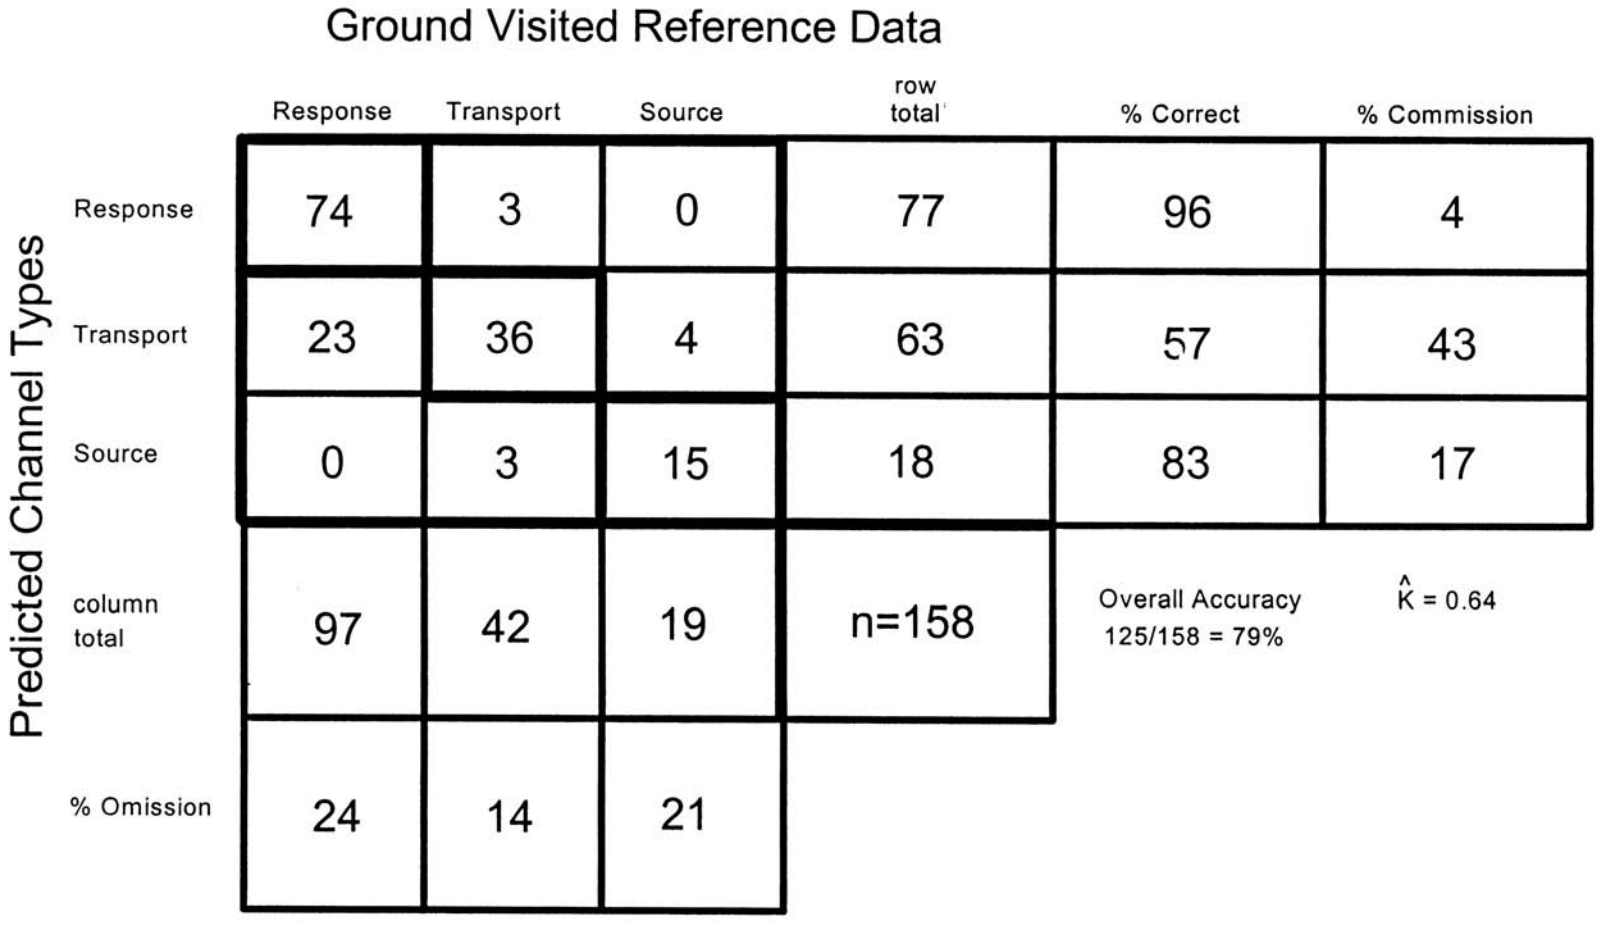
LWD abundance in the response reach channel type. We also presumed that large conifer riparian forests tend to be associated with greater LWD abundance than open or early seral stage riparian areas. Hence, the fundamentally important outputs of our analyses are the extent and location of response reaches (slope <0.04) and the condition of riparian forests along response reaches. The extent and location of response reaches identifies areas that may provide suitable habitat for

Table 14.5. Error Matrix Comparing Ground Visited Reference Data to the Predicted Stream Reach Data



salmonids, and riparian forest conditions indicate the likelihood that those reaches have the forced pool-riffle morphology that salmonids favor.

Our accuracy assessment generally supports the assumptions listed above. However, users of such data should be aware that, while the model typically underrepresents the extent of response reaches, areas identified as response reaches are likely to be correct. Field efforts designed to more accurately identify locations of potential salmonid habitat should therefore focus on areas identified as transport reaches. Field data suggest that those response reaches incorrectly identified as transport reaches are often located where tributary channels enter the valleys of larger channels.

The analyses were less accurate at predicting channel morphology within response reaches, although results generally support the hypothesis that increased forest age is associated with increased LWD abundance. Also, we found little difference in the proportion of forced pool-riffle channels between early and mid-forest seral stages. Histograms of GIS-generated data provide a broad-brush description of channel and riparian conditions at scales that are useful to managers with statewide or regional jurisdiction (Figure 14.4). These data provide a crude but comprehensive characterization of landscape and stream channel attributes that influence the abundance and condition of salmonid habitats.

A qualitative comparison between the preceding results and a field-based assessment of habitat losses in the Skagit River basin reveals that our GIS-based predictions are generally consistent with field data collected independently of this study. Based on the results of our analysis, we predict that the greatest habitat losses have occurred in the Skagit river floodplain and delta where little late seral stage forest remains. Beechie et al. (1994) found that by far the greatest proportion (73%) of coho salmon-rearing habitat losses were associated with diking, ditching, and dredging in the floodplain, and that these losses were associated primarily with urban and agricultural land uses. Hence, our GIS-based results at least grossly predict the same result as a field-based assessment.

Beechie et al. (1994) further noted that industrial forestry had less impact on coho-rearing habitat losses at the river basin scale, but was nevertheless strongly associated with habitat losses in tributary streams (channel widths <10 meters). Thus, forestry was associated with less severe impacts to coho salmon-rearing habitat than were urban and agricultural uses. Our results are also consistent with this relative ranking of severity of impact by type of land use. We show no late seral stage forest in WAUs where nonforest land uses dominated response reach zones, suggesting that the most severe impacts to habitat would be located in those WAUs. By contrast, we found a broader range of percent late seral stage in WAUs where forestry borders the majority of response reaches, indicating that impacts to rearing habitat should be less severe in those WAUs.

Although not all response reaches were bordered by late seral stage forest prior to European settlement, our results suggest a dramatic change in riparian conditions during the last 100 to 200 years. Prior to European settlement, forest fires, floods, and channel migration were dominant influences on stand ages and types near streams (e.g., Agee, 1988). Certainly these processes would create in a patchwork of stands along channel networks, resulting in a range of forest types and seral stages along response reaches. Our data for WAUs contained partially or fully within national parks and wilderness areas give some indication of this patchwork (Figure 14.8). The median percentage of response reaches in late seral stage WAUs located substantially in park and wilderness areas was 54%. This compares to 22% for commercial forestry, and <10% for urban-agriculture land uses. We caution, however, that the percentages shown in Figure 14.8A should not be construed as representative of "natural" conditions because many WAUs contain significant amounts of development.

In addition to a relative ranking, the data distributions can provide useful information for the development of preservation and/or restoration prescriptions. For example, some WRIAs have a

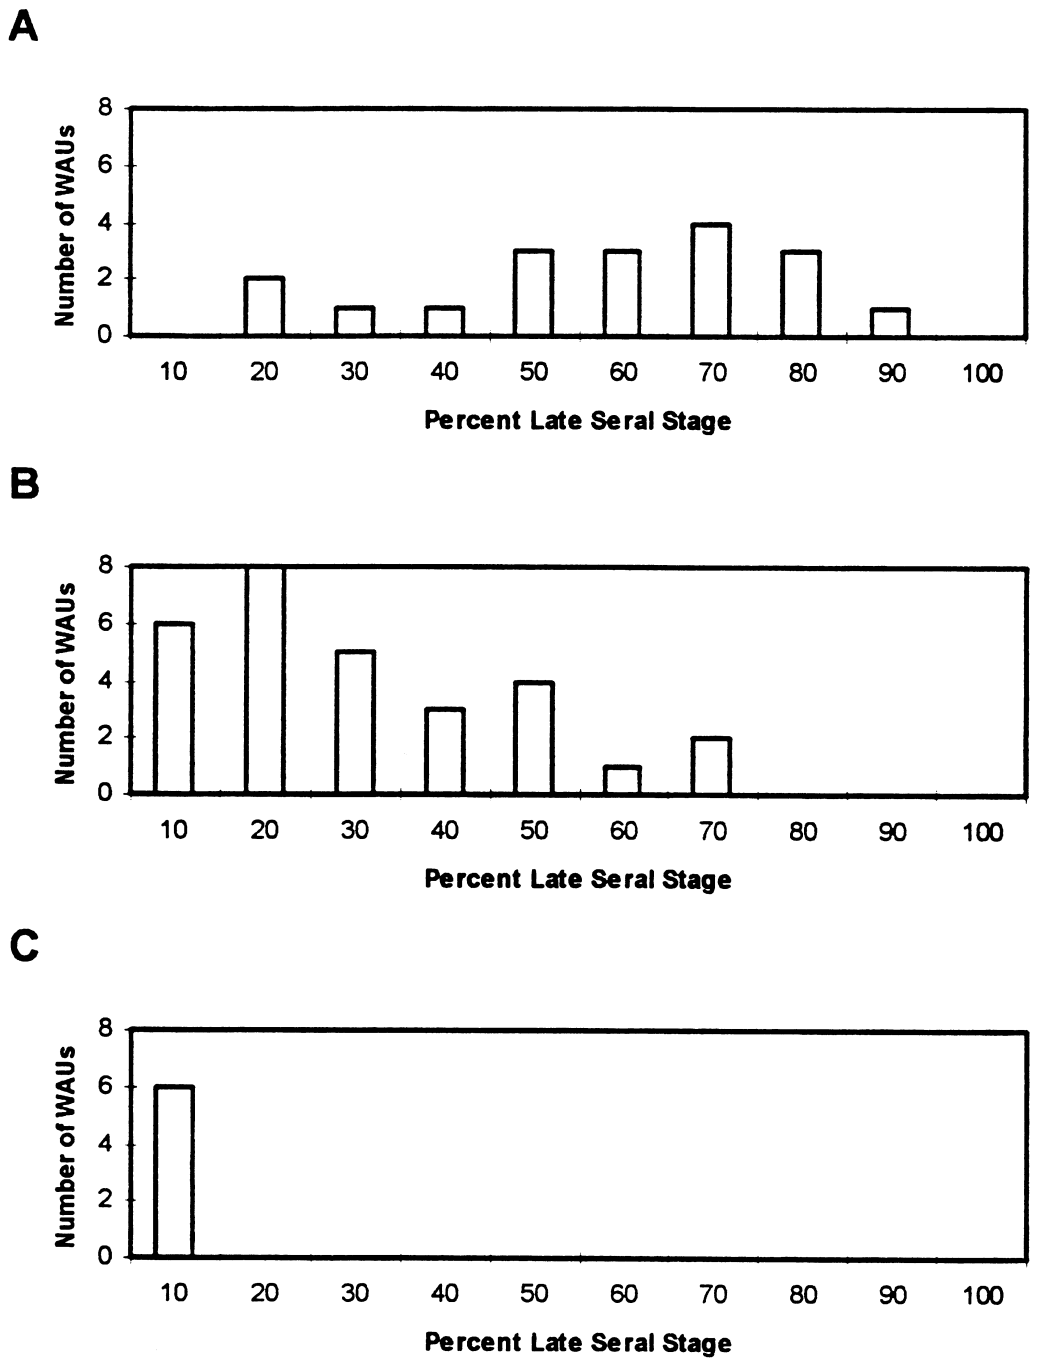


Figure 14.8. Frequency distribution of percent late seral stage along response reaches in WAUs dominated by (a) park and wilderness, (b) commercial forestry, and (c) urban-agriculture land uses.

relatively low percentage of response reaches in the late-seral forests, but a high percentage in mid-seral forests. A rational restoration consideration for these WRIAs may be the preservation of existing mid-seral forests in WAUs with a high density of response reaches. However, use of these analytical tools for identifying tasks or priorities for salmon habitat preservation and restoration can only be accomplished through a process that includes involvement of experts with knowledge of in situ habitat conditions. With the proper expertise and selected ancillary data (e.g., physical barriers to fish migration), map products identifying specific attributes of WRIAs and WAUs could provide a valuable data source to help prioritize the expenditure of preservation and restoration resources.

CONCLUSIONS

Our efforts demonstrate that remote sensing data and GIS methods can be applied to assess landscape attributes that influence the condition of salmon habitat at subbasin to watershed scales. GIS-based analytical products can be used to predict the locations of response reaches likely to provide salmon habitat. By using GIS buffering procedures along response reaches, the likelihood of finding a forced pool-riffle morphology based on the adjacent stream bank vegetation associations can be estimated. Both types of predictions have quantifiable error rates. These products could be used to target reaches where predictions are poor (e.g., the 23% of reaches predicted to be transport reaches that were response reaches), thereby increasing the efficiency of field efforts. Furthermore, such products can rapidly identify the quantity, extent, and condition of habitats at a scale useful for prioritizing regional protection or restoration efforts. We believe that such a wide-area, uniform database (uniform map themes and uniform coordinate system) can complement existing watershed screening protocols and help accomplish prioritization more rapidly and with greater reliability and objectivity.

SUMMARY

Categorization of 164,083 kilometers of stream length has provided the first quantitative measure of the extent and location of potential salmon stream habitat throughout western Washington State. Reach slope and forest seral stage provided a coarse indicator of channel condition across the region. Reach-average slopes calculated for individual stream reaches using 30-meter digital elevation model (DEM) data correctly identified low-gradient (<4.0% slope) response reaches that typically provide habitat for anadromous salmon with an accuracy of 96% (omission and commission error rates of 24.0 and 4.0%, respectively). Almost one-quarter (23.2%) of all stream length categorized consisted of response reaches, of which, only 8.7% were associated with late seral and 20.7% with mid-seral forest stages. Approximately 70% of the total stream length potentially providing anadromous salmon habitat is associated with nonforested and early-seral stage forests. GIS-based analytical techniques provided a rapid, objective, and cost-effective tool to assist in prioritizing locations of salmon habitat preservation and restoration efforts in the Pacific Northwest.

CHAPTER 15

Physical Characterization of the Navarro Watershed for Hydrologic Simulation

Jeffrey D. Colby

INTRODUCTION

The Navarro watershed is an important natural resource in Costa Rica (Figure 15.1). The watershed is located at the headwaters of the Reventazón River basin, which may have the greatest hydropower potential of any drainage unit in the country (Quesada, 1979). High sediment loads and streamflow variability affect the proximate Cachí Reservoir (Quesada, 1979; Jansson and Rodriguez, 1992) and additional planned hydroelectric projects. Due to rich volcanic soils, the watershed is an important producer of agricultural products for the country (Cortés and Oconitrillo, 1987). In addition, groundwater is an important water supply source within the watershed.

The city of Cartago is located in the watershed and is part of the Gran Area Metropolitana (GAM). The GAM is the primary population center of the country, and increasing population growth raises important environmental issues (Monzón, 1993). For example, the effects of urban fringe growth on water resources is a concern of the Programa Nacional de Desarrollo Urbano Sostenible (PRODUS).

The 279 km^2 Navarro watershed is one of two located at the headwaters of the Reventazón River basin. The watershed exhibits diverse topography, and particularly dramatic relief (Figure 15.2). The elevation ranges from approximately 3300 m near the summit of the Irazú volcano to 1029 m at the La Troya streamflow gauge.

Management of surface and subsurface water in the Navarro watershed is important for hydroelectric power production and water supply maintenance. Simulating the hydrologic response of the watershed using spatially distributed characteristics could provide a valuable tool for hydrologic research and watershed management. This chapter will describe the physical characterization of the Navarro watershed using geographic information technologies and data to enhance distributed hydrologic modeling efforts. In particular, the processing of digital elevation data will be described.

The hydrologic model used to simulate runoff in the Navarro watershed was the Precipitation Runoff Modeling System (PRMS). The PRMS is a modular modeling system designed to evaluate impacts of climate and land use on surface runoff, sediment yields, and general basin hydrology (Leavesley et al., 1983). Parameterization of PRMS was undertaken based on modeling response units (MRU). MRUs are units of a watershed partitioned on the basis of characteristics such as vegetation type, precipitation distribution, slope, aspect, and soil type. The PRMS was operated within the Modular Modeling System (MMS). The MMS is an integrated computer software sys-

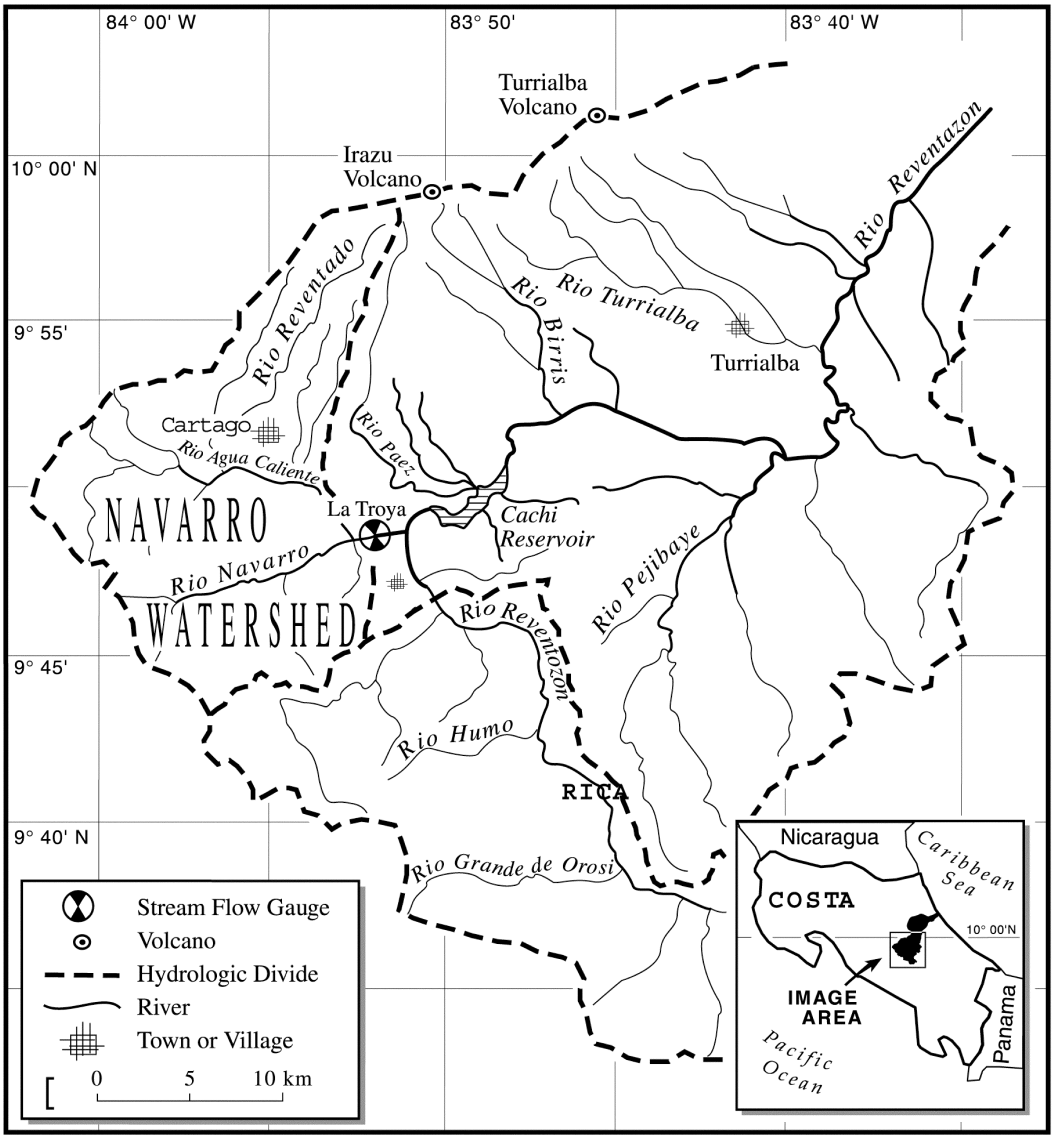

Figure 15.1. The upper watersheds of the Reventazón River Basin (Reprinted by permission, International Journal of Remote Sensing).

tem which provides an operational framework for development of algorithms and their application toward modeling physical processes (Leavesley et al., 1996).

PHYSICAL CHARACTERIZATION

The factors that influenced the selection of data for this study were requirements to complete the study and availability. In comparison to other Central American countries the amount and quality of environmental data available in Costa Rica is relatively high. However, initial assessment of data resources revealed significant gaps in some areas (e.g., soils data) and discrepancies in scales between others.

The availability of data for this watershed may be seen as deficient compared to that required

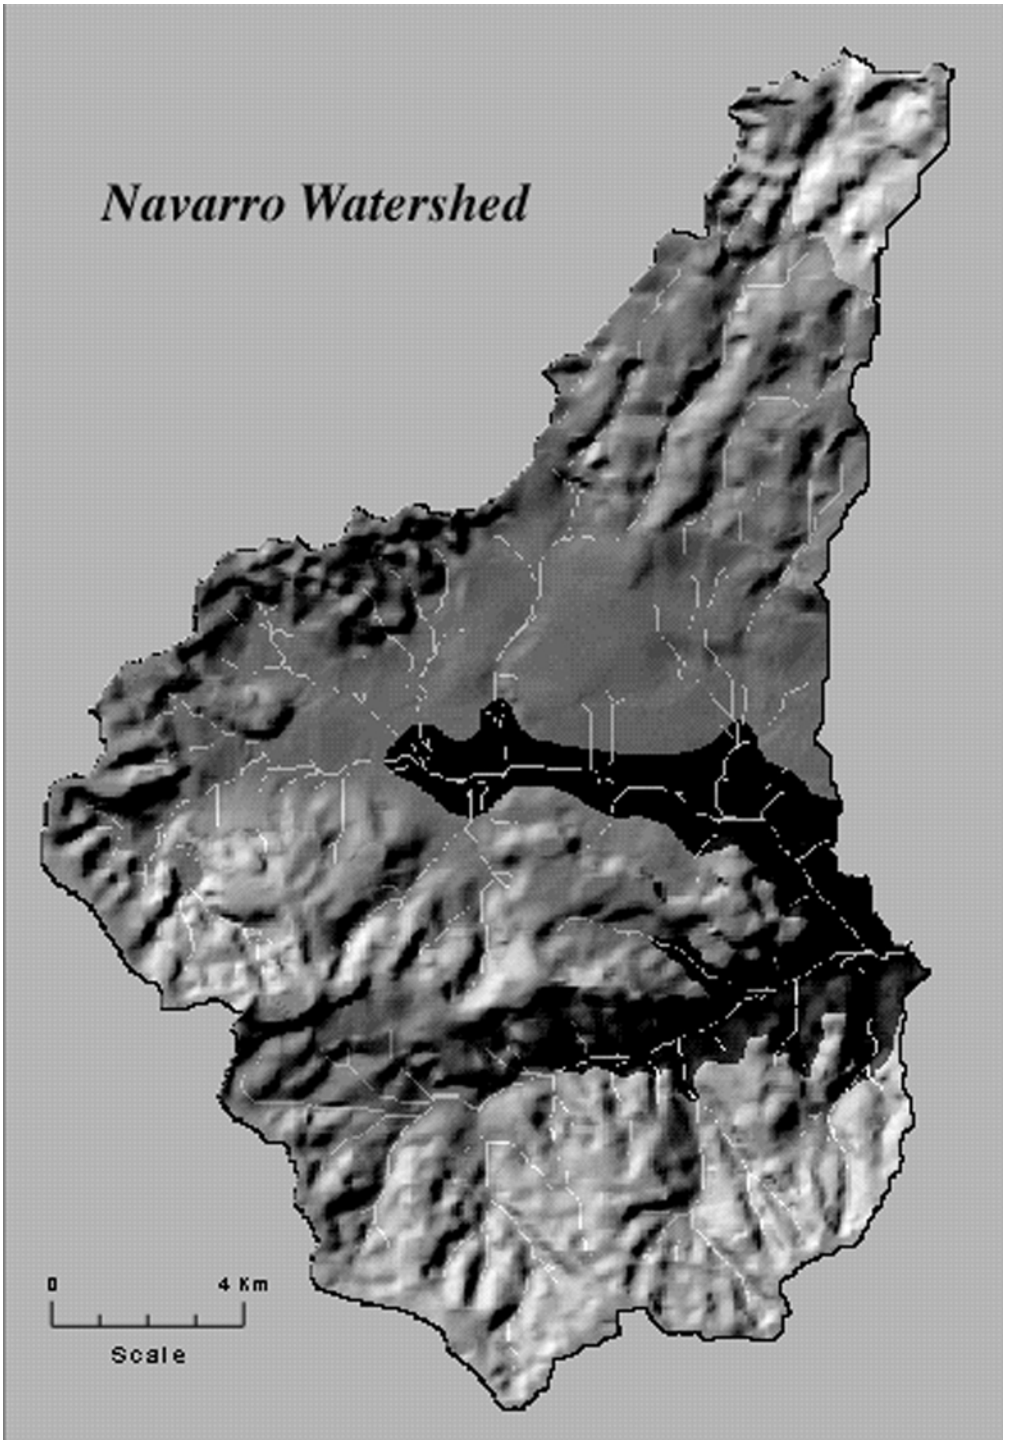

Figure 15.2. Shaded relief image of the Navarro Watershed.

for an experimental watershed in which it is desired to apply a fully distributed hydrologic model. However, this state of data availability lends itself to testing a distributed hydrologic modeling approach utilizing MRUs. In the MRU delineation process used in this study thematic data were aggregated, and homogenous units created from which more generalized parameter values were extracted for modeling purposes. Three types of data were utilized to develop GIS layers for the delineation of MRUs: elevation, digital satellite data, and precipitation.

Digital Terrain Elevation Data Processing

The primary elevation data used was the U.S. National Imagery and Mapping Agency (NIMA) Digital Elevation Terrain Data (DTED). Other elevation data considered bore constraints which were difficult to overcome. For example, topographic maps at 1:50,000 scale which covered the watershed were obtained, but digitizing the entire watershed was judged prohibitive for this study. In addition, complete coverage of the watershed by same scale stereo aerial photographs was not available for construction of a digital elevation model.

The DTED data were distributed in 1° by 1° cells, with a 16-bit range of elevation values. Two cells of DTED Level 1 data were utilized in this study. The boundaries of these cells extended from 9° N to 10° N and from 83° W to 85° W. According to the NIMA, the data for the cells were digitized or scanned from cartographic sources at a scale of 1:250,000, in the mid- to late 1970's. The DTED data were provided in a 3 arc second format. The resolution of this data between 9° N and 10° N latitude was 92.161 m^2. Elevation was represented by a regular grid of post points spaced at 100 m and interpolated with an inverse distance weighted routine using eight neighbors.

Preliminary Steps

A projection file was created in ARC/INFO to enable rectification of the original points from a geographic grid to a Lambert Conformal Conic projection. This projection was chosen because at low latitudes its conformality property possesses true shape of small areas, and also the ancillary maps available for the study area were represented in this projection. To enable integration with additional data sets the DTED file was resampled to 90 m using a bilinear interpolation routine.

Drainage Network and Watershed Delineation

A multiple step process was enacted in ARC/INFO GRID to define the drainage pattern and boundary of the watershed. Essentially four steps were carried out to delineate the drainage network using the elevation data: removing sinks in the DEM; assigning flow direction per cell; assigning flow accumulation values per cell; and determining the threshold flow accumulation value that best represented the drainage pattern (Jenson and Dominique, 1988).

In order to delineate the boundaries of the watershed, the drainage pattern was first displayed and the location of the streamflow gauge estimated. The streamflow gauge location on the derived drainage pattern was accurate in an east-west direction but approximately 550 m south of the actual location, according to a 1:50,000 scale topographic map. The topography in the area where the La Troya streamflow gauge was located opens to relatively level terrain, which may have contributed to the difficulty in defining the location of the gauge. The area draining to the streamflow gauge was identified using the Watershed function in GRID and the flow direction map. The resulting map defined the boundary of the watershed and provided a mask for delineating the boundary on additional GIS data layers.

Physical Characteristics Derived from Elevation Data

Additional analysis steps were carried out to derive physical characteristics of the watershed from the elevation data, including area, elevation parameters, perimeter of the watershed, and drainage density. These parameters were compared with parameters produced in previous studies of the watershed.

In a technical report generated by Solís et al. (1991) and a thesis by Baltodano and Hidalgo (1992), similar physical characteristics were extracted from 1:50,000 scale topographic maps for the Navarro watershed. In an earlier technical report, Elizondo (1979) extracted watershed characteristics from the 1:200,000 scale topographic map, San José CR2-CM–5, published by the Instituto Geographico Nacional (IGN). The report utilized the Puente Negro streamflow gauge which, due to flood damage, was later replaced downstream by the La Troya gauge.

In this study the area of the watershed was calculated using the GRID function Zonalarea. The perimeter was calculated using Zonalperimeter. The elevation parameters, such as maximum, minimum, and mean elevation values, were extracted in ERDAS IMAGINE. These parameters as well as drainage density were compared to estimates from Solis et al. (1991), Elizondo (1979), and estimates from the primary utility company in the country, the Instituto Costaricense de Electricidad (ICE) (Table 15.1).

Table 15.1. Physical Characteristics Derived from Elevation Data

Parameters Station	Colby L.Troya	Solis et al. L.Troya	Elizondo P.Negro	ICE L.Troya	ICE P. Negro
Area (km^2)	278.57	282	273.3	273.6	273.3
Elevation max.	3427	3200	3300	—	—
Elevation min.	1057	1020	—	1028.6	1048.62
Elevation mean	1691	1725	1620	—	—
Perimeter (km)	108.54	87	78	—	—
Drainage density	0.66	0.88	0.46	—	—

Drainage density, or the length of streams per unit area, was calculated using (Black, 1991):

$$D_d = L/A \quad (1)$$

where: D_d = drainage density
L = length of streams (km)
A = area of the watershed (km^2)

Slope values for the watershed were computed in ERDAS IMAGINE and the GIS IDRISI. The following percentage distributions were calculated for the watershed:

(1). 0–4 degrees, 29.5%
(2). 5–9 degrees, 22.8%
(3). 10–15 degrees, 24.9%
(4). 16–19 degrees, 12%
(5). 20–28 degrees, 9.8%
(6). 29–48 degrees, 1%

Elevation Data Quality Assessment

An advantage of using DTED data in this study was the ease with which parameters such as physical characteristics were derived. Use of previously derived digital elevation data provided

flexibility and analysis capabilities in a timely fashion. The trade-off was the lack of quality control in data development.

The drainage pattern derived from the DTED data provided a generally representative depiction of the watershed. However, errors were encountered. Accuracy was assessed by comparisons to drainage patterns from a 1986 Landsat Thematic Mapper (TM) image, 1:10,000 scale land use maps, 1:50,000 scale topographic maps, and aerial photographs. An overlay of the drainage pattern on a false color composite TM image (Figure 15.3, see color section) revealed nonsystematic errors in the correspondence of the location of the drainage pattern, especially along the slopes of the Irazú volcano in the northern section of the watershed. In other areas the drainage patterns matched.

These errors were due in part to the quality of the DTED data and the level of sophistication of GIS software tools used for drainage pattern extraction. The poor representation of the rivers in the northern section of the watershed raised the question of whether the cartographic source for the elevation values was produced before the 1963–1965 eruption of the Irazú volcano.

The most recent eruption of the Irazú volcano began in March of 1963 and continued to spew large volumes of lithic ash through March of 1965. Accumulation of ash on the slopes of the volcano altered the hydrologic regime of the rivers. A hard impervious crust formed on the mantle of ash which reduced infiltration, increased runoff, and resulted in increased slope erosion, frequent flash floods and deadly debris flows. Emergency measures were undertaken such as channel improvements, the construction of levees to protect Cartago, and watershed rehabilitation by terracing, drainage diversion, contour trenching and artificial revegetation (Waldron, 1967).

The area, mean elevation, and drainage density values derived for the Navarro watershed fell between the values produced from analog sources (Table 15.1). The maximum and minimum elevation and perimeter values calculated from the DTED data were somewhat higher than that produced from the 1:50,000 and 1:200,000 scale topographic maps. The absolute vertical accuracy of the DTED data may have affected the differences in elevation values, and the perimeter differences were likely due to grid cells representing the watershed outline, rather than a vector line. Overall, the quality of the elevation data and the derived drainage pattern, though not optimal, supported its application in a distributed hydrologic modeling exercise utilizing MRUs.

Land Cover Classification

The digital Landsat TM satellite image was classified to provide land cover characterization. Variable illumination angles and reflection geometry due to different slope and aspect orientations limit the effectiveness of Landsat TM classification efforts in mountainous terrain. A method for reducing the resulting anisotropic reflectance effects, which was developed in a temperate region (Smith et al., 1980; Colby, 1991; Hodgson and Shelley, 1994) was tested in the neotropical environment of central Costa Rica (Colby and Keating, 1998).

Aerial photographs and land use maps provided reference information for classification of the TM image. Black and white aerial photographs for the north-central section of the watershed (1989) at a scale of 1:20,000 and for the southern section of the watershed (1992) at a scale of 1:60,000 were obtained from the IGN. Also, 1:10,000 scale land use maps (field checked in 1989) were obtained for the central part of the watershed.

Improved classification accuracy was obtained using topographic normalization routines (Colby and Keating, 1998). The resolution and quality of the elevation data was believed to have reduced topographic normalization effectiveness and classification accuracy.

Precipitation Distribution

The Navarro watershed is located between diverse precipitation regimes. One of the driest areas in the country extends from Cartago through the Valle Central (Janzen, 1983). The highest rainfall rates in the Upper Reventazón River basin, 7500 mm a year, are found approximately 25 km southeast of Cartago (Jansson and Rodriguez, 1992). The mean annual precipitation recorded at stations used in this study varied from 1329 mm at the centrally located Comandancia station to 3264 mm at the Belen station located in the southeast near the southern border of the watershed.

To develop an image of the spatial distribution of precipitation across the watershed, a number of trend surface analyses were undertaken using the GIS IDRISI. Second and third order trend surfaces were derived using mean annual rainfall figures calculated from complete years of data for the 20 year period between 1967 through 1986 (IMN, 1988). Trend surfaces were created using data from 7 to 22 stations located in and near the watershed.

Generally, third order surfaces had the highest goodness of fit (R^2) values, but did not represent the spatial distribution of precipitation in the southwest section of the watershed accurately due to a scarcity of precipitation stations in the area. The final image chosen was a second order trend surface created using 14 stations. The R^2 value for this surface was 91.35%.

APPLICATIONS

Once digital spatial characteristics of the watershed had been generated MRUs were delineated using thematic GIS data layers of watershed subbasins, a distance buffer from the stream, precipitation distribution, and land cover categories. The subbasins were delineated using the same techniques as described above to delineate the watershed; however, research and management criteria were taken into consideration in determining outflow points. A distance buffer from the stream was created based roughly on the variable source area concept (Troendle, 1985). The precipitation distribution layer consisted of a three category aggregation of the second order trend surface described above. The land cover layer included the following categories: bare areas, grass, shrubs, trees, and impervious areas. MRUs were delineated using the four thematic layers and a GIS-based methodology (Colby, 1995).

Following delineation of the MRUs, hydrologic simulation of the watershed was undertaken for August through January during the 1987–1988 Costa Rican water year. Parameters for PRMS were extracted using the MRU boundaries, the MRU thematic layers, and additional data layers such as elevation, slope, and aspect. The accuracy of the simulations was determined to be sufficient to proceed with a scaling analysis using multiple resolutions of land cover data.

In the scaling analysis a series of MRU patterns aggregated at 90 m^2 intervals, from 90 m^2 to 1260 m^2, provided areal dimensions to parameterize PRMS. Simulation of hydrologic runoff was undertaken at each resolution. The fractal dimension D values of the MRU patterns were also calculated at each resolution. A strong correspondence was found between the range of resolutions at which accurate hydrologic simulations were achieved and the range of self-similarity of the MRU patterns, as measured by their fractal dimension (Colby, 2001).

DISCUSSION AND CONCLUSION

The data available for this study were sufficient to carry out the intended applications; however, shortcomings did exist. An obvious gap was the lack of soils data available at a useful resolution. The resolution and quality of the elevation data affected the derivation of several watershed characteristics and anisotropic reflectance correction efforts. The status of data available for this study

may be representative of many watersheds in tropical countries in which watershed modeling and management are desired. For example, in these countries topographic maps at a scale larger than 1:200,000 or 1:250,000 may not be available. Physicial characterization of this watershed provided the opportunity to evaluate the effectiveness of utilizing a distributed hydrologic modeling approach based on MRUs. The capability to aggregate thematic data and form hydrologic units provided flexibility to work with less than optimal data. The MRU modeling approach delivered effective watershed characterization and hydrologic simulation accuracy which enabled the desired research to be accomplished. Utilization of geographic information systems provided essential capabilities for improving the processing, management, and analysis of available data.

CHAPTER 16

Hydrologic Modeling Using Remotely Sensed Databases

James F. Cruise and Richard L. Miller

INTRODUCTION

Recent developments in the evolution of hydrologic modeling using remotely sensed data sources are discussed. The latest remote sensing instruments as well as traditional devices are addressed in terms of spectral characteristics and spatial resolutions. Products of interest to hydrologic modelers are described, as are techniques for their derivation. Hydrologic modeling techniques that make use of these data sources are examined, particularly at the macroscale level. Scientific development in the areas of global change analysis and atmospheric forecasting establish the context of research in hydrologic modeling using spatial databases. Of primary importance are issues involving data scale and resolution requirements for hydrologic modeling. The evolution of this research is discussed and the authors present a study that makes use of recently developed modeling techniques along with remote sensing data products. The results demonstrate that macroscale hydrologic modeling in conjunction with conventional remote sensing data sources can lead to accurate simulations of observed climatologies over fairly long time periods.

Background

Spatial databases are frequently a critical component of hydrologic models. The requirements for modeling over larger spatial domains imposed by the global change and atmospheric forecasting communities have dramatically altered some conceptions relative to modeling strategies and data requirements. The formulation of coupled atmospheric/hydrologic modeling systems to operate in the macroscale spatial domain has placed a premium on data acquisition and processing techniques. The development of comprehensive databases, and hence effective models, is therefore a major focus of most modeling efforts. Remote sensing can provide unique data for constructing spatial databases. These data may include analog aerial photography or digital images representing the emission or reflectance of radiant energy from ground surfaces. Remotely sensed data are available from a variety of instruments mounted on satellite and aircraft platforms. Following acquisition, these data must be processed to correct for the influence of the intervening atmosphere, remapped to a geographic or spatial grid, and analyzed to derive information required specifically for hydrologic modeling.

The purpose of this chapter is to present some of the latest developments in the use of remotely sensed data and geographic information system tools in hydrologic modeling. Sources of remotely sensed data, capabilities of important sensors, acquisition techniques, and hydrologic modeling strategies to make use of these data will be discussed. Data requirements relative to temporal and

spatial scale of modeling domains will be examined, primarily within the context of global change hydrology. Finally, a recent study completed by the authors that made use of many of the data sources and modeling techniques discussed in the chapter will be presented.

DATA REQUIREMENTS FOR HYDROLOGIC MODELING

Hydrologic models require different types of data depending on the processes modeled and the relevant time and space scales of these processes. Models are generally classified temporally as either single event or continuous. Single event models are designed to simulate a single climatic event and thus do not attempt to model hydrologic conditions between events. Continuous models attempt to simulate all hydrologic conditions on a watershed at some specified time step (e.g., hourly or daily) for a long period of time (months or years). In general, continuous simulation models require more extensive climatic data and, possibly, soils and vegetation data sets than do single event models.

Different modeling strategies describe the spatial variation of watershed characteristics at various levels of detail and complexity. Models are classified spatially as either lumped or distributed. The least complex are the lumped parameter models where the spatial variability of select watershed characteristics are described by a few simple parameters (e.g., *lumped* together). Typical parameters include watershed lag (time from centroid of precipitation excess to centroid of runoff hydrograph), time of concentration (travel time from most remote point in the watershed to the basin outfall), and storage factor.

The unit hydrograph method is an outstanding example of a lumped parameter hydrologic model. The more spatially complex distributed models attempt to describe more fully the spatial variation in topography, soils, surface characteristics and meteorology and to explicitly include these in the model. When using this method, the watershed surface is discretized into a spatial grid and the characteristics of the watershed are described within each grid cell. Between the extremes of the lumped and distributed models, several semidistributed techniques have recently been developed which combine the advantages of the distributed models with the simplicity of the lumped parameter method. Of these, the hydrologic response unit technique is quite popular and will be described in further detail in the applications section of this chapter.

All hydrologic models require physical data such as topography and soils characteristics, land-use data such as land cover and vegetation characteristics, and climatic data such as precipitation and temperature. In addition, data quantifying some aspect of streamflow within the watershed are generally required for model calibration and verification.

In constructing databases for hydrologic modeling, consideration must be given to the data requirements for model calibration and the spatial and temporal scale of the model. Products of interest to hydrologic modelers that can be derived from spatial databases include surface representation (slope, aspect, plain geometry), soils characterization (permeability, conductivity, storativity), antecedent moisture conditions, land cover and condition, and vegetation characteristics and biomass. Input parameters are either included directly in the database (i.e., hydraulic conductivity) or calculated from the raw data layers (i.e., slope, land cover). Traditionally, distributed models have employed databases at spatial resolutions on the order of meters. The models may execute on a time scale of minutes or hours, but normally the spatial database is updated on time scales of months or seasons to take into account land use and vegetation changes.

Unfortunately, it is not feasible to construct databases at optimal spatial resolutions for hydrologic modeling on anything but the smallest basin or subbasin scale due to the lack of suitable data and computational resources for the model. Zhang and Montgomery (1994) have suggested a grid resolution of 10 m as appropriate for hydrologic modeling. However, at this resolution the

data are usually not available over large areas. Hydrologic studies are normally conducted using raster (gridded) data sets at spatial resolutions of 30 m or less if possible. More recently, semi-distributed macroscale models constructed at coarser resolutions (1–4 km) have been developed, particularly to function with atmospheric circulation models (Kite et al., 1994; Nijssen et al., 1997).

A number of researchers have conducted investigations of the effect of scale and data resolution on the accuracy of hydrologic models. Wolock and Price (1994) used a topographically driven hydrologic model (TOPMODEL) to investigate the effects of map scale and resolution on hydrologic modeling. They compared results using the 1:24,000 scale USGS maps at grid resolutions of 30 m and 90 m and the 1:250,000 scale, 90 m resolution maps. In general, they found that runoff estimates tended to increase (as did the ratio of surface runoff to total runoff) with increasing map scale and resolution. They attributed this observation to the effect of increasing grid size on the topographical index in the model. However, they did not conclude that the finer scale and resolution maps were necessarily better for hydrologic modeling purposes. Instead, they pointed out that the surface of the saturated soil water zone (which controls runoff generation) may be smoother than fine-scale surface topography, and so would correspond better to coarser resolution data. Likewise, Zhang and Montgomery (1994) found that runoff tended to increase with increasing grid cell sizes in a study based upon topographical information obtained from a 1:4,800 scale base map. In this study grid cell resolutions varied from 2 to 90 m. The authors found that slope representations of an area decreased with increasing grid size, while contributing drainage area increased with grid size. On a similar point, Wood et al. (1988) reported that runoff from areas of variable topography and soils characteristics demonstrated minimum variance at a resolution of about 1 km^2, thus indicating that hydrologic modeling with coarse raster data sets is reasonable. The macroscale model results reported by Kite et al. (1994) and Nijssen et al. (1997) also appeared to show that coarse resolution modeling holds considerable promise.

Representation of basin topography and soil characteristics can be accomplished using either vector- or raster-based data sets. Watershed surface topography is represented by use of a Digital Terrain Model (DTM). The DTM represents the topographic characteristics of the basin through either a grid cell (raster) or data string (vector) formulation (Sole and Valanzano, 1996). The raster-based digital elevation model (DEM) data sets available on-line provide elevation data at grid sizes ranging from 90 to 200 m. Vector-based digital line graph (DLG) data are essentially digitized versions of contour strings from standard topographic maps. The contour intervals range from 5–10 ft (1.5 to 3.0 m) to 50 m.

Surface features may be represented within the GIS by using the raw topographic data in raster or vector format, or by refinements such as the Triangular Irregular Network (TIN). In this method, an area is represented by irregular triangles with the elevation specified at each triangle vertex. The elevation is assumed to vary linearly over the triangle (Singh and Fiorentino, 1996). This formulation allows for the specification of irregular features which might not be possible with gridded data and is commonly employed in hydrologic modeling (Silfer et al., 1987; Maidment et al., 1989; Goodrich et al., 1991; Greene and Cruise, 1996).

Land cover data for hydrologic modeling purposes are usually obtained from interpretation of aerial photographs or multispectral data acquired by satellite or aircraft mounted sensors. High resolution black and white or infrared aerial photographs are available for most of the United States through the U.S. Geological Survey. The photographs are available at scales of 1:30,000 or less for most places. The Survey periodically determines land cover for the U.S. by interpretation of these photographs. Multispectral data sources and products derived from them are discussed later in this chapter.

ON-LINE DATA SOURCES

Several large databases that are available on the internet may be valuable for hydrologic modeling, particular at the macroscale level. In general, these databases are maintained at low spatial resolutions. A valuable source of hydrologic, topographic and land cover data for the United States is the EROS Data Center (EDC) of the U.S. Geological Survey. Topographic data are archived at the EDC in both Digital Elevation Model (DEM) and Digital Line Graph (DLG) format, depending on the location. For instance, the largest scale topographic maps that are commercially available for the U.S. are the 7.5′, 1:24000 scale maps (30m resolution) produced by the U. S. Geological Survey. However, these maps have only been digitized for select areas of the country. Instead, the 15′, 1:250,000 scale digital elevation model (DEM) maps are universally available at the EDC for topography, while the 1:100,000 scale digital line graph maps provide hydrography and transportation data. The grid cell size of the raster-based 15′ DEM data varies from 90 m to 200 m. This type of coarse resolution data may be appropriate for macroscale hydrologic modeling. The EDC is also the repository of the Land Use and Land Cover (LULC) database that is composed of 200 m raster images derived from aerial photographs that cover the entire conterminous United States.

The availability of fine resolution digital soils data for the U. S. is more problematic than are the topogaphic and hydrographic maps. The highest resolution soils data commonly employed in the U.S. are the county soil surveys conducted by the National Resources Conservation Service (NRCS). These surveys are mapped onto aerial photographs at a scale of 1:12,000 or 1:63,360 with individual soil series as the mapping units. NRCS provides soils data in both raster and vector formats at various scales and spatial resolutions. The Soil Survey Geographic Data Base (SSURGO) consists of the digitized county soils maps in vector (DLG) format. These files are released as they are completed and verified and are currently available only in scattered areas of the country.

The State Soils Geographic Database (STATSGO) is a generalization of the county surveys in which the individual mapping units have been aggregated based upon statistical analysis of the soil series. STATSGO is a vector database in which the smallest mapping unit is 1546 acres. The associated data tables include most of the soil matrix and parameter information contained in hard copy surveys. The Penn State University Environmental Sciences Systems Center has developed the Conterminous United States Soils (CONUS) database. CONUS is a raster database at 1 km resolution which represents the STATSGO soils polygons in a standardized 11 layer matrix format.

For land-use determination, various satellite mounted sensors are available that acquire multispectral data at spatial resolutions from 10 m to 1.1 km and temporal resolutions from 6 hours to 16 days. These data sets are used to obtain images of an area of the earth's surface that can be classified in terms of land cover or vegetation characteristics. Classified images are routinely used to obtain land cover information needed in hydrologic modeling such as forest canopy cover and/or biomass, agricultural crop coverage and characteristics (cultivated or noncultivated), urban land use acreages, etc. (Tan and Shih, 1988; Wilkening, 1989; Kite and Kouwen, 1992; Miller and Cruise, 1995). Satellite data are archived in a number of institutions in the United States. The Distributed Active Archive Centers (DAAC) associated with the NASA Earth Observing System Data and Information System (EOSDIS) network are a primary source of satellite data. The EDC serves as the DAAC for the global 1.1 km resolution images from the Advanced Very High Resolution Radiometer (AVHRR) instrument. These images have been archived since 1974. The Marshall Space Flight Center (MSFC) is the primary archive for data associated with the hydrologic cycle.

REMOTE SENSING

A useful operational definition of remote sensing is *to observe an object at some distance without contacting the object*. The large observational scale and unobtrusive nature of remote sensing make this technology a valuable tool for the study of multiscale features of the earth's surface. Although remote sensing cannot provide direct measurements of most hydrologic processes, remote sensing and related technologies such as image processing and Geographic Information Systems (GIS) can provide critical data and products for parameterizing many hydrologic models.

Remotely sensed data are obtained using several different data acquisition technologies. In general, images are formed based on the reflected or emitted energy from a defined spatial element (e.g., pixel, or ground resolution) over select interval(s) of the electromagnetic spectrum. A remote sensing instrument measures the energy at the detectors from either passive (ambient) or active (instrument-generated) energy sources. Although nonimaging instruments such as satellite altimeters do exist, this discussion will focus on the principles and data products derived from imaging instruments, particularly digital multispectral (*few* spectral bands) and hyperspectral (*many* spectral bands) sensors which provide useful data for application in hydrologic modeling. For example, standard CIR (color infrared) aerial photographs, or images, are formed by exposing film to reflected visible and infrared energy. This is an analog process. Important information on landscape patterns, land-use characteristics, and ground cover vegetation can be extracted from such aerial photographs using basic photogrammetric techniques (see for example, Paine, 1981; Graham, and Read, 1986). However, the processing and analysis of photographs using these techniques are time-consuming and labor-intensive. In contrast, the recent rapid development of digital multi- to hyperspectral instruments and low-cost computer systems has established digital remote sensing as an easy-to-use, affordable, and efficient tool for monitoring earth system processes (Miller, 1993; Miller and DeCampo, 1994; Miller et al., 1995).

Multispectral classification is a primary tool for translating remotely sensed data for use in many basic and applied research disciplines. This method is used here to provide a comprehensive example of the processes involved in applying remote sensing to hydrologic models. Multispectral classification is based on a spatial analysis and grouping of surfaces with a similar or correlated reflectance spectrum (i.e., spectral signature). Figure 16.1 shows representative spectra for several surface types along with the spectral bandpass (detection intervals) for the Landsat Thematic Mapper (TM), a satellite-based sensor. A ground point or image pixel is assigned to an image *class* if the pixel's spectral signature is statistically similar to the class mean spectrum. Statistical criteria are derived using multivariate classification methods such as the maximum likelihood classifier, principal component analysis, generalized eigenvalue analysis, and artificial neural networks (Jensen, 1986; Lillesand and Kiefer, 1993; Smith et al., 1994; Venkateswarlu and Singh, 1995; Roger, 1996; Atkinson and Tatnal, 1997; Murai and Omatu, 1997; Paola and Schowengerdt, 1997) These methods yield classified images of land-cover/land-use, soil type and moisture, landscape or drainage patterns, and hydrologic units (Bober et al., 1996; Cialella et al.,1997; Homer et al., 1997; Su et al., 1997; Van Deventer et al., 1997). The digital format of these products allows for a greatly simplified numerical analysis and data extraction process through the use of readily available image processing software. Classification results can then be directly integrated into a GIS, a hydrologic model, or used to derive model coefficients.

The utility of a classified image in hydrologic modeling depends on the accuracy of the classification scheme employed. Classification accuracy is related to the variability in the reflectance spectra for each derived class, band position and width, radiometric sensitivity and noise (e.g., spectral characteristics) of the instrument, and numerical precision of the classification algorithm.

Both the spectral shape and reflectance of a class can vary significantly in time and space as a

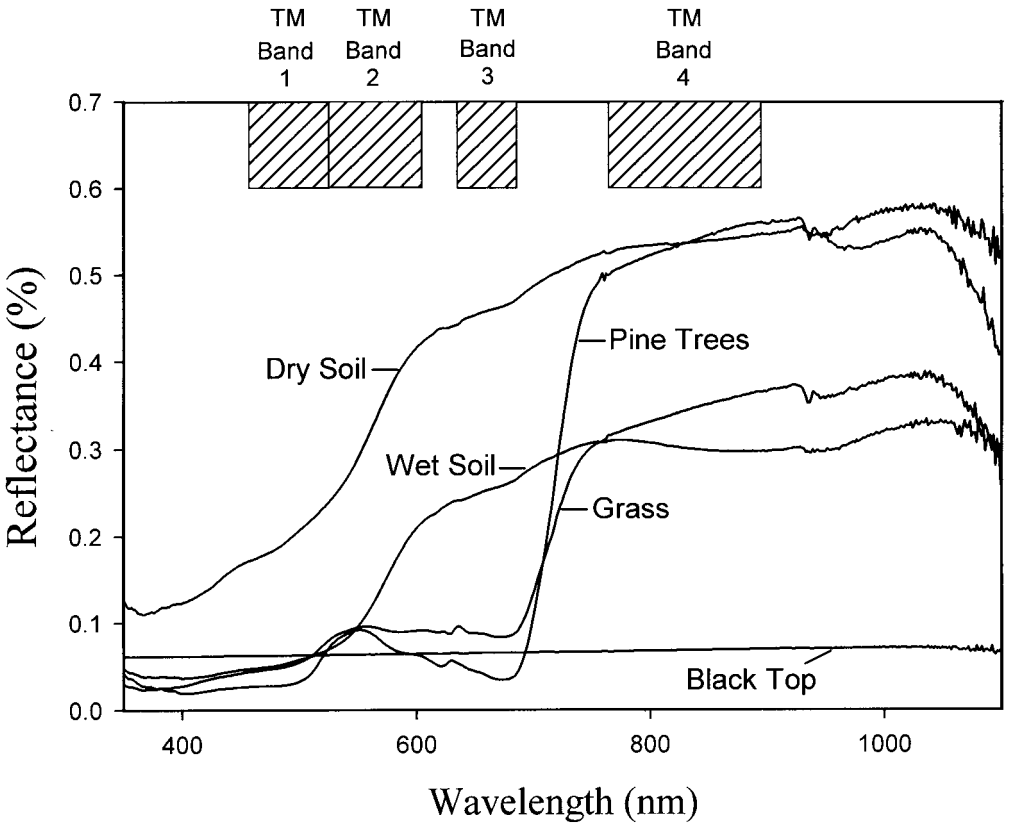

Figure 16.1. Reflectance characteristics of various surfaces observed by Landsat Thematic Mapper.

complex function of many processes. For example, the percent reflectance of vegetation at several wavelengths will increase with decreasing chlorophyll pigment concentration in response to physiological stress (Carter, 1993; Carter and Miller, 1994; Carter et al., 1996). The reflectance of soils in the visible spectrum will change as a function of soil moisture. Surface soil moisture can be measured using passive reflectance and microwave instruments through detecting changes in the soils physical and dialectric properties (Engman, 1990; Jackson et al., 1996; O'Neill et al., 1996). Synthetic Aperture Radar (SAR) systems are also useful in measuring soil moisture (Poncet et al., 1994; Sabburg, 1994; Boisvert et al., 1997; Wegmuller, 1997). The classification of pervious or impervious urban surfaces also changes with surface moisture and temperature. Hence, the ability to detect and resolve changes resulting from intraclass variability from a transition to a different hydrologic unit is an important aspect of current remote sensing research.

Recent advances in remote sensing technology and algorithm development are reducing misclassifications and improving the definition of the hydrologic response of various hydrologic units. Multispectral instruments are generally designed for a specific application. The spectral bands available may be less than optimal for other applications, resulting in large classification errors. An increase in the number of an instrument's spectral bands, as well as narrower band widths, will provide more accurate estimates of the shape (e.g., inflection points) of the surface reflectance spectrum for each class. Narrower bands also help isolate changes in reflectance to specific physical, chemical, and biological processes. Hyperspectral instruments (e.g., AVIRIS, CASI,

HYDICE) with hundreds of bands are effectively imaging spectrometers and may be used for a broad range of applications. The user simply chooses the bands most appropriate for a particular application based on a priori information or comprehensive processing to determine which may reveal information most relevant to a given study. Table 16.1 lists the characteristics of current and planned remote sensing instruments and examples of derived products for hydrologic modeling.

Algorithms based on a combination of bands reduce the effects of nonclass processes. For example, data from two bands, the red and near infrared, are used to compute the Normalized Difference Vegetation Index (NDVI). The NDVI is a simple, yet robust, algorithm to estimate vegetation abundance or *greenness* (Jensen, 1986; Goetz, 1997; Rasmussen, 1997; Ricotta et al., 1997). Similarly, hyperspectral sensors provide the potential to develop highly refined algorithms for classifying ground surfaces and hydrologic processes. Additional research in the spectral response of class components (e.g., plants, soils) to a range of processes will significantly improve

classifications by providing more reliable training fields in supervised (interactive) classification algorithms using hyperspectral data.

Remote sensing technology is well established for measuring hydrologic variables or processes related to transport, snow and ice reservoirs, evaporation, and precipitation. The movement of water through rivers, estuaries, and coastal waters can be monitored using reflectance and thermal imagery. For example, a time series of red and near infrared reflectance images may indicate water movement using suspended particulates as a tracer (Miller and Cruise, 1994; Miller et al., 1994, Schultz, 1996). Multiple images of thermal data can indicate water mass structure, mixing, and flow patterns between areas of different temperatures. Thermal imagery is also used to measure evapotranspiration of forested landscapes (Luvall and Hobo, 1991; Courault et al., 1996) and evaporation in urban environments (Lo et al., 1997). The integration of data from multiple sources and remote sensing can help develop comprehensive models for analyzing the hydrology of a watershed, associated coastal zone, or components of the hydrologic cycle.

CASE STUDY: RIO GUANAJIBO, PUERTO RICO

In this section, we describe a recent study completed by the authors that made use of many of the data sources and hydrologic methods described in the previous sections. A joint project between the NASA Science and Technology Laboratory at Stennis Space Center, MS and the University of Puerto Rico was initiated in 1987 to examine the effects of changing landscapes on the water quality of local rivers and Mayaguez Bay, Puerto Rico (Otero et al., 1992). A particular focus of the study was to examine the correlation of anthropogenic activities such as agricultural practices, deforestation, and urbanization to increased sediment and nutrient-enhanced productivity in the bay. As part of this effort, a mathematical model was used to simulate runoff and sediment yield from the contiguous drainage basins over various periods of time (Cruise and Miller, 1993, 1994; Miller and Cruise, 1995; Mashriqui and Cruise, 1997). Data used during these studies were obtained from several different sources (both in situ and remote sensing) and in varying formats (digital and analog). Remotely sensed data were used in conjunction with soils and topograpic data to provide the basis for the simulation of runoff and sediment yield from the area.

Mayaguez Bay encompasses an area of approximately 100 km^2 on the west coast of Puerto Rico (Figure 16.2). As shown on the figure, three relatively small watersheds drain into the bay; the Anasco (360 km^2), the Guanajibo (311 km^2), and the Yaguez (17.4 km^2). Land-use activities within these basins include various agricultural enterprises (sugar, coffee, and dairy) as well as commercial and industrial developments. Sugar harvesting is confined to the floodplains along the main stems and major tributaries while coffee plantations are located in the upland areas. In addition, large portions of the Anasco and Guanajibo basins consist of undisturbed forested areas. The present study focused on the Guanajibo basin which is composed of agricultural and forested areas with only a small amount of urbanization.

Three streamflow gauging stations are maintained by the U.S. Geological Survey within the Guanajibo basin. Two stations are located on the main stem and one is on Rio Rosario which is the major tributary to the main channel. The Rio Rosario gauge is a continuous stage recorder and water quality station and encompasses a drainage area of 47.4 km^2. This subbasin was the initial focus of the study because in addition to discrete water quality samples, continuous suspended sediment records were available for this gauge. The simulation model was first constructed and verified for this small basin (Cruise and Miller, 1993; Mashriqui and Cruise, 1997) and then extended to the main Guanajibo watershed. Initial Guanajibo simulations covered the period 1988–1990 (Cruise and Miller, 1994), while subsequent simulations were run for the period

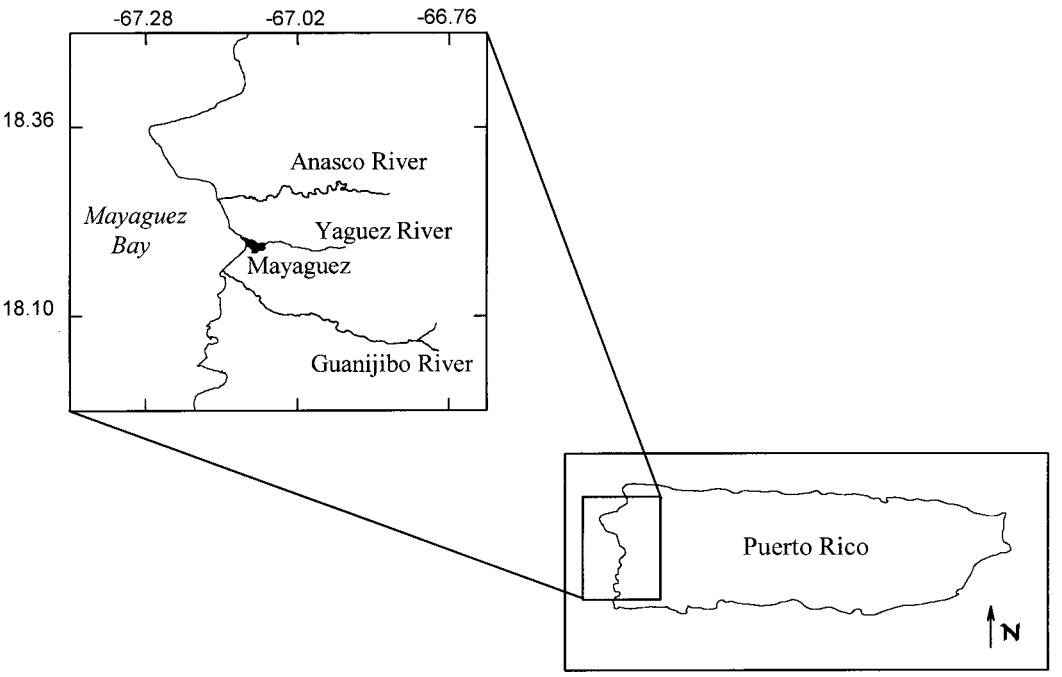

Figure 16.2. Location map: Western Puerto Rico and Mayaguez Bay.

1973–1982 (Miller and Cruise, 1995). Different sources of remotely sensed data were used to derive land cover information for the basin corresponding to these periods of time.

The northern portion of the Guanajibo watershed is composed of steep mountainous ridges (including the Rosario) which comprise about 58% of the total area. Terrain slopes within these regions vary from 32% to 56%. The less significant mountains on the southern rim (average slope = 25%) comprise about 14% of the area. The remaining 28% is comprised of the very mild floodplain area where sugar harvesting is the primary activity. Soil associations in the mountainous areas are generally clays or silty clays while silty clay loams dominate the floodplain region (Gierbolini, 1975).

Digital Data Acquisition and Processing

Data requirements for the hydrologic model included climate records, topography, soil characteristics, land use activities, and ground cover. Regional topography and hydrography (streams) were obtained from DLG files of 1:20,000 scale quadrangle maps available from the U.S. Geological Survey. Contour intervals were 10 m in areas of high relief with intermediate lines of 5 m in the coastal floodplain regions. Soil associations were hand-digitized from published soil surveys available from NRCS.

Estimates of land use and land cover were obtained for the various simulation periods using three sources of remotely sensed data: aerial photography (1975), Calibrated Airborne Multispectral Scanner data (CAMS, 1990), and a Landsat TM image (1985). The photography consisted of black and white images at a scale of 1:30,000 (U.S. Geological Survey). The photos were acquired using an antivignetting filter to minimize tonal variation within a frame. Individual photos were digitized to 256 gray scale levels using a Microtek (PC-based) desktop scanner at a 100 DPI reso-

lution to yield a pixel ground resolution of 7.5 m. Only the portion of each photo with a consistent illumination was scanned. Twenty-six photos were required to provide complete coverage of the Guanajibo watershed. The digitized images were digitally mosaicked using the ELAS (Beverly and Penton, 1989) and Figment (Miller, 1993) image processing software. The mosaicked image was then resampled to a resolution of 30 m to correspond to the CAMS and TM data. Statistical analyses were performed on pixels within areas of known ground cover in order to determine threshold reflectance values (gray scale levels) for separation of classes. The 90th percentile point in each distribution was selected as the threshold reflectance value for that particular class (i.e., the reflectance for which 90% of the pixels were less than that value). Next, a masking routine was applied to the mosaicked image using the threshold gray scale values to separate the image into four relevant classes (e.g., highly reflectant, clear or bare ground, agriculture, and forest) for hydrologic analysis. The resulting image was georeferenced using Universal Transverse Mercator (UTM) map coordinates for the location of gauging stations (highway bridges) identified on the image. The digitized boundaries of the study areas were overlain onto the image to extract statistics and data required for the hydologic model.

Verification of the classification procedure was based on the original aerial photographs. Sample sites of approximately 50 x 50 pixels were selected at 20 random locations within the study area. These sites were then cross-referenced with the photographs. Results indicated that in 95% of the selected sites at least 80% of the pixels were correctly classified. In 50% of the cases, at least 90% of the pixels were correctly classified. Based on these results the errors in the classification procedure applied to the scanned photographs were deemed to be within acceptable limits. The classified image is shown in Figure 16.3a (see color section).

An unsupervised classification was performed on the 1985 Landsat TM data using the ERDAS software package (Figure 16.3b, see color section). A maximum likelihood classification was performed using TM channels 2, 3, and 4 with a maximum of 10 classes specified. Classes representative of hydrologically similar land cover were combined to yield class types consistent with the classification of the digitized photography. Because the TM scene had a number of clouds over the study area, these clouds and their shadows were left in separate classes and were reconciled later.

A land-cover / land-use classification of the CAMS data was created using ELAS (Figure 16.4, see color section). The CAMS data were preprocessed to remove the effects of the atmosphere using Figment. A single flight line of CAMS 30 m data was georeferenced to a UTM projection for classification. ELAS module SRCH provided unsupervised training statistics for 14 classes based on CAMS channels 2 (0.52 to 0.60 mm), 4 (0.63 to 0.69 mm), and 6 (0.76 to 0.90 mm). Using these statistics, the ELAS module CLMAXL produced an image based on a maximum likelihood classifier. The final classified image was then cross-referenced with the CAMS photography to assign specific land-use / land-cover definitions to each class. All digital data were converted to an ELAS image format for final analysis and data extraction for the hydrologic model.

Hydrologic and Sediment Yield Modeling

The hydrologic and sediment yield modeling for the Rosario and Guanajibo watersheds was accomplished using the "grouped response units" technique developed for macroscale modeling by Tao and Kouwen (1989), Kite and Kouwen (1992), and Kite et al., (1994). This method is a semi-distributed technique that makes maximum use of remotely sensed data and GIS capabilities (Cruise and Miller, 1993, 1994; Mashriqui and Cruise, 1997). Database environments utilized in this study included ELAS, ARC/INFO, and Map II (Panzer et al., 1992). The spatial database was used to represent the study area by identification of preliminary computational zones for modeling

purposes based upon relative homogeneity of soils and topographic characteristics. Important soils characteristics include depths of layers corresponding to particular matrix definitions, porosity, and hydraulic conductivity. Topographic parameters include mean slope, stream density, and flow plain geometry. These characteristics were derived from the database and used to define preliminary computational zones (CZ) within the study area. Frequency histograms of hydrologically relevant properties were used to examine spatial homogeneity for CZ definition (Mashriqui and Cruise, 1997). The land cover classes were then overlain onto the computational zones and final hydrologic response units (HRU) were defined as areas of identical land cover. HRU are areas of homogeneous hydrologic characteristics such that the response to climatic forcing would be uniform (Vieux, 1988; See et al., 1992). The assumption is made that areas of equal land cover within a computational zone can be aggregated into HRU regardless of their location within the zone (Kite and Kouwen, 1992; Kite et al., 1994; Mashriqui and Cruise, 1997). Figure 16.5 (see color section) shows the computational zones for the Rosario subbasin overlain onto the land classes derived from the 30 m 1990 CAMS image. The 1985 TM image and the 1975 aerial photo image were employed in a similar manner in the Guanajibo simulations (Miller and Cruise, 1995).

A water budget model was executed once for each land class present in each computational zone (Cruise and Miller, 1993, 1994; Mashriqui and Cruise, 1997). The results from all the HRU were then summed to determine the total response from the zone. The responses from all the zones were summed in turn on a weekly basis to estimate the total basin response at the outfall point. The U.S. Agricultural Research Service model CREAMS (*C*hemical, *R*unoff, *E*rosion from *A*gricultural *M*anagement *S*ystems, Knisel, 1980) was employed for water balance accounting and sediment yield modeling using the methodology outlined above. A particular point of interest is that the CREAMS model uses the Soil Conservation Service curve number method (USDA, 1986) to separate surface runoff from infiltrated water. The curve number is significantly related to the land cover of a particular area. Research has shown that remotely sensed data, particularly TM images, can be employed with great reliability to estimate runoff curve numbers (Ragan and Jackson, 1980; Slack and Welch, 1980; Rango et al., 1983) as was done in this study. Observed runoff and sediment loading from the Rio Rosario gauge was used to calibrate and verify the initial model while runoff data were used to verify the extended Guanajibo model.

RESULTS

The results of the runoff and sediment yield simulations for the initial Rosario simulations are shown in Figures 16.6a, b and 16.6c, d, respectively (Cruise and Miller, 1993). The model was initially calibrated for the period 1986–1989 and then verified compared to observations for 1990–1991. The results of the two sets of runoff simulations for the entire Guanajibo watershed are shown in Figures 16.7 (1988–1990) and 16.8 (1973–1982), respectively (Cruise and Miller, 1994). These results demonstrate that the modeling strategy was fairly consistent in simulating runoff and sediment yield from these watersheds. As with any real-world modeling effort, some inconsistencies in model veracity are inevitable. These irregularities were due primarily to the sparse rain gauge network in the region which caused several storms to be underestimated or missed altogether in the modeling. However, taking these irregularities into account, the model appeared to respond properly to changing soil moisture regimes, thus indicating that the water budget mechanism was adequately calibrated.

The results appear to verify the modeling strategy which was largely based upon the land cover characteristics of the spatial database. The classified spectral images revealed the pattern of land use and land cover throughout the basin and aided in the subdivision of the Rosario and Guanajibo watersheds into computational zones and response units for the model. The results appear to ver-

ify that hydrologic variables such as SCS curve numbers and vegetation characteristics can be reliably estimated from remotely sensed images. More significantly, the results support the contention that remotely sensed data from different sources can be integrated into a consistent data base for hydrologic modeling. The land-cover data were obtained from different sources corresponding to the periods of time when particular sources were available. Of particular note are the results of the 1973–1982 simulations (Figure 16.8) that were based upon the land cover obtained from the classified aerial photographs and the 1985 TM image. The simulations for this period were as accurate (r = 0.89) as were the more recent simulations (r = 0.87) for the Guanajibo based on the CAMS images (Figure 16.7).

CONCLUSIONS

Remotely sensed data integrated into a GIS environment has been shown to be a valuable asset in hydrologic modeling. In fact, recent developments have shown that remotely sensed data and GIS tools are virtually indispensable resources for modeling over large spatial domains. The development of macroscale hydrologic models, either to serve as land surface components of atmospheric circulation models, or to function in conjunction with such models, is largely predicated upon remote sensing/GIS principles. Remotely sensed data makes it possible to update hydrologic parameters at relevant temporal scales (monthly, seasonally, annually) over very large spatial domains. The increased speed, efficiency, and cost-effectiveness of GIS and image processing hardware and software have brought these capabilities down to the desktop level. In addition, the products derived from remotely sensed data, as well as the raw images themselves (many of which are available on-line at no charge) are available to virtually every hydrologic modeler. A large variety of remote sensing instruments are currently available with even more planned for launch in

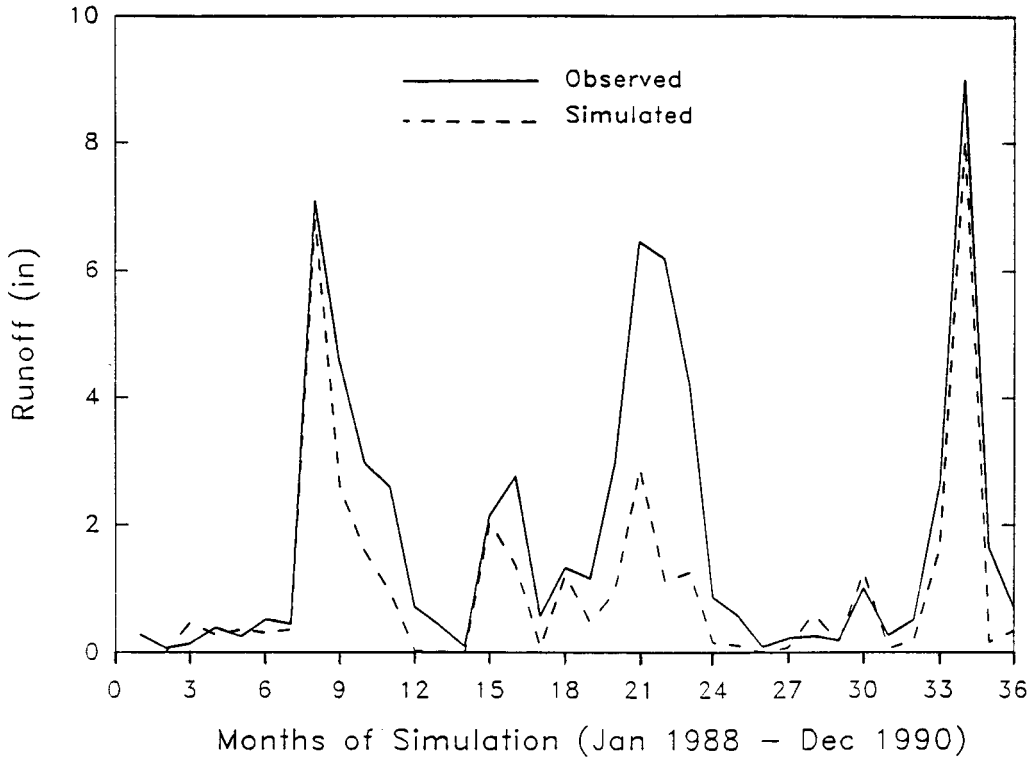

Figure 16.7. Runoff simulation results versus observed data for Rio Guanajibo, Puerto Rico; 1988–90 (Cruise and Miller, 1994).

the near future. These new hyperspectral instruments will greatly increase the use of remotely sensed data in hydrology by providing the basis for more accurate estimation of such products as soil moisture, snow cover, precipitation distribution, land cover, and vegetation biomass. Advances in hydrologic modeling methods to make use of these data at varied spatial and temporal resolutions will continue to be a major focus of research in the hydrologic sciences.

ACKNOWLEDGMENTS

A large portion of the research on hydrologic processes in Puerto Rico was conducted while the senior author was supported by a joint NASA/National Research Council Associateship at Stennis Space Center (SSC), MS. Dr. Armond Joyce, Education Affairs officer at SSC, provided assistance during this period. Additional financial support for this work was provided by NASA under grant NAGW–849 from the office of University Affairs, NASA Headquarters. Mr. Hassan Mashriqui of Louisiana State University, Baton Rouge, LA aided in classification of the Landsat TM data. We thank Jim Anderson, Greg Booth, Greg Carter, and Marco Giardino for their comments on an earlier version of this chapter.

CHAPTER 17

Technological Advances in Automated Land Surface Parameterization from Digital Elevation Models

Jurgen Garbrecht, Lawrence W. Martz, and Patrick J. Starks

INTRODUCTION

Topography plays an important role in the distribution and flux of water and energy within natural land surfaces. Classical examples include surface runoff, evaporation, infiltration, and heat exchange which are hydrologic processes that take place at the ground-atmosphere interface. The quantitative assessment of the processes depend on the topographic configuration of the land surface, which is one of several controlling boundary conditions. Many topographic parameters can be computed directly from a Digital Elevation Model (DEM) (Band, 1986; Jenson and Domingue, 1988; Mark, 1988; Martz and Garbrecht, 1992, 1993; Moore et al., 1991; Tarboton et al., 1991; Wolock and McCabe, 1995). This automated extraction of topographic parameters from DEMs is recognized as a viable alternative to traditional surveys and manual evaluation of topographic maps, particularly as the quality and coverages of DEM data increase. Manual evaluation of topography is general tedious, time-consuming, error-prone, and often subjective (Richards, 1981).

This chapter presents four advances in computerized methods to extract topographic parameters from DEMs. The first two advances address the treatment of depressions and flat surfaces in the DEM. Most existing methods for handling depressions and flat areas in DEM processing for drainage analysis are based on some common and fundamental assumptions about the nature of these features. These assumptions are largely implicit to the methods and are usually not recognized explicitly. These are: (1) that closed depressions and flat areas are spurious features that arise from data errors and limitations of DEM resolution; (2) that flow directions across flat areas are determined solely by adjacent cells of lower elevation; and (3) that closed depressions are caused exclusively by the underestimation of DEM elevations. While the first of these seems reasonable, the others are not. It is possible to make more reasonable assumptions about the controls on flow direction and the cause of closed depressions and to incorporate these assumptions into new algorithms for handling difficult topographic situations encountered in raster DEM processing for drainage analysis. The two new algorithms presented here are based on a deductive but qualitative assessment of the most probable nature of depressions and flat areas in raster DEM.

The last two advances address the identification of the topology of the channel network from raster images, and the parameterization of irregular overland or hillslope areas. The topology of the channel network is captured in terms of network node indexing and channel ordering by the Strahler method (Strahler, 1957). Channel ordering and node indexing is fundamental to the automation of flow routing management in distributed surface hydrology models and morphometric

evaluation of channel network structure. The node index numbers can also serve to link network nodes and channel data stored in tabular format. The parameterization of subcatchments quantifies the length, width, and slope of rectangular planes representing irregularly shapes overland and hillslope contributing area. This rectangular subcatchment conceptualization is often used in distributed modeling of hillslope runoff and erosion processes. The presented subcatchment parameterization algorithms are an important contribution to traditional watershed modeling because the algorithms automate a task that is subjective and requires experience in interpretation and conceptualization of irregular hillslope features.

In the following section the fundamental principles underlying the algorithms and the essential components of the algorithms are presented. Related discussions in the broader context of water resources can be found in Garbrect and Martz (1999a). Issues relating to technical details and the implementation of these algorithms into digital land surface processing exceed the framework of this chapter. The presented technological advances are incorporated in the topographic parameterization model TOPAZ (TOpographic PArameteriZation) which automatically segments and parameterizes watersheds from DEMs for water resources, hydraulic, and hydrologic applications (Garbrecht and Martz, 1999b, 2000).

TREATMENT OF SPURIOUS DEPRESSIONS IN DEMS

Depressions are groups of raster cells completely surrounded by other cells of a higher elevation. They are usually artifacts that arise from data inaccuracies, interpolation procedures, and limited horizontal and vertical resolution of the DEM (Mark, 1983, 1988; Tribe, 1992; Zhang and Montgomery, 1994). They represent a major difficulty for DEM processing procedures that are based on the downslope flow routing concept (Martz and Garbrecht, 1992) because the existence of a downslope flow path at every cell is assumed. In the case of a depression there is, by definition, no outflow, and procedures based on an assumed downslope flow path are bound to fail.

The traditional solution to this problem is to remove all depressions in the DEM by raising the elevations within the depression to the elevation of its lowest outlet. This procedure is called "filling" of the depression. Two assumptions are implicit to this approach: (1) depressions are spurious features that arise from interpolation errors or insufficient precision in elevation values; and, (2) all depressions are due to the underestimation of elevation and should be filled. The practice of eliminating depressions solely by filling is likely to introduce systematic bias into the modified DEM. In reality, elevation errors in the DEM are as likely to result from elevation overestimation as from underestimation, and some depressions arise from the obstruction of flow paths by over-

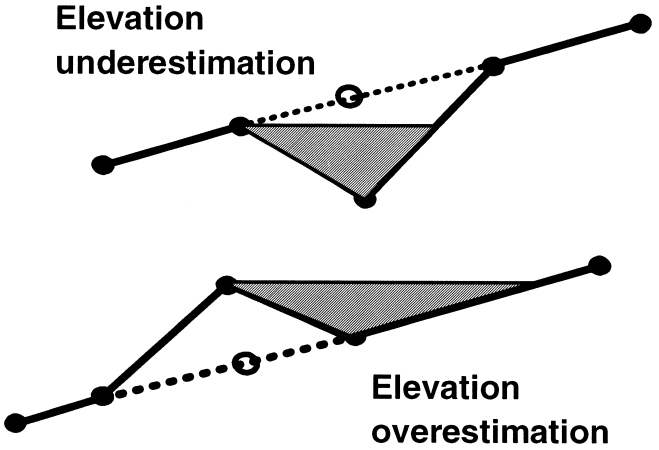

Figure 17.1. Two dimensional schematic profiles illustrating depressions arising from elevation underestimation and elevation overestimation (figure from Martz and Garbrecht, 1997).

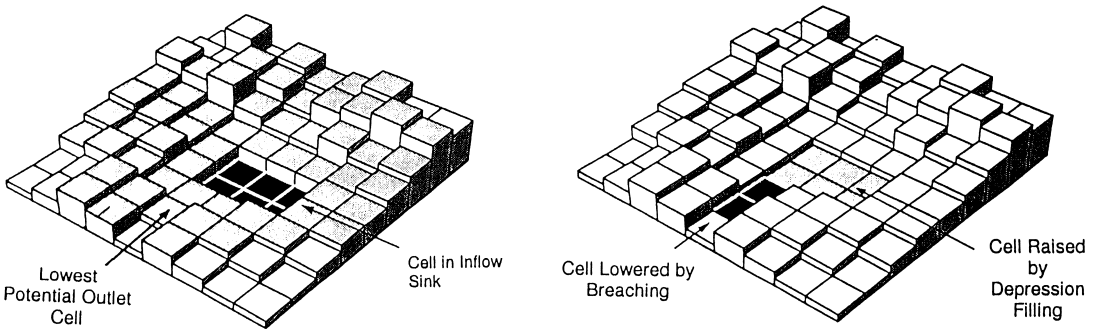

Figure 17.2. Breaching and filling of a spurious depression in a DEM: (2a) depression and outlet identification; (2b) outlet breaching and final filling of depression (figure from Garbrecht, Starks, and Martz, 1996).

estimated elevations (Figure 17.1). In such cases, breaching the obstruction is more appropriate than filling the depression created behind the obstruction. This breaching approach reduces or eliminates the filling of depressions created by narrow obstructions. It is particularly effective in DEMs of low relief landscapes in which obstruction of flow paths are more prevalent.

A three-step algorithm is used for breaching narrow obstructions along flow paths. First, the spatial extent of each depression and its contributing area is delineated. Second, potential outlets or overflow points on the edge of the depression area are defined. Potential outlets are those raster cells within the depression area which are: (1) adjacent to a cell outside the depression area, and (2) at a higher elevation than a cell outside the depression area. The lowest of these potential outlets is selected as the depression outlet. Third, the selected outlet is evaluated for possible lowering to simulated breaching (Figure 17.2a). The number of cells at the outlet that may be lowered by breaching is termed the breaching length. To restrict breaching to relatively narrow obstructions, the breaching length is arbitrarily set to one or a maximum of two cells. If the breaching length is longer than two cells the flow obstruction is likely to be a true topographic feature, and outlet breaching is not permitted. In the presence of a one- or two-cell breaching length, the elevation of the outlet cell(s) are lowered to the lesser elevation of the cells outside or inside of the depression at the breaching site (note: both cells outside and inside the depression at the outlet are of lower elevation per definition of the breaching length). This third step changes the elevation of the outlet and effectively breaches the obstruction responsible for the depression (Figure 17.2b). If more than one potential breaching site exists, the one with the greatest breaching depth (primary criterion), and the shortest breaching length (secondary criterion) is selected. Finally, regardless of whether a breach is performed or not, the elevations of the remaining cells inside the depression and at a lower elevation than the outlet are changed to the elevation of the outlet (Figure 17.2b). This produces a continuous flat surface at the location of the depression. A more detailed coverage of depression breaching/filling can be found in Martz and Garbrecht (1999).

TREATMENT OF FLAT SURFACES IN DEMS

Truly flat land surfaces seldom occur in nature. However in DEMs, areas of limited relief can translate into perfectly flat surfaces. Perfectly flat surfaces in DEMs can be attributed to the following three causes: (1) too low a vertical and/or horizontal DEM resolution to represent the landscape, particularly affecting low relief landscapes; (2) filling of depressions; and (3) landscape that is truly flat, which seldomly occurs. Whatever their origin, flat surfaces are problematic because

flow direction on a perfectly flat surface is indeterminate (Speight, 1974; Tribe, 1992). This problem arises in automated drainage analysis with both the widely used D–8 flow routing approach (Fairchild and Leymarie, 1991) and for various multiple-direction and aspect-driven approaches (Costa-Cabral and Burges, 1994).

Traditionally, flow direction over flat surfaces in DEMs is defined using a variety of methods ranging from landscape smoothing to arbitrary flow direction assignment. For a short review of existing methods the reader is referred to Tribe (1992). Flow direction assignment over flat surfaces is particularly difficult within the framework of the D–8 method (Fairchild and Leymarie, 1991) because landscape properties are defined by the DEM cell at the point of interest and its immediate surrounding eight adjacent cells. Since all DEM cells on a flat surface have the same elevation value, a unique flow direction cannot be assigned. In the following, a generic numerical scheme is presented that allows for the identification of flow direction over flat surfaces.

This numerical scheme is based on the recognition that natural landscapes generally drain toward lower terrain while simultaneously draining away from higher terrain. This effect is incorporated into DEMs by incrementing elevations on flat surfaces to produce two gradients: one forces flow away from higher terrain; the second draws flow toward lower terrain. The selected elevation increment is arbitrarily small (say, 1 mm). Such small elevation increments are sufficient to identify flow direction over the flat surface, yet from a practical point of view they do not significantly alter the elevation of the digital land surface.

The gradient toward lower terrain is imposed by incrementing the elevation of all cells in the flat surface that are not adjacent to a cell with a lower elevation (outlet) or an existing downslope gradient. This incrementation is applied successively and repeatedly to all cells that after each incrementation pass still remain with no downslope gradient. In this way, a flow gradient toward lower terrain is constructed as a backward growth from the outlet(s) into the flat surface while at the same time satisfying all boundary conditions imposed by the higher and lower terrain surrounding the flat surface.

The gradient away from higher terrain is imposed by first incrementing the elevation of all cells in the flat surface that are adjacent to higher terrain and have no adjacent cell at a lower elevation. The imposed increment introduces a downslope gradient away from higher terrain for all cells immediately adjacent to higher terrain. In subsequent passes the incrementation is applied to all cells that have been incremented in previous passes, and also those cells that are in the flat surface and adjacent to an incremented cell, but not adjacent to a cell of lower elevation. The result of this incrementation is a gradient away from higher terrain which is grown from the edges of the higher terrain into the flat surface.

In a final step, the cumulative gradients applied in the previous two steps are linearly added for each cell to determine the total incrementation. Adding the total incrementation to the initial elevation of each cell results in a surface that is no longer flat and includes a gradient away from higher terrain, and a gradient toward lower terrain. The net effect of the elevation incrementation is the modification of elevations on the flat surface which will produce, by means of subsequent DEM processing, a flow direction pattern that is consistent with the topography surrounding the flat surface and that displays flow convergence properties. A more detailed description of drainage identification over flat surfaces can be found in Garbrecht and Martz (1997a).

The effect of the algorithm is illustrated using a saddle topography between two mountains (Figure 17.3). The saddle consists of a flat surface between higher terrain to the right and left (hatched) and three locations of lower terrain (circles). Additional complications are introduced by a wedge of higher terrain protruding into the flat surface from the bottom, and a rectangular indentation of the flat surface into higher terrain at the top right corner of the figure. The arrows show the computed drainage over the flat surface. The arrow size is proportional to the upstream

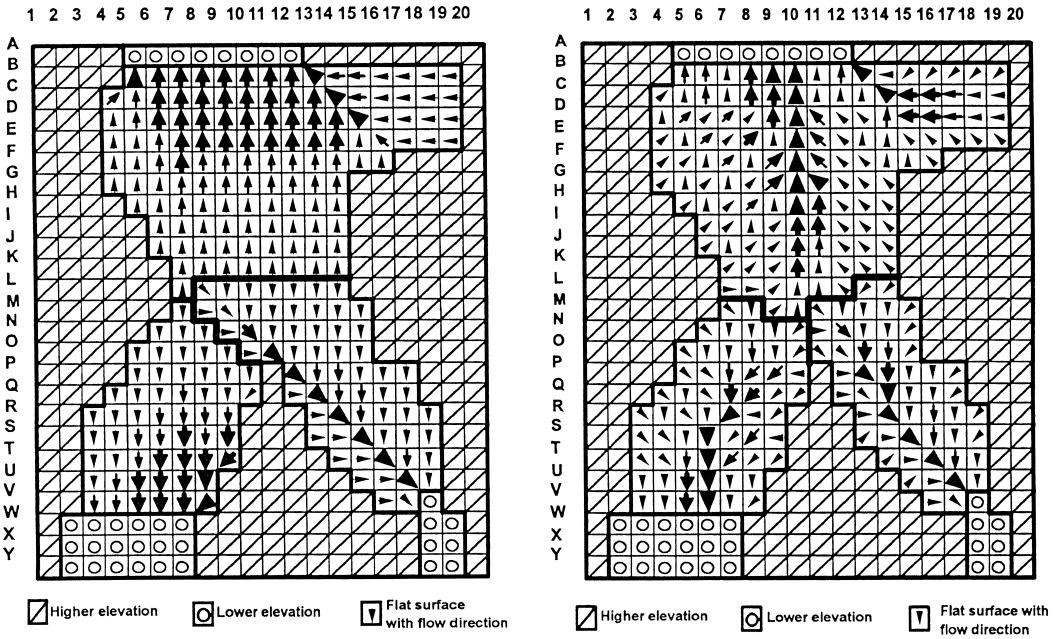

Figure 17.3. Drainage pattern over a saddle topography: (a) traditional approach; (b) new approach (figure from Garbrecht and Martz, 1997a).

drainage area of the flat surface. Figure 17.3a shows the drainage pattern produced by the model of Martz and De Jong (1988) and Jenson and Domingue (1988). This drainage pattern suffers from the "parallel flow problem" and a lack of flow convergence (Fairchild and Leymarie, 1991). Figure 17.3b shows the corresponding drainage pattern produced by the presented procedure. The drainage displays flow convergence properties and is much more consistent with the topography of the overall saddle configuration.

A second example illustrates a curved valley with a flat floor flanked by higher terrain (Figure 17.4). In addition, a small hill in the valley center creates an obstruction to drainage. The arrows show the path of the main drainage line around the inside corner of the valley bend. Drainage from behind and below the small hill converge rapidly and join the main drainage line. Any tributary from the higher valley sides would enter the flat surface, follow the indicated arrows, and join the main drainage line within a short distance. The flow convergence and drainage pattern in Figure 17.4 is reasonable, given that the initial valley floor was flat and contained no topographic information to guide the drainage identification.

NETWORK AND SUBCATCHMENT INDEXING

Once the channel network and direct contributing areas are automatically defined from DEMs, they are usually displayed as a raster image which consists of strings and groups of raster cells with numeric codes or colors that distinguish the network and subcatchments. For these images to be useful in watershed management and runoff modeling, individual channel links and contributing areas must be explicitly identified and associated with topological information for upstream and downstream connections. Such identification is often possible in vector GIS, but usually not in raster GIS. An algorithm that can analyze images of raster channel networks, index network nodes,

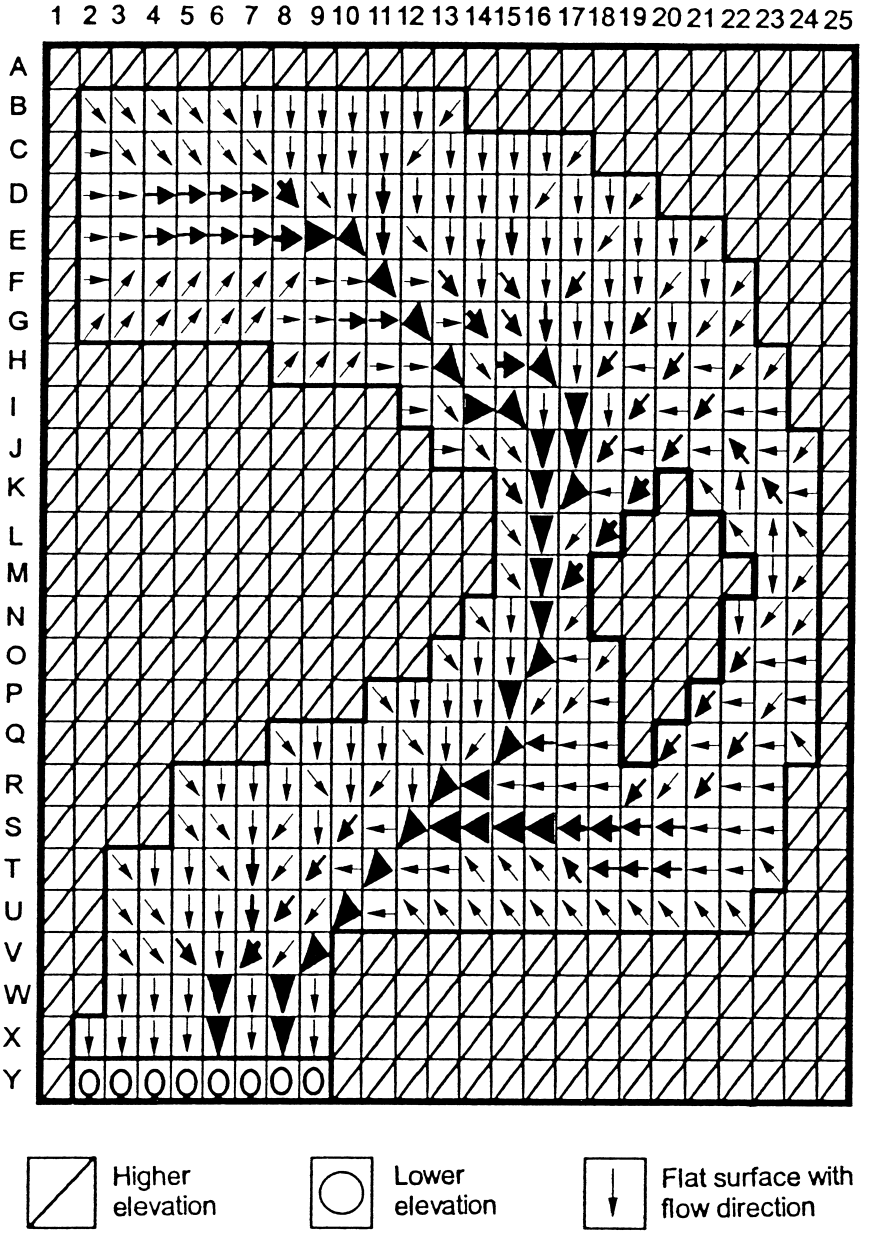

Figure 17.4. Drainage pattern on a flat valley floor (figure from Garbrecht and Martz, 1997a).

and order the channels by the Strahler method is presented. This algorithm provides a direct link between GIS images and hydrologic models, and leads to automated processing of segmented watersheds by distributed hydrologic models.

It is assumed that an image of an unidirectional, fully-connected network has already been defined. Four steps are required to fully identify the topology of the network and subcatchments. In the first step, flow direction information at each raster cell is used to move cell by cell along the channels of the network from upstream to downstream to determine the Strahler order (Strahler,

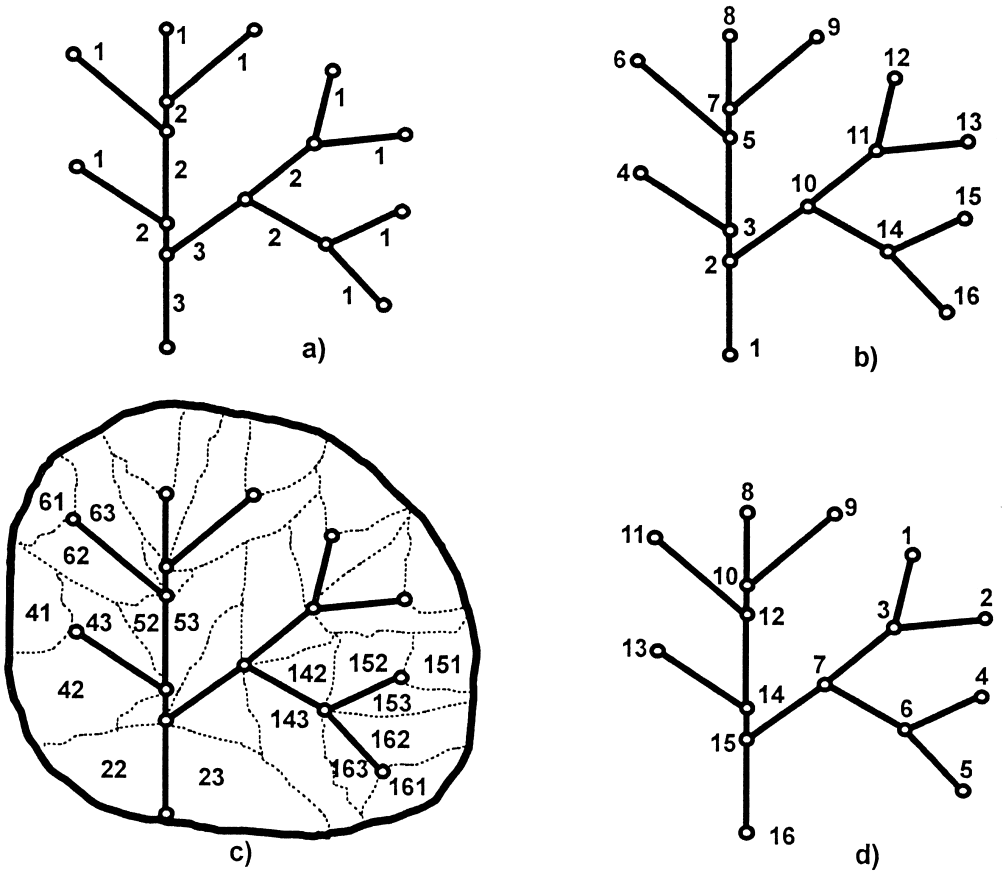

Figure 17.5. Drainage network and node indexing: (a) Strahler orders; (b) node indexing; (c) subcatchment indexing for selected node numbers 2, 4, 5, 6, 14, 15 and 16; (d) sequence in which the channels are to be processed for flow routing (figure from Garbrecht and Martz, 1997b).

1957) of each channel link and to identify the location of all source and junction nodes (Figure 17.5a). Flow direction is determined as the steepest downslope flow path from the current cell to one of the eight neighboring cells. In the second step, the node location and flow direction information are used to simulate a walk along the left bank of the channel network beginning and ending at the watershed outlet (Croley, 1980). The walk begins at the watershed outlet which is assigned node number 1. Then the walk traces the channel that ends at the outlet to the next node upstream. At that node the left channel is followed further upstream. As each node is passed during this walk, it is assigned the next sequential node number (Figure 17.5b). When a source node is encountered the walk moves in the downstream direction until a partially evaluated node is encountered, at which time the node-by-node walk is resumed again in an upstream direction along the unevaluated channel branch.

In the third step, the subcatchment areas for each channel link are identified. These consist of direct contributing areas into the left-bank, right-bank and, in the case of exterior links, into the source of the channel link. Subcatchments are assigned an identification code based on the previously assigned node numbers. For all subcatchments, a base identification number is assigned which is the node number (NN) at the upstream end of the link to which the subcatchment drains multiplied by 10 (NN*10). For source node subcatchments a value of 1 is added to (NN*10), for

left-bank subcatchments a value of 2 is added, and for right-bank subcatchments a value of 3 is added. Channel cells (which are not considered to be part of the right-bank, left-bank, or source node subcatchments) are assigned an identification code of (NN*10) plus 4 (Figure 17.5c).

These identification codes provide a basis on which network links, nodes, and subcatchments can be associated with one another. Most importantly, in a fourth step the node numbering scheme can be used to determine the optimal routing sequence to be used in modeling streamflow through large and complex networks (Garbrecht, 1988) (Figure 17.5d). The algorithm makes possible the automated quantification of network structure from raster network images and greatly enhances the direct linkage of GIS-generated channel networks and hydrologic and hydraulic models. Further details on this algorithm can be found in Garbrecht and Martz (1997b).

OVERLAND AREA PARAMETERIZATION

Automated identification of landscape parameters for individual overland areas within a subdivided watershed is the next step in automated DEM processing for hydrologic/hydraulic model application (Goodrich and Woolhiser, 1991). Overland areas are defined as undissected hillslopes of irregular shape that drain directly into a channel link. For hydrologic modeling these overland areas are often approximated by a rectangular plane of given width (W), length (L) and slope (S) (Wooding, 1965; Smith at al., 1995; Feldman, 1995). Such a Wooding representation of a subcatchment consists of two rectangular planes joined to form a V-shaped valley along which the stream flows (Figure 17.6). The geometric dimensions W, L, and S of the plane are essential for the determination of the magnitude, shape, and timing of the overland runoff hydrograph, and are used in models such as KINEROS (Smith et al., 1995) and the kinematic option of HEC–1 (Feldman, 1995). Three numerical expressions are presented that identify the plane parameters to reproduce the hydraulic runoff characteristics of the original overland areas. These expressions are implemented using flow path, accumulated area and elevation data derived from the DEM raster. This raster data can be obtained by suitable DEM processing software such as the digital landscape analysis tool TOPAZ (Garbrecht and Martz, 1999b, 2000).

The definition and assumption necessary for the first algorithm are: (1) a flow path is the route traveled by the water from an upstream source to the channel at the downstream edge of the overland area; and, (2) flow paths with large discharge contribute proportionally more to the runoff hydrograph characteristics than flow paths with small discharge. Based on this definition and assumption the model for hydraulically representative plane length (L) can be formulated as a discharge-weighted mean length of all flow paths within the irregular overland area. Furthermore, the discharge on hillslopes is often proportional to upstream area, and the expression for plane length can be formulated as follows:

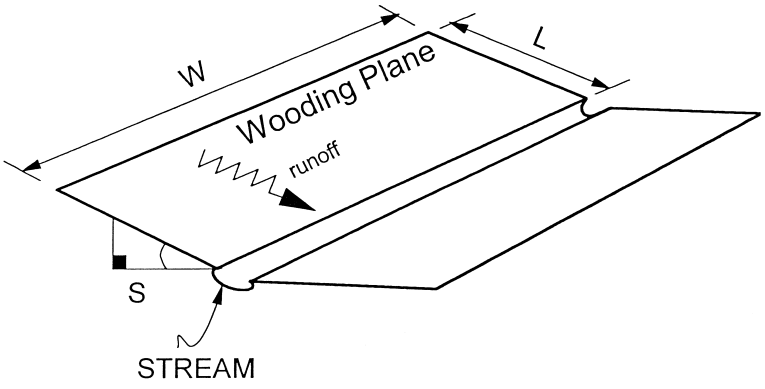

Figure 17.6. Wooding catchment representation (figure from Garbrecht, Martz, and Goodrich, 1996).

$$L = \frac{\sum_{i=1}^{n} l_i * a_i}{\sum_{i=1}^{n} a_i} \tag{1}$$

where l is flow path length, a is upstream drainage area, and subscript *i* is flow path counter.

The second numerical expression defines the plane width and is derived from area and water conservation considerations. To ensure water continuity and area conservation, plane width is computed as the overland area (A) divided by the plane length (L) computed by Eq. 1.

Finally, the expression for plane slope is a weighted average of all flow path slopes. Flow path slope is defined as the change in elevation from the top to the bottom of the flow path divided by flow path length. All flow paths in the irregular overland areas are considered. The expression for the plane slope is given by:

$$S = \frac{\sum_{i=1}^{n} s_i * k_i}{\sum_{i=1}^{n} k_i} \tag{2}$$

where s is flow path slope and k is a weighting factor. The weighting is defined in one of three ways: (1) upstream drainage area weighted with $k_i=a_i$; (2) flow path length weighted with $k_i=l_i$; or, (3) upstream drainage area times flow path length weighted with $k_i=a_i*l_i$.

In the first case, length weighting is used because slope estimates of long flow paths are generally more accurate since the elevation and length values have been obtained over a larger number of discrete raster units, effectively reducing the raster resolution noise. Length weighting also favors flow paths with larger drainage areas (i.e., larger discharge) because drainage area and flow path length are often related. In the second case, drainage area weighting is used to emphasize flow paths with larger drainage areas which contribute proportionally more to the runoff hydrograph characteristics than those with smaller drainage areas. The third case is a combination of the first and second case with the product of length and drainage area as the weighting factor. Until further research establishes the most appropriate method for the estimation of plane slope, the results of each of the three methods should be considered in the determination of the final plane slope.

A more detailed discussion of the overland area parameterization can be found in Garbrecht et al. (1999).

CONCLUSIONS

Advances in the treatment of depressions and flat surfaces, the identification of network topology, and the parameterization of overland areas are presented. The proposed depression removal by a combination of breaching and filling, as well as the gradient imposition of flat surfaces, produce a more realistic and consistent drainage pattern than traditional depression filling and local drainage searches over flat areas. The presented improvements are particularly important for drainage and erosion investigations.

The identification of channel network and subcatchment topology from raster images provides an important linkage between DEM-derived drainage features and automated watershed management and hydrologic modeling. Finally, the length and slope of the rectangular overland area ap-

proximation are computed as drainage area weighted averages over the length and slope of all flow paths in the irregular overland areas. The strength of the procedure lies in its consideration of the geometric properties of each contributing flow path rather than relying on a lumped approach, and in the consideration of qualitative cause-effect relations between flow path and runoff characteristics to emphasize flow paths that are more important to the runoff process.

CHAPTER 18

Aerial Photointerpretation of Hazardous Waste Sites: An Overview

Donald Garofalo

INTRODUCTION

Much interest has been expressed recently by scientists interested in the capabilities and limitations of various remote sensors for characterizing hazardous waste and waste disposal sites. Special attention has been focused on the ability of these sensors to locate and characterize waste and waste site activities at abandoned facilities. As such, sophisticated new radar systems, thermal sensors, and other multispectral and hyperspectral scanners are being assessed as potential candidates for addressing the waste discovery and characterization problem.

Airborne radars can penetrate sand in hyperarid environments, between 1–6 meters in depth (Sabins, 1987); penetration is minimal in humid soil areas. Thermal sensors can display temperature variations at the surface, sometimes suggestive of subsurface conditions and multispectral and hyperspectral scanners can detect subtle changes in the surface environment which may be suggestive of buried features. The historical aerial photograph, however, frequently has resolutions for detecting barrel size or smaller features, and the ability to show site conditions long ago. Thus, the historical aerial photograph, unlike many newer and more sophisticated sensors, is an inexpensive source of invaluable information which can be used to locate a waste disposal site and measure accurately the size and dimensions of currently buried or overgrown features and to generally track the history of waste disposal site activity from beginning to end.

THE HISTORICAL AERIAL PHOTOGRAPH

The historical aerial photograph is the sensor of choice of the Environmental Protection Agency's Environmental Photographic Interpretation Center (EPIC), which for the past 25 plus years has been applying this tool for locating potential waste disposal sites and characterizing these sites and associated waste disposal practices. The historical aerial photograph is an extremely powerful remote sensing tool. It is the only remotely sensed data to have recorded events at sites frequently as far back in time as the 1930s. This is of immense value to the Superfund program which is charged with looking for and evaluating abandoned hazardous waste disposal sites, sites which today may display no evidence at the surface of their former use (Slonecker et al., 1999). The tool is of substantial value in litigation as evidence of the past waste disposal practices of PRPs (Principal Responsible Parties), and has been highly successful at assisting EPA and Department of Justice lawyers in winning their cases. In addition, the ability to view the aerial photo stereoscopically (in 3-D) and to measure, using photogrammetry, the heights, depths, volumes, and other dimensions of features and materials currently present, long removed from, or buried at

a site has also contributed invaluable evidence in courtroom situations, and has helped to reconstruct pictorially for jurors and judges alike and in an easily understandable format, the activity at a site over time. Finally, the availability of historical aerial photographs from both government and private sources, and the extent of aerial photo coverage of the United States, through various federal agency mapping programs such the Agricultural Stabilization and Conservation Service (now Farm Services Agency), and the U.S. Geological Survey, to name only two, have literally ensured that a hazardous waste disposal site located within the conterminous US has been overflown and site conditions documented more than once during the site's disposal history.

This chapter focuses on the value of the historical aerial photograph and the various image analysis and mapping functions which use aerial photos for analyzing hazardous waste disposal sites.

THE BASICS OF AERIAL PHOTOINTERPRETATION FOR WASTE SITE CHARACTERIZATION

Backlighting and Variable Magnification

Using backlighted tables with adjustable illumination, and high-power magnification zoom stereoscopes, aerial photographs are interpreted for site size, drainage patterns, type of fill materials, leachate, burial sites, lagoons, impoundments and their contents, and general condition of the site. Locations and descriptions of tanks, drums, open storage areas, evidence of vegetation stress, on-site obstacles, structures, equipment, access routes, and other details may also be obtained through photo analysis. Historical analysis provides the information necessary to obtain a chronological understanding of a site's development and activities. This information is particularly important for describing and illustrating past activities and conditions at abandoned hazardous waste disposal sites which fall under the jurisdiction of the Comprehensive Environmental Response, Compensation, and Liability Act (aka Superfund) program.

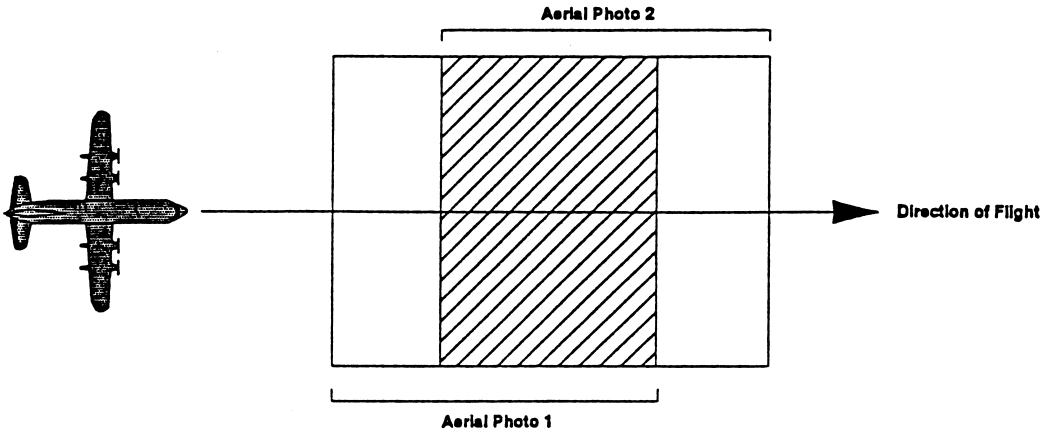
Film Transparencies

The use of aerial photo transparencies on backlighted variable illumination tables maximizes the available information content of analyzed aerial photographs. Aerial photo transparencies are first generation copies of originally exposed film. Each additional step of film processing, such as producing additional film copies or photographic prints degrades from the original product and reduces the amount of information contained in the original photo. High-powered magnifying scopes are used to identify subtle, but often significant features on aerial photos which can easily be overlooked if not viewed with the benefit of backlighting and variable magnification.

Stereoscopy

The importance of stereoscopy in the photointerpretation process cannot be ignored. Stereoscopy allows the photo analyst to see features on an aerial photograph in three dimensions (3-D). Through stereoscopic parallax (the apparent displacement of the position of a feature in an image caused by a change in the position of observation) a stereoscope may be used to view overlapping aerial photographs to provide a three-dimensional effect of features on the ground (Figure 18.1). When coupled with various measuring devices such as stereo comparators or other digital photogrammetric devices highly accurate measurements can be made of the dimensions (height, widths, lengths, depth) of features seen on the aerial photograph. Volumes of materials and volu-

Acquisition of Stereoscopic Aerial Photographs and Stereoscopic Parallax *



Area of 60% Forward Lap
Area of Forward Lap represents the same ground area photographed along a flightline by two overlapping aerial photos.

* Stereoscopic parallax is the displacement of the position of a feature in an image caused by a shift in the observation position. A stereo pair are two overlapping photos containing stereoscopic parallax, and which may be viewed using a stereoscope to provide a three-dimensional effect. The same effect can be obtained with a hand-held camera by taking a picture of the same object from two separate locations and then viewing the pair of pictures together with a stereoscope (Sabins, 1987).

Using special photogrammetric equipment accurate measurements can be made on stereo photo pairs. Contour maps which show differences in terrain elevation are also made using this technique.

Dimensions of features such as their length, width, and height, as well as volumetric measurements such as amounts of mounded materials, or depths and sizes of excavations can be calculated using photogrammetric tecniques.

Figure 18.1. Acquisition of stereoscopic aerial photographs and stereoscopic parallax. The area of 60% forward overlap is shown as the cross-hatched area, and it represents the same ground area photographed along a flightline by two overlapping aerial photos.

metric capacities of excavations can be calculated. This same technique is used to make topographic maps which show land surface elevations using contour lines.

The Signature Concept

A basic part of photointerpretation is the extraction of useful information from an image. Although this may be performed by human (manually) or machine (electronically by computer) depending on the form of the original data (e.g., as analog, hard copy photos versus digital images, respectively) the photo analysis performed by EPIC in support of EPA's hazardous waste program is conducted almost exclusively by manual, not machine analysis. Using manual methods, some types of information displayed on aerial photos are obvious to anyone used to reading a map. An example includes large bodies of water. However, the vast bulk of information is not evident to the untrained or inexperienced viewer.

The training and experience that makes feature identification possible on aerial photos is based on learning to recognize combinations of imagery characteristics called *signatures*. A *signature* is a combination of visible characteristics (such as color, tone, shadow, texture, size, shape, pattern, and association) which permit a specific object or condition to be recognized on an aerial photograph. The relative potential of a given signature to enable possible, probable, or positive identification of an object or condition is the *degree of certainty*. *Possible* is a term signifying a degree of certainty of signature identification when only a few characteristics are discernible on a photo or these characteristics are not unique to a signature. *Probable*, on the other hand, is a term signifying a degree of certainty of signature identification when most characteristics, or strong or unique characteristics of a signature are discernible but fall short of positive identification.

When interpreting an aerial photograph, the analyst is generally searching for the signature of one or more objects or conditions by viewing aerial photo stereopairs through stereoscopes. An analyst relies either on experience or "ground truth" information (corroborative information obtained through other data sources or on-site field visits to the site) in identifying signatures. When working with historical aerial photographs of areas that have changed or are inaccessible, experience becomes critically important. For some forms of photo-interpretation, e.g., to map wetlands vegetation or forest types, signatures representative of various vegetation types are confirmed by on-site visits and then extrapolated over a much larger area to map vegetation types displaying the same signatures, but not visited on the ground.

The *signature* concept is not an all or none concept since signatures can vary in degree of certainty. Because of this it is essential to clearly distinguish between positive identifications and calls of lesser certainty. Because hazardous waste site characterization by aerial photo interpretation may be used to support civil or criminal litigation, it is important that the degrees of certainty be clearly stated by the photo interpreter.

The characteristic signature of a given object or condition can vary with the type of film or imagery, scale, resolution, and other factors. Therefore, aerial photos vary in suitability depending on the object of the analysis. For example, 55-gallon drums can be positively identified on average quality, 1:6,000 scale aerial photographs. On the other hand, typical 1:20,000 scale aerial photos do not normally allow for positive identification of drums, but may allow for *possible* or *probable* identifications to be made. Even smaller scale (higher altitude) imagery is so inappropriate for drum identification that even *possible* identifications cannot be made. Variability in photo type also affects the interpretability and signatures of objects. Natural color, color infrared, and black and white aerial photos, for example, have no sensitivity for heat detection, while thermal scanner imagery can reveal temperature differences of objects. An experienced photo interpreter is able to use a variety of remote sensing tools and is fully knowledgeable of the capabilities *and* limitations

Table 18.1. Hazardous Waste Disposal Site Features/Activities Routinely Extracted by Image Analysis from Historical Aerial Photographs

Access road	Extraction area	Pressure tank
Berm	Feature boundary	Probably underground drainage
Building	Feature outline	Railroad
Channelized drainage	Fence	Refuse
Chemical storage	Fenced site boundary	Revegetated
Cleared area	Fill	Revetment
Container	Flow direction	Site boundary
Crates/boxes	Graded area	Sludge
Culvert/bridge	Ground scar	Solid waste
Cylindrical object	Historical boundary	Stacked objects
Dark-toned	Horizontal tank	Stain
Debris	Impoundment	Standing liquid
Dike	Indeterminate drainage	Structure
Disposal area	Lagoon	Study area
Disturbed ground	Landfill	Surface runoff
Drainage	Leachate	Suspected drainage
natural	Light-toned	Tank farm
channelized	Liquid	Tank trailer
suspected or historical	Material	Trench
indeterminate flow	Medium-toned	Unfenced site boundary
natural	Mounded material (extensive)	Vegetated
channelized	Mounded material (small)	Vegetation stress
tidally influenced	Objects	Vehicle
natural	Open storage	Vehicle access
channelized	Outfall	Vertical tank
Drums	Pipeline	Waste disposal area
Edge of slope	Pit	Wastewater treatment plant
Excavation	Pond	Wetland
Excavation, pit (extensive)	Possible drum area	

of these tools for specific applications. Table 18.1 is a listing of the kinds of features, natural resources, and site activities which are routinely identified on aerial photographs by skilled image analysts for characterizing waste disposal sites.

OVERVIEW

Hazardous Waste Site Analyses

Hazardous waste disposal site characterization using historical and current aerial photographs comprises a major part of EPIC's workload. Utilizing the vast archives of aerial photographs of the country maintained by government and private sources, dating back to the 1930s, EPIC's analysts reconstruct the waste handling and disposal history of a site in order to support site cleanup and regulatory or enforcement efforts. Aerial photographs have proved to be powerful tools in court in the form of evidence and to support expert witness testimony and for facilitating the recovery of millions of dollars in site cleanup costs and penalties from responsible parties (Garofalo and Wobber, 1974; Erb et al., 1981; Evans and Mata, 1984; Stohr et al., 1987; Mata and Christie, 1991).

The information interpreted from an aerial photograph is annotated onto a clear film overlay which identifies and delineates the location of significant ground features and activities. Accom-

Figure 18.2. Sample historical site analysis prepared by EPIC. October 19, 1958. No significant activity was evident on the 1946 or 1947 photographs (not shown here). Significant features observed on the 1951 photographs are annotated and discussed in conjunction with the following analysis.

The landfill study area consists of two landfills, the Western Landfill and the Eastern Landfill. Both landfills are south of Wheatfield Road. No significant activity is visible within the portion of the study area north of Wheatfield Road throughout the analysis, and this area will not be discussed further.

Each landfill is divided into three portions for the purpose of discussion. The northern, central, and southern portions will not be annotated further. Fill areas are annotated in both landfills throughout the analysis, but are not discussed individually. Disposal activities noted within fill areas are annotated and discussed.

Drainage at and around the landfill is shown in the Wetland and Drainage analysis (Figure 18.10). Minimal changes were evident in the overall drainage routes throughout the years of analysis. Minor variations in drainage resulted from the gradual development of the landfill. These transient drainage routes are annotated for each year of analysis, but are not discussed unless a significant change is visible.

Western Landfill. No significant activity is evident.

Eastern Landfill. Northern portion. In 1951, possible refuse (R) was noted in a possible fill area (FA) outside the eastern site boundary.

In 1958 the east side has been partially cleared (not annotated). Material (M) is piled in three areas within the clearing. A possible excavation (EX) with dark-tone (DK) liquid (LQ) is noted on the south edge of the clearing. Possible refuse remains evident in the possible fill area outside the eastern site boundary.

Central and southern portions. No significant activity is evident.

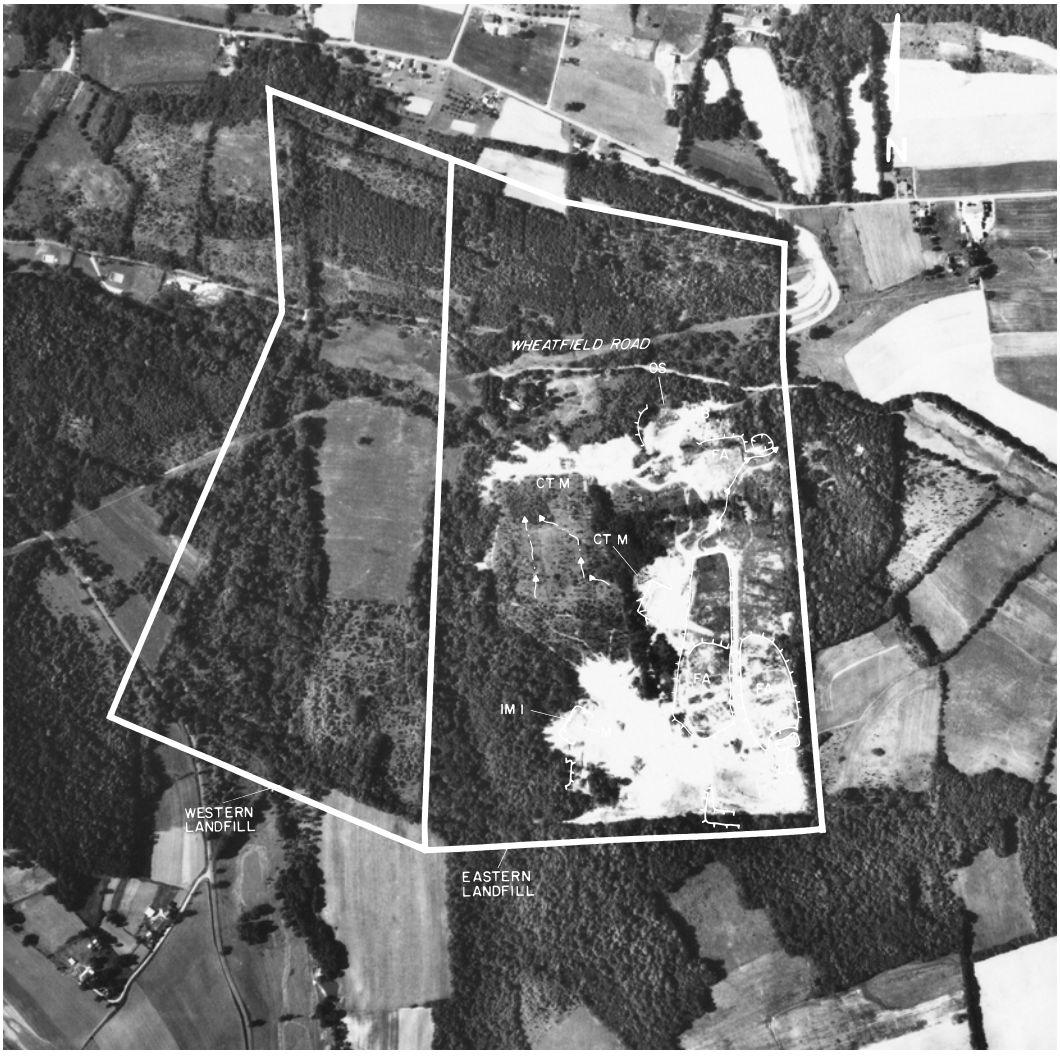


Figure 18.3. June 17, 1964. Western Landfill. No significant activity is evident.

Eastern Landfill. Extensive clearing (not annotated) is underway in the eastern landfill, and brush piles (not annotated) are scattered throughout the clearing.

Northern portion. The material and possible excavation with liquid seen in 1958 are no longer visible. Piles of coarse-textured (CT) material, an open storage (OS) area, a building (B) with a parking area, and an empty excavation, possible a catchment basin, are noted in the northern portion of the landfill. A variety of objects and equipment are visible in the open storage area. The open storage area, building and parking area remain active and expand throughout the analysis, and will be annotated but not discussed in detail.

The possible refuse seen outside the eastern site boundary in 1958 is no longer visible.

Central Portion. Piles of coarse-textured material and a rectangular bermed area are visible. The bermed area appears empty, and its use is not evident.

Southern Portion. An impoundment (IM1) and an excavation are visible. IM1, a leachate collection impoundment, is dry inside and contains a small amount of material. The excavation contains murky liquid.

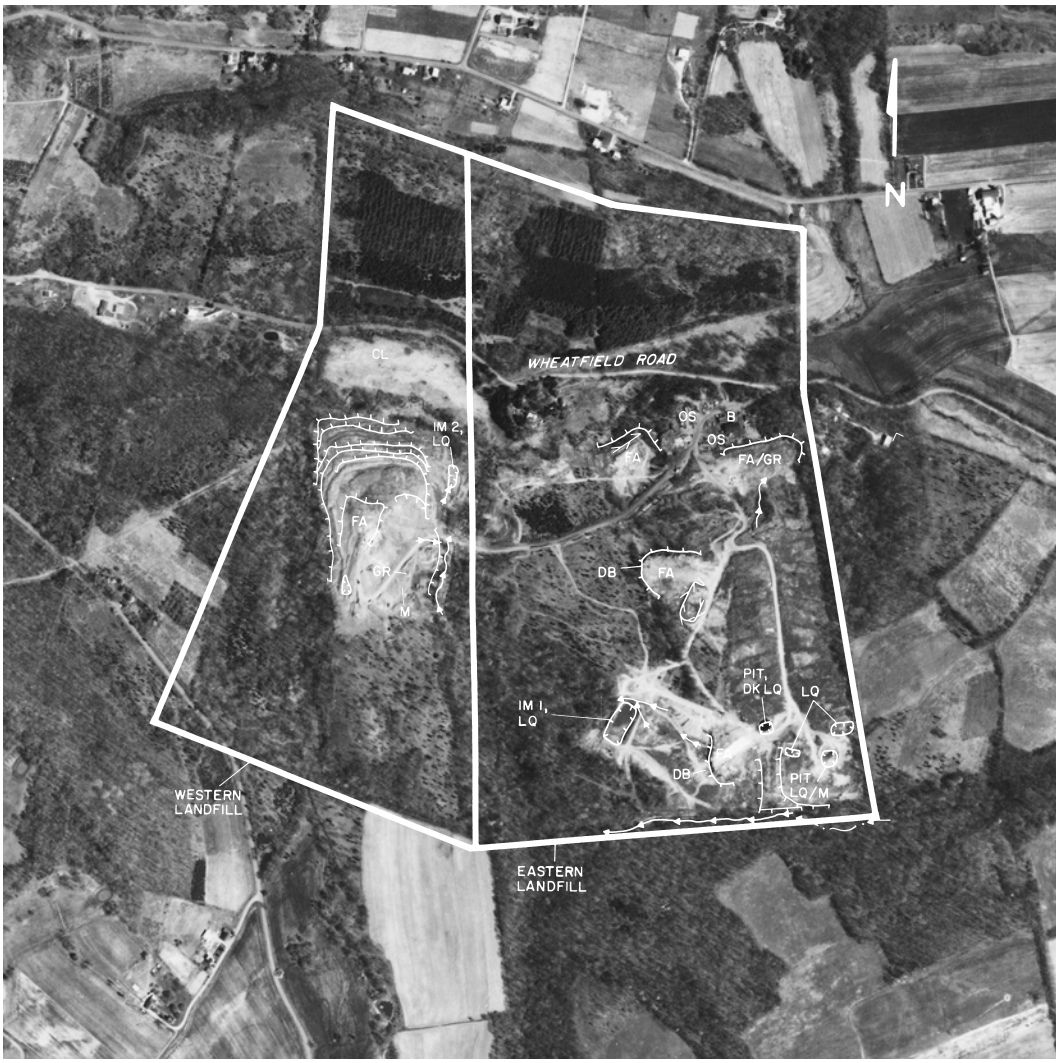

Figure 18.4. April 17, 1968. Western Landfill. North portion. A wetland has been cleared (CL); however, there is no evidence of fill activity in this location.

Central Portion. Extensive filling has occurred since 1964, an impoundment (IM2), an excavation, grading (GR), and material are evident. A channel leads from the east edge of the landfill into IM2. Murky liquid is visible in the channel and in IM2. The excavation is on the southwest side and appears to be empty.

Southern portion. No significant activity is evident.

Eastern Landfill. Northern portion. The coarse-textured material noted in 1964 is no longer present. A berm and the grading of a fill area are evident in the northern portion. The graded fill area includes the former excavation which was noted in 1964.

Central portion. The bermed area and debris (DB) are visible. The bermed area remains empty, and the debris is along the edge of a fill area.

Southern portion. IM1, debris, two pits, and two excavations are visible. IM1 contains liquid, the debris is along the edge and sides of a fill area, the northern pit is full of dark-toned liquid, and the southern pit contains a small amount of dark-toned liquid/material. Both excavations contain murky liquid.

A drainage channel is visible at the south edge of the site. It receives runoff from slopes south and east of the landfill as well as from on-site. The channel leads west to the natural drainage, which flows north (Figure 18.10).

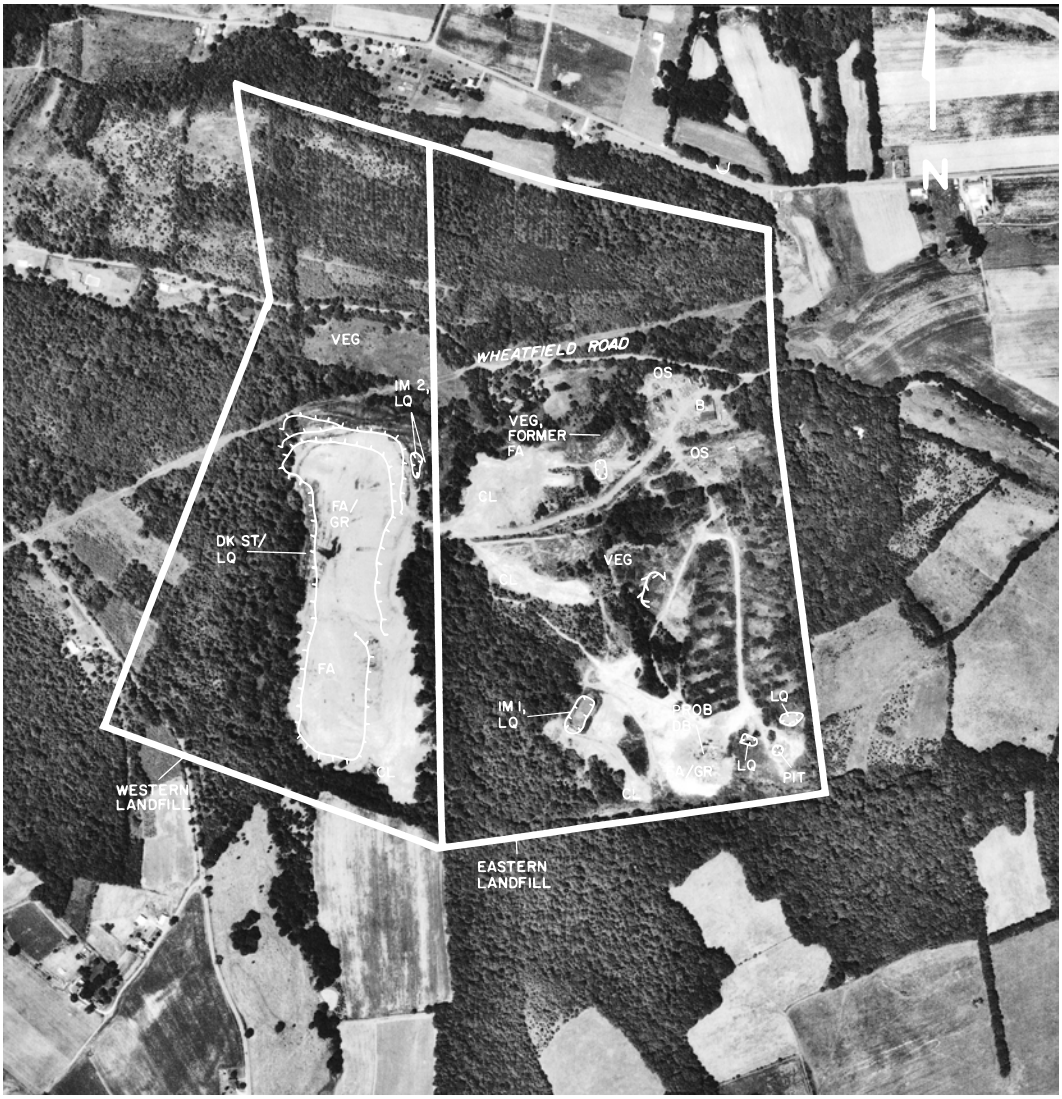

Figure 18.5. July 18, 1971. Western Landfill. North portion. Vegetation (VEG) is growing where the clearing of a wetland was noted in 1968.

Central Portion. Filling has continued since 1968, and the upper surface of the landfill has been graded. IM2 contains dark-toned liquid. Dark-toned liquid is adjacent to the east side of IM2, indicating the possibility of a breach or overflow in the impoundment. The western excavation is no longer visible. A dark-toned stain (ST) extends from the top of the landfill downslope to the base, as if caused by a liquid.

Southern portion. Extensive filling has occurred since 1968. A clearing is noted along the southeast edge.

Eastern Landfill. Northern portion. The fill area with a berm noted in 1968 is vegetation. A shallow excavation is noted south of the former fill area. The graded fill area noted in 1968 and part of the parking area around the building are in use for open storage. A large clearing is seen on the west side of the landfill.

Central Portion. Vegetation is growing where a fill area with debris was noted in 1968. The bermed area appears inactive and is partially overgrown with vegetation. A clearing is seen on the west side of the landfill.

Southern portion. The northern pit seen in 1968 is no longer present; the southern pit is smaller and appears empty. IM1 contains liquid. The debris seen along the edge of a fill area in 1968 is no longer visible, and the top of the fill area has been graded. A small amount of probable debris is evident on top of the fill area. The two excavations remain and contain murky liquid.

Tree canopy obscures the drainage channel seen along the south edge of the landfill in 1968.

panying text provides a full site description. Figures 18.2 through 18.11 illustrate a standard historical site analysis of a hazardous waste disposal site, and show the kinds of information that can be extracted from an analysis of these photos, and changes at the site over time. The historical analysis clearly shows and documents the location of major fill areas which were evident during the life of the landfill. Disposal-related activities identified within the fill areas include debris, material, refuse, dark-toned liquid in erosion rills, excavations, and pits containing liquid. Between 1964 and 1984 a leachate collection impoundment was present on the site and a second leachate collection impoundment was present from 1968 through 1984. An upgraded leachate collection impoundment was present from 1980 through 1992.

Inventories of Potential Hazardous Waste Sites

Inventories of potential hazardous waste sites covering large areas and decades in time are a very cost-effective way to discover sites for future investigation. The aerial photographs are systematically searched for specific features or to identify types of sites. Type might include landfills, open dumps, scrap salvage yards, chemical handling and storage facilities, impoundments, or abandoned industrial sites. Identified sites are located on overlays to topographic maps accompanied by data sheets describing site conditions. The site conditions are presented chronologically with the period of site activity shown on the map overlay. This approach is helpful to determine the origin of a progressive problem and to identify a hazardous site that is currently hidden by new development.

Emergency Response

EPIC reacts through quick response capabilities to emergency situations such as hazardous material releases and natural disasters like hurricanes (Hugo) and earthquakes (San Francisco/Oakland, CA). Aerial photographs are flown, processed and analyzed to provide immediate information to on-site personnel regarding circumstances not easily or safely observed from the ground. Typical products for an emergency response include an immediate telephone report to on-site personnel followed by photographs or positive film transparencies with interpretation results annotated on overlays, annotated topographic maps, and a short letter report describing analysis results.

Wetlands

Wetlands analyses are performed by EPIC in support of various sections of the Clean Water Act concerning enforcement, permitting, and advance identification. Analysis of historical aerial photographs is often the only means of establishing the prior existence of wetlands on lands that have been dredged or filled, and for calculating wetlands loss acreage necessary for mitigation settlements. Aerial photographs also provide information concerning vegetative type, periodicity of flooding, tidal influences, and affected drainage patterns.

EPIC image analysts perform various types of wetlands mapping depending on the needs of the requesting EPA headquarters or regional program office. A *wetlands/upland* boundary delineation is the simplest form of mapping performed (Figure 18.10). The purpose for this delineation is to identify the location of wetlands and to separate wetlands from nonwetlands areas. A *detailed wetlands analysis* is performed to identify and classify various wetland types, often using the wetlands and deepwater habitat classification developed for the Fish and Wildlife Service by Cowardin et al. (1979). Using *jurisdictional wetlands delineation* procedures and associated fieldwork, EPIC maps wetlands in support of Section 404 of the Clean Water Act which protects wet-

lands from unpermitted dredge and fill activities. Also, in support of the *Advance Identification* process of Section 404, wetlands maps are prepared as a cost-effective way to identify wetlands in advance of permit application and evaluation. EPIC also performs image interpretation for wetlands delineation in support of EPA enforcement cases. Historical aerial photographs are used along with field checking to map wetlands losses and change due to filling and/or dredging activities. Photogrammetry is used to make accurate quantitative measurements of wetlands losses, extent of filling, and overall area changes. Geographic Information Systems (GIS) technology is applied to produce maps and graphics displays which are suitable for courtroom presentations and which clearly illustrate these changes.

Photogeology

EPIC employs aerial photointerpretation to study the geology of an area from an analysis of landforms, drainage, tones/textures, and vegetation distribution. EPIC conducts two types of photogeologic analysis and mapping: fracture trace and lithologic.

Fracture trace analysis involves the use of aerial photographs and other types of remote sensing imagery to identify linear features on the earth's surface that are naturally occurring and are surface manifestations of subsurface fracture zones in the bedrock (Figure 18.9A). When viewed in cross-section, fracture traces are seen to be vertical or near vertical breaks in the bedrock. Fractures are of particular environmental concern because contaminants are likely to move more easily through zones of fractured bedrock than through the surrounding more consolidated bedrock material. Thus, fracture traces can be used to identify possible migration routes of pollutants and are often used in the placement of monitoring/remedial wells around hazardous waste sites (Stohr et al., 1987; Scheinfeld et al., 1988; Mata and Christie, 1991).

EPIC conducts *lithologic mapping* (mapping of distinct rock types or units) from aerial photographs in order to produce a more accurate geologic map in areas where geologic mapping is incomplete due to limited fieldwork, small map scale, or other factors (Figure 18.9B). This procedure is usually performed by consulting available geologic maps of the area.

Photogrammetric Mapping

In support of EPA's mission, EPIC produces highly accurate topographic and planimetric maps, generally at a large scale, which conform with National Map Accuracy Standards and EPA Photogrammetric Mapping Specifications. Map scales, contour intervals, and planimetric details can be varied to suit specific requirements.

EPIC uses analytical stereoplotters, digital video plotters, or other digital photogrammetric methods to measure the area and volume of hazardous wastes; determine the height and placement of containment berms, dikes, and impoundments (Figure 18.8); and determine the depth of waste pits. Changes in size, shape, and other physical characteristics of a waste site are documented through sequential photogrammetric mapping (Slima, 1980).

Photogrammetric techniques are also used by EPIC to establish precise location and orientation data to support geophysical monitoring or for monitoring well placement.

Geographic Information Systems (GIS)

EPIC applies GIS technology to support a variety of EPA Headquarters or Regional Program Office Needs. For example, a National Priorities List (NPL) hazardous waste site investigation was performed using information from diverse sources (including numerous years of historical

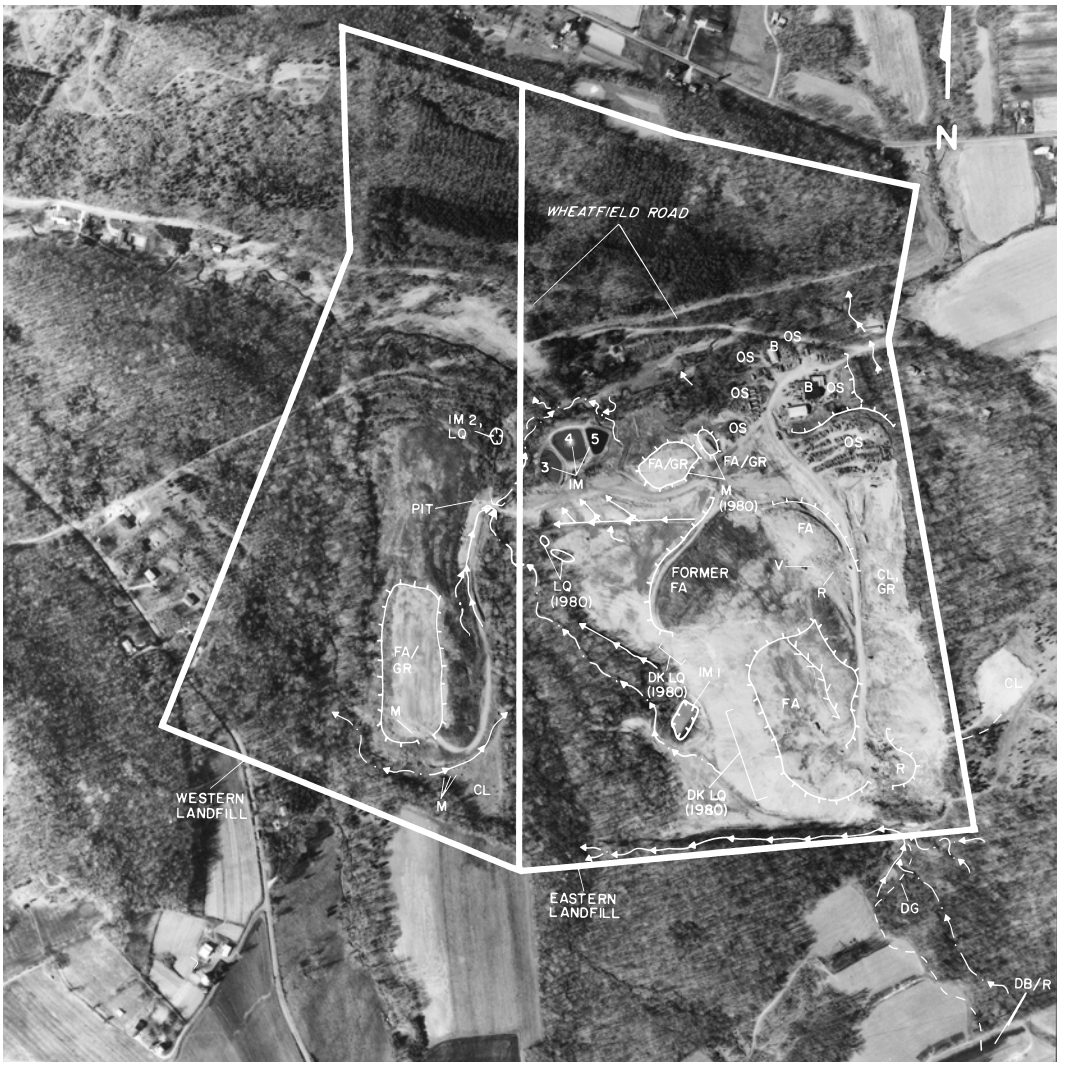

Figure 18.6. April 7, 1981 Significant features seen on the 1980 photograph are annotated and discussed with the following analysis on page 231.

Figure 18.6, continued. Western Landfill. Central portion. In 1980 IM2 contained a small amount of liquid. In 1981 there is an increase in the amount of liquid in IM2. The road (not annotated) on the east side of the landfill has been widened. A shallow pit, at the bottom of which appears to be a drain, possibly associated with the leachate collection system, is visible on the northwest side of the widened road.

Southern portion. In 1980 a clearing was visible on the west side. In 1981 the clearing (not annotated) is expanded and graded. A slight increase in the elevation indicates fill activity since 1980. Debris (not annotated) is evident along the edges of the fill area. Several piles of earthen-toned material are visible on the south side of the fill area, and in the clearing along the southeast edge.

Eastern Landfill. Northern portion. In 1980 the leachate collection system was visible in the large clearing where grading was seen in 1975. The leachate system consisted of IM3, IM4 and IM5, all of which contained liquid. One large and one smaller pile of material were seen in a former fill area which was used for open storage in 1975. This may have been excess soil dug out while excavating the leachate collection impoundments. An increase in open storage was noted around the buildings.

In 1981 IM3, IM4, and IM5 contain liquid. Both piles of material are graded. There has been a further increase in open storage since 1980.

Central portion. In 1980 extensive filling was evident. Dark-toned liquid was pooled in two areas on the west side. Partial clearing occurred along the east side. In 1981 filling is in progress in a new area. A vehicle (V) and refuse are visible in the new fill area, indicating current activity. The east side has been completely cleared and grading is in progress.

Southern portion. In 1980 extensive filling had occurred since 1975 and the east edge was partially cleared. Dark-toned liquid was visible in numerous erosion rills on the west side of the fill area. IM1 contained liquid, and its edge was more well-defined than in previous years, suggesting that the impoundment was dredged and redug. An access road led to a clearing east of the study area. Disturbed ground (DG) was noted along a second access road which led southwest of the study area, turned southeast, and continued to a wooded area where debris/refuse was evident. The same access road also continued southwest, and debris/refuse was evident at the edge of a second wooded area (not shown). The two wooded areas south of the study area are also accessible from roads outside of the landfill.

In 1981 further filling has taken place. The east edge is completely cleared and grading is in progress. The dark-toned liquid seen in 1980 is no longer visible. There is a significant increase in the grade east of IM1, which contains liquid. Refuse is abundant in the southeast corner.

The access road and clearing remain east of the study area. Disturbed ground remains evident along the access road seen south of the study area, and debris/refuse remains visible in both wooded areas.

The drainage channel previously seen along the south edge of the landfill is visible and contains liquid.

Figure 18.7. April 17, 1988. Significant activity observed on the 1983, 1984, and 1987 photographs is discussed, but not annotated in conjunction with the following analysis on page 233.

Figure 18.7, continued. Western Landfill. Central portion. In 1983 IM2 contained liquid, and the pit seen northwest of the widened road in 1981 was no longer visible. In 1984 IM2 contained liquid, and a small clearing was noted at the end of an access road. In 1987 IM2 was no longer visible, trees had been cut around the area where it was previously located, and revegetation was evident. The clearing seen at the end of an access road in 1984 was no longer visible. In 1988 no significant activity is noted.

Southern portion. In 1983 the clearing seen in 1981 was vegetated except for a small portion on the south side. The debris and material were no longer visible, and the clearing seen at the southeast edge in 1981 was vegetated. In 1984 the southern clearing remained and no further significant activity was evident. In 1987, an access road led west from the southern clearing to a ground scar at the creek. Clearings were seen on the southwest and southeast edges; debris was noted in the southwest clearing. In 1988 linear objects (LO), probably uprooted trees, are piled in the southern clearing. A series of objects, possibly straw bales for erosion control (not annotated), are noted between the southern clearing and a long clearing. This is the same location where an access road and ground scar were noted in 1981. Refuse is seen in the southeast clearing, and linear objects, probably uprooted trees, and refuse are seen in the southwest clearing.

Eastern Landfill. Northern portion. In 1983 IM3, IM4, and IM5 contained dark-toned liquid. Disturbed ground/light-toned material was noted southwest of the office buildings. In 1984 IM3, IM4, and IM5 contained dark-toned liquid. IM6 had been constructed and was empty. The disturbed ground/light-toned material was no longer visible. Clearing and fill activity were evident southeast of IM3, IM4, and IM6. In 1987 IM5 was full of dark-toned liquid, IM4 was partially filled with dark-toned liquid, IM3 appeared empty, and IM6 was surrounded by vegetation and contained dark-tone liquid. Extensive filling and grading occurred in the area southeast of the impoundments. In 1988 IM5 and IM6 contain dark-toned liquid and IM3 and IM4 contain medium-toned liquid. The vegetation has been cleared from around IM6 and the edges appear higher. No further filling or grading is evident in the area southeast of the impoundments.

Central portion. No significant change was noted in 1983 or 1984. In 1987 extensive filling and grading had occurred. In 1988 a series of excavations, possibly catchment ponds, containing murky liquid and linear objects, probably uprooted trees, are noted on the west side.

Southern portion. In 1983 IM1 remained and contained liquid. The access road and clearing remained active east of the study area. In 1984 IM1 remained and contained liquid, and trees were cleared west of IM1. The access road and clearing remained active east of the study area. In 1987 IM1 was no longer present. Disturbed ground was evident in the area where it was previously located. The access road and clearing east of the study area were vegetating. In 1988 no significant change is evident. Debris/refuse remains visible in both wooded areas south of the study area. Between 1984 and 1987 the drainage channel along the south edge of the site was rerouted northward through a culvert as shown in the Wetlands and Drainage Analysis (Figure 18.10). It continues west to the natural drainage, which flows north.

Figure 18.9a. Introduction. This fracture trace analysis presents findings based on the study of aerial photographs and geologic literature (see References) for the area on and around the landfill.

Fracture traces and other geologic lineaments are considered to be the surface expressions of vertical to near vertical zones of fracture concentration in bedrock. Fracture trace analysis is the technique of using aerial imagery for locating fracture traces or geologic lineaments on the earth's surface based on photogeologic signatures such as soil-tonal variations and vegetational and topographic alignments.

The landfill and surrounding area are astride the boundary separating the Great Valley section of the Valley and Ridge Physiographic Province. The bedrock geology of the landfill and surrounding area consists of Paleozoic and Triassic age sedimentary rocks, Triassic age igneous rock, and assorted contact metamorphosed rock.

Findings. Of particular note are the upper Cambrian carbonates (Millback Formation) which straddle the northern section of the site (Figure 18.9B). The Millback carbonates, reported to be highly permeable (well yields in the 225 gpm range), are surrounded by rock (diabase, meta sandstones and shales) having significantly lesser yields. Because of this, contaminants from the site may have difficulty moving out of the Millback aquifer, possibly concentrating in the Millback.

Efforts to characterize the groundwater regime around the landfill should in part focus on delineating the areal extent of the Millback (mapped by MacLachlan et al. as inferred). Although a photogeologic analysis of presite imagery (1946, 1947, and 1951) basically corroborates the MacLachlan et al. map, a more detailed field analysis is warranted.

Groundwater flow through the bedrock in this area is predominantly through secondary openings such as frac-

tures, and in the Millback perhaps through solutionized conduits. Identification of fracture traces is important when modeling aquifer contamination because the fracture traces may act as conduits for concentrated groundwater flow. Fracture trace analysis can be used to map possible pathways along which contaminants may migrate away from sites via subsurface routes. Once these possible pathways have been mapped, a monitoring well network can be designed to take into account the fracture pattern identified during the photogeologic analysis.

Figure 18.9b, above. A total of 25 fracture traces was identified using 1946, 1947, and 1951 imagery. They are presented on a photographic enlargement of the 1980 aerial photograph (Figure 18.9a). Of note are fracture traces labeled A, B, and C. A and B bisect the landfill area and therefore have a high likelihood of carrying contaminants. Fracture trace C, oriented north-south, is located along the expected direction of regional groundwater flow away from the site (west-north-west), and could deflect the groundwater flow away from this expected route.

Secondary openings in the Millback carbonates may be solutionized, resulting in an enhanced groundwater flow. Depending on the degree of solutionization, any cones of depression developed around wellheads can greatly influence groundwater flow direction. Caution should be exercised if fracture traces are to be used in the location of monitoring wells. Differences of a few feet can determine whether or not a well is located on a fracture trace; therefore, it is important that a geology field team and a photogeology analyst with stereo aerial photographic transparencies and related interpretation equipment be on site for precise placement of the monitoring wells or well network.

Recommendations. Based on the findings of this photogeologic analysis, future groundwater characterization efforts at the landfill should be directed toward: (1) defining the areal extent of the Millback Formation, (2) placing monitoring wells on fracture traces A, B, and C, and (3) determining the degree of solutionization in the Millback Formation.

Figure 18.10. Wetlands and drainage analysis. Wetlands (W), open water (OW), uplands (U), and drainage are annotated for the area at and around the landfill using photographs from April 17, 1988. The general direction of drainage flow is north and west through a series of unnamed streams which eventually lead into the north-flowing Main Creek (not shown). The on-site drainage flows through a series of wetlands that contain emergent and forested vegetation.

aerial photographs, geological data, digital line graph data, soil data, property ownership, monitoring well data, etc.). These data were combined to produce topical maps and analyses for use in the Remedial Investigation/Feasibility Study decision-making process under Superfund. Another project in support of the Environmental Monitoring and Assessment Program (EMAP) involved the ecological characterization of a pilot site using photo-derived information on land use, vegetation,

Figure 18.8. Landfill Area Measurements from Photogrammetry of Leachate Collection Impoundments.

YEAR	IM1	IM2	IM3	IM4	IM5	IM6
1971						
Hectares	0.143	0.073	not	not	not	not
Acres	0.353	0.181	present	present	present	present
1981		no				
Hectares	0.108	significant	0.095	0.145	0.077	not
Acres	0.267	change	0.235	0.359	0.189	present
1988						
Hectares	not	not	0.116	0.166	0.097	0.172
Acres	present	present	0.287	0.409	0.240	0.424
Increase (+) or Reduction (–)		no				N/A
Hectares	–0.035	significant	+0.021	+0.021	+0.020	(one year
Acres	–0.083	change	+0.052	+0.050	+0.051	measured)

Area measurements were obtained for impoundments 1–6 using photographs representing the year of peak landfill activity (1971), an intermediate year (1981), and the year of final closure (1988). The impoundments were digitized from photographic prints using an XY digitizing table. The digitizing table coordinates were transformed into the UTM coordinated system to facilitate area measurements, using a GIS.

IM1 was visible from 1964 through 1984, and decreased in size by 0.035 hectare (0.083 acre) between 1971 and 1981. IM2 was visible from 1968 through 1984, and was 0.073 hectare (0.181 acre) in 1971. Changes in the size of IM2 were minimal, and therefore have not been measured. IM3, IM4, and IM5 were visible from 1980 through 1992, and were each enlarged by approximately 0.021 hectare (0.05 acre) between 1981 and 1988. IM6 was visible from 1984 through 1992, and was 0.172 hectare (0.424 acre) in 1988.

wetlands, and landforms to produce maps and overlays for landscape characterization and trend analysis (Norton and Slonecker, 1990).

Global Positioning Systems

Global positioning systems (GPS) technology is used by EPIC primarily to produce accurate latitude/longitude coordinates for sites under investigation, and as a means to evaluate and quantify the spatial accuracy of digital map data, and to create accurate cartographic products. In 1990 EPA adopted its Locational Data Policy (LDP) for the purpose of ensuring the collection of accurate, fully documented locational coordinates as part of all agency-sponsored data collection activities. An accuracy goal of 25 meters was established and GPS is considered the best method for achieving this goal. GPS is used to provide accurate latitude/longitude ground control points for producing accurate maps from aerial photographs and to precisely locate hazardous waste disposal sites (Wells et al., 1986; Slonecker and Groskinsky, 1993).

Miscellaneous Analyses

Additional image analyses performed by EPIC in support of EPA needs include interpretation of thermal infrared imagery for detection of illegal river discharges and landfill and mine fires;

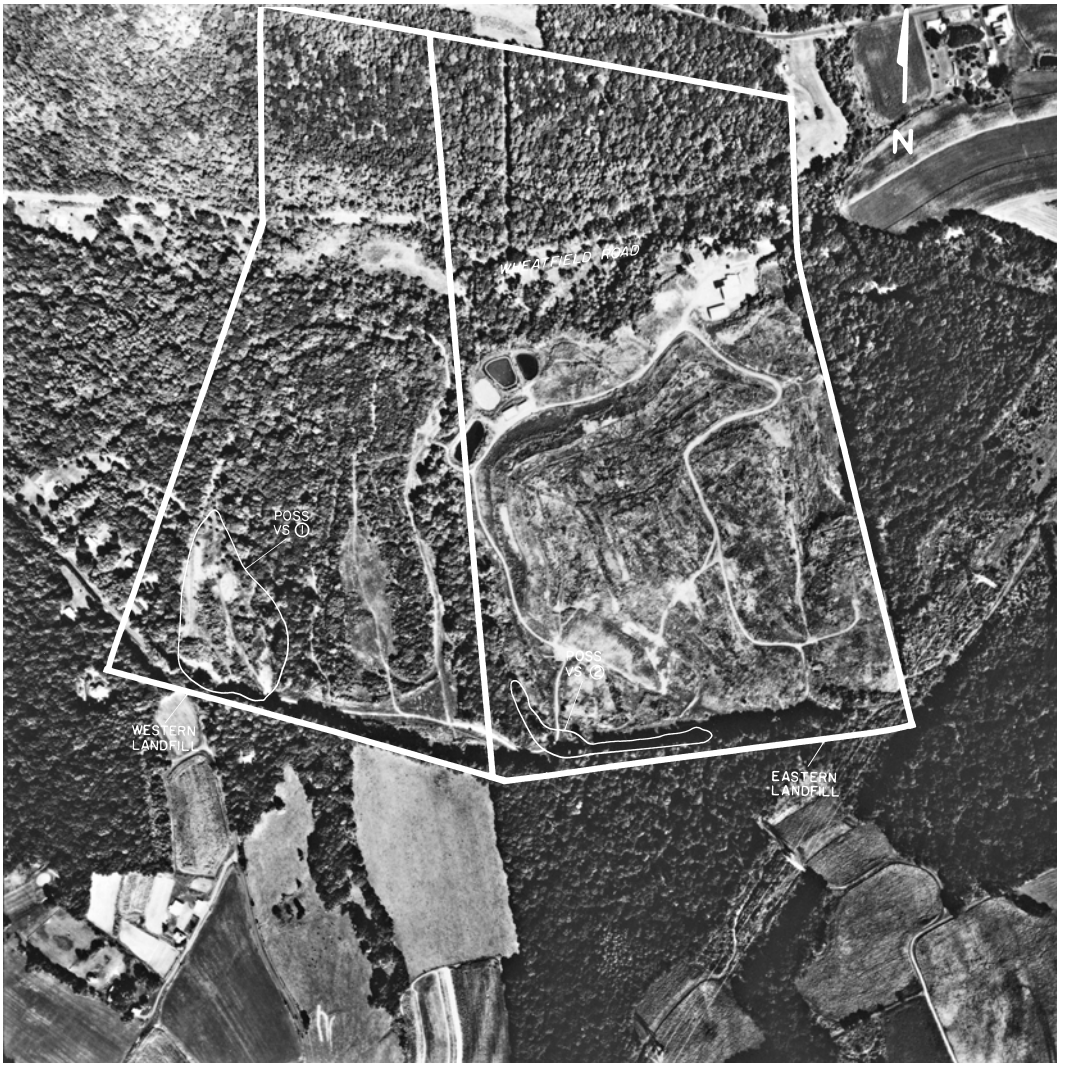

Figure 18.11. Vegetation stress analysis, September 24, 1992. A color infrared overflight was acquired for the landfill during full leaf-on conditions to facilitate the vegetation stress analysis. The photo shown here is a black and white copy of the color infrared image which normally shows vegetation as various shades of red.. Vegetation stress (V) can be caused by many interrelated factors such as insect infestation, disease, drought, water inundation due to natural and/or man-made changes in hydrology, and soil compaction, as well as contaminants. Often vegetation can be weakened by one factor and consequently become susceptible to one or more of the others. Due to the abundant rainfall and below-normal temperatures throughout the eastern United States during the summer of 1992, it is unlikely that vegetation stress has been caused by drought conditions.

Since individual dead trees are likely to be naturally occurring snags, they have not been identified. In some cases dead or stressed vegetation may have been overcome with climbing vines, resulting in a healthy vegetation signature.

A standard or "normal" signature was developed for the vegetation at the landfill by studying the areas at and around the site and establishing a generalized spectral reflectance pattern. Possible vegetation stress was identified based on deviations from the "normal" vegetation signatures and is discussed for the western and eastern landfills.

and aerial photointerpretation for detection of abandoned oil, gas, and water wells; mapping of submerged aquatic vegetation; and land use and drainage mapping.

Aerial Photo Acquisition

EPIC acquires historical photographs, dating to the late 1930s, from a wide range of federal, state, and local government agencies and private aerial survey companies. EPIC sets the specifications for overflight of new aerial photography, to meet the Agency's varying needs. New aerial photography is acquired through a network of private aerial survey companies across the country. These companies are also available on short notice for emergency response efforts.

SUMMARY

EPIC is a facility of the Landscape Ecology Branch, Environmental Sciences Division, National Exposure Research Laboratory, Office of Research and Development, and has been performing aerial photointerpretation and mapping in support of EPA headquarters and program offices since the early 1970s. Over the years the technology of remote sensing and mapping has advanced dramatically. EPIC has maintained pace with this technology and today provides the agency with the benefits derived from its use. An evolution has also been occurring with regard to environmental concerns. The health and well-being of our nation's ecological resources, and concerns about global climate changes have added a new dimension to the way we view the environment, and require methods for efficiently collecting data inexpensively and over large areas. Advances in remote sensing and mapping technology provide important tools to help us learn more about these regional and global problems. EPA's EPIC is poised and prepared to take on these new challenges through the next century.

Notice: The U.S. Environmental Protection Agency, through its Office of Research and Development (ORD) funds and performs the work described here. This document has not been sub-

Western Landfill. The overall vegetation patterns appear healthy, and a few small patches of irregular vegetation growth (not annotated) are evident. 1. Possible vegetation is noted in the most recently active clearing, which is located in the southeast corner of the landfill. Irregular patches of vegetation are growing within barren areas, and vegetation along the adjacent natural drainage route (Figure 18.10) appears stressed. The healthiest vegetation within the clearing is growing on top of the remaining probable uprooted trees noted in 1988.

Eastern Landfill. In general, the vegetation is growing irregularly, with healthy patches interspersed with possible stressed patches (not annotated), and numerous areas which are void of vegetation. 2. Possible vegetation stress is noted along the drainage route at the south edge of the landfill, and continuing west to the natural drainage (Figure 18.10). The lowlands along drainage routes are of particular importance because they offer a natural pathway for the migration of contaminants. It was not possible to determine deviations in the vegetation signature of the on-site wetlands due to the small size and number of these areas (Figure 18.10). A generalized spectral reflectance pattern can only be established when a number of similar areas within the site vicinity can be compared to each other.

The most effective way to verify possible vegetation stress and to investigate causes of vegetation stress is with a combination of aerial photograph analysis and a field check of the study areas during the active growing season.

jected to the Agency's review; therefore, it does not necessarily reflect the views of the EPA. The U.S. government has the right to retain a nonexclusive, royalty-free license in and to any copyright covering this article.

CHAPTER 19

Remote Sensing and GIS for Site-Specific Farming

John G. Lyon, Andrew Ward, Bruce C. Atherton,
Gabriel S. Senay, and Tom Krill

INTRODUCTION

There are a number of capabilities that have been postulated to be useful in agriculture. These capabilities have been realized through numerous efforts over the years (e.g., Moran et al., 1997). The focus now is to demonstrate the capabilities of available technologies for operational and practical applications.

The hope is that research can demonstrate that available remote sensor, GPS, and GIS technologies can supply good information for management of crops, soils, and waters on a within-field basis, and do so at reasonable cost. The goals are to potentially improve yields while maintaining or improving soil tilth and water quality (Ward and Elliot, 1995; Blackmer and Schepers, 1996; Gowda et al., 1999).

Precision agriculture approaches can be implemented using a suite of technologies. To address within-field management concerns it is necessary to navigate over short distances and small elevations. The advent of Differential Global Positioning Systems (Van Sickle, 1996) now provides for the required precision and accuracy. The need for mapping the spatial data collected through a variety of means is met by position information from GPS and mapping capabilities of Geographic Information Systems (GIS)(Lyon and McCarthy, 1995). GIS supplies the maps of soil grid sampling, management applications, and on-the-go yield, and can do so for each season and each year of evaluation with high accuracy (Bolstad and Smith, 1995). To supply detail as to crop, soil, and hydrological conditions over the growing season and from year to year, remote sensor data from aircraft or spacecraft are employed (Eidenshink and Haas, 1992; Thenkabail et al., 1992, 1995; Ward and Elliot, 1995; Yang et al., 1998). Use of different parts of the electromagnetic spectrum can help to separate types of crops and weeds, general soil and soil moisture characteristics, and the potential influences of hydrology on soils and crops (Huete and Tucker, 1991; Lyon et al., 1998).

Our work over the last 12 years and the work of others helps to illustrate the experimental and operational capabilities of remote sensor, GPS, and GIS technologies for agriculture. Here, the background to these methods, their results, and options for the future are described and discussed using our experience from three experiments on commercial farms in Ohio, and the experience of other researchers.

BACKGROUND

In this chapter we focus on the variables which are most useful in site-specific farming and can be best related to remotely sensed data. These techniques and methods can be incorporated with GIS and watershed models to answer important water resource questions. In general, the following variables can be measured in fields and related to remotely sensed measures of light: wet and dry biomass, crop residue, leaf area index (LAI), plant population density, areal cover of crop canopy, concentration or quantity of chlorophyll, leaf tissue nutrient content, crop height, plant moisture content, yield after harvesting, on-the-go yield, soil moisture content, soil texture, soil fertility, soil nitrogen, soil phosphorus, soil potassium, soil water release characteristics, the presence and location of weeds, wet and droughty areas, and plant stresses associated with diseases, insects, or other factors.

Crop Characteristics

The wet, green biomass of healthy plants can be measured in a number of ways remotely using the visible, near, and middle infrared regions of the electromagnetic spectrum (Singh, 1989; Thenkabail et al., 1994; Senay et al., 2000a, 2000b). A number of people make use of the fact that green plants absorb most of the red light from sunshine for photosynthesis, and reflect very little red light to the sensor above the crop (Price, 1992). In addition, green plants absorb little near infrared light, but reflect great quantities of it to the sensor above. This differential light reflectance can be used as a tool to identify green plants from the background materials including soils, crop residue, and water.

Conversely, plants that do not perform optimally or are "stressed" will often have less chlorophyll and be chloretic or yellow (Blackmer and Schepers, 1996). This decrease in chlorophyll can be detected by a decrease in red light absorbance and infrared light reflectance. This differential light reflectance can be used as a tool to identify green plants from the background materials including soils, crop residue, and water (Figure 19.1).

Residue

An important consideration to many farm management activities is the maintenance of crop residue cover during the nongrowing season. The reasons for this practice include decreasing soil erosion from water and wind, reduction of plowing costs, decreasing water quality problems downstream, and others. The implementation of crop residue cover or conservation tillage practices has been of great interest, as have methods for measuring the extent of this practice (Messer et al., 1991; Jakubauskas et al., 1992). We have conducted work on measuring crop residue to track the implementation of conservation tillage, and to better understand residue influences on spectral responses during the growing season. This work began in the early 1980s and continues today (Thenkabail et al., 1992, 1994; Van Deventer et al. 1997; Gowda et al., 1999).

Crop residue or senescent plants reflect different amounts of light as compared to green plants or soil. It is possible to identify crop residue because of these differences, that include the absence of chlorophyll, presence of nonchlorophyll plant pigments, difference in water holding capabilities as compared to live or green plants, different leaf or stalk structure as compared to live plants, and different water holding, pigment, and structural characteristics as compared to soils. These differences manifest themselves as a distinct spectral signature or differential light reflectance that can be measured in the visible, near, and middle infrared regions of the spectrum (Ward and Elliot, 1995).

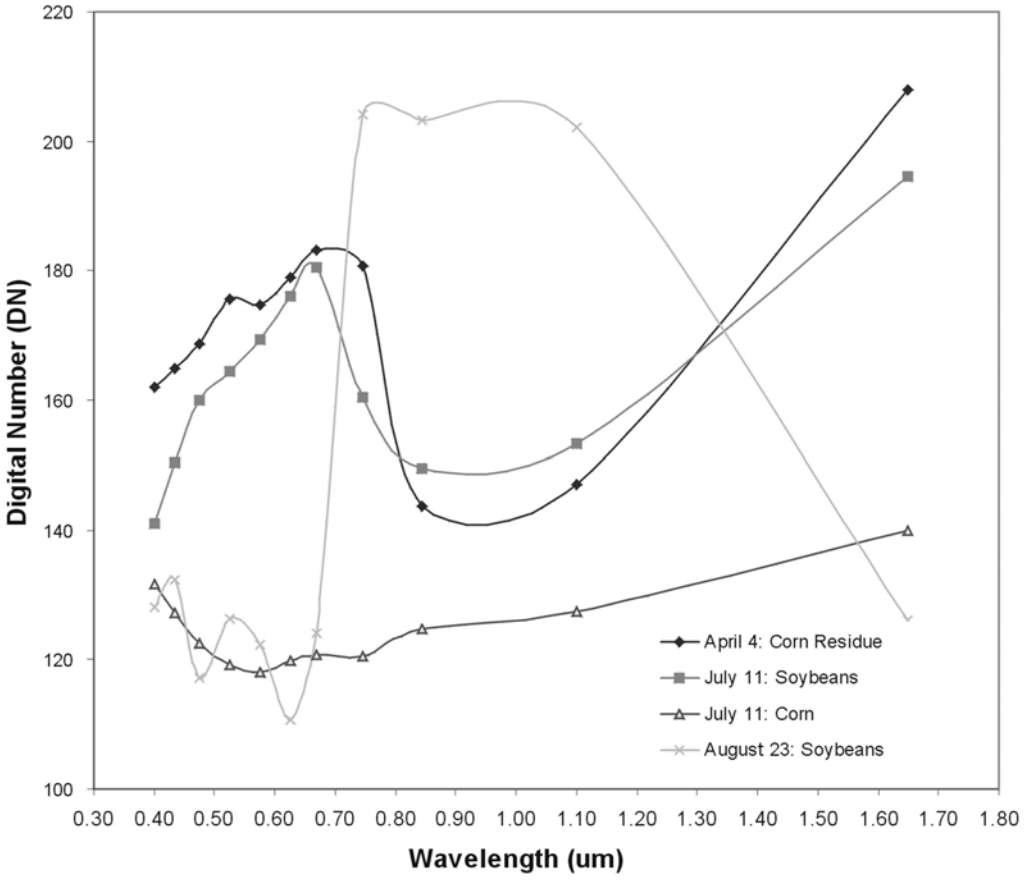

Figure 19.1. Spectral responses of corn and soybeans during vegetative growth stages, soybeans at maturity and corn residue.

Soils

The reflectance characteristics of soils are related to the parent materials, the texture, the moisture content, organic matter, and to a certain extent slope and elevation. Soils are generally lighter or brighter toned than plants and water. The exceptions would include soils of high organic matter or low bulk density or high moisture content. Bright tones of soils can be distinguished from plant materials in the visible and infrared portions of the spectrum. Work on using remote sensing to study a wide range of soil properties has been conducted by many researchers (Hatfield and Pinter, 1993; Moran et al., 1997)

An important consideration is that a dense crop canopy will obscure the bright tone of soils. This supplies a ready method to make estimates of canopy closure or leaf area index due to the darkness of the plant biomass obscuring the soil background. Conversely, measures of the presence of bare soil can help assess the absence of crop or crop canopy that has not developed (Lyon et al., 1986).

Water in a Crop Environment

Water characteristics of plants and soils can be identified and differentiated from other materials due to the fact that water or wet soils or wet plants have a lower reflectance of light to the sensor above (Lyon and McCarthy, 1995; Ward and Elliot, 1995). In general, the presence of water in any concentration decreases the light reflectance of materials. This is well known for the case of soils, where the presence of either water at the surface, water saturation, or standing water will greatly reduce the generally relatively bright reflectance of dry or relatively dry soils (Lyon, 1993).

A major use of remote sensor data is in the evaluation of crop moisture conditions. In particular, the middle infrared (approximately 1.5 and 2.2 μm) and to a certain extent the near infrared (approximately 0.7 to 1.1 μm) supply good detail as to relative plant moisture conditions of the leaves and stalk.

METHODS

Several experiments were developed over time to test the capabilities of remote sensor data for precision agriculture. The results of those experiments are presented here and in other publications. In general, the experiments included: evaluations of satellite and ground measurements of crop, soil, and hydrology variables for more than 50 commercial farms in Seneca County of north central Ohio (Thenkabail et al., 1992, 1994; Van Deventer et al., 1997); evaluations of crop, soil, hydrology, and weather characteristics using fine spatial resolution (1 m picture elements or pixels) and moderate spectral resolution (12 spectral bandwidths) for a commercial farm in Pike County of south central Ohio used in the Midwest Systems Evaluation Area (MSEA) studies (Senay et al., 1998, 2000a, and 2000b); and evaluations of low-cost aerial photographs taken from low altitudes of four commercial farms and one experimental farm station in Van Wert County of west central Ohio, and the MSEA site. Details on the methods to collect and analyze field data for these experiments are reported in several publications (Thenkabail et al., 1992, 1994; Nokes et al., 1997; Senay et al., 1998).

Landsat Thematic Mapper Data

During a three-year period, ground and satellite data were collected and analyzed for commercial farms in Seneca County (Thenkabail et al., 1992, 1994; Van Deventer et al., 1997). The goal was to evaluate the utility of Landsat satellite Thematic Mapper (TM) data for crop, soil, residue, and hydrology characteristics. This large experiment involved many field data collections during the growing season as detailed elsewhere. For remote sensing purposes, the research team visited the county on a biweekly basis to collect data during the Landsat satellite overpasses. The result was a very rich data set to evaluate field and satellite measured characteristics of crops, soils, and management practices.

Landsat 5 TM data and now Landsat 7 ETM+ data provides 30 m by 30 m resolution data every 16 days or so, and some type of Landsat data has been available for 25 years. It provides information in the visible, infrared, and thermal wavelengths.

Airborne Multispectral Scanner Data Collection

Several overflights of the MSEA site in Pike County were conducted in 1994. The platform was an Aero Commander twin engine aircraft with a camera bay holding the Daedalus Multispectral Scanner (MSS) instrument (model 1260) and an aerial camera by Wild (RC–8). The overflights were made on April 4, July 11, August 15, August 23, and September 15, and corresponded to

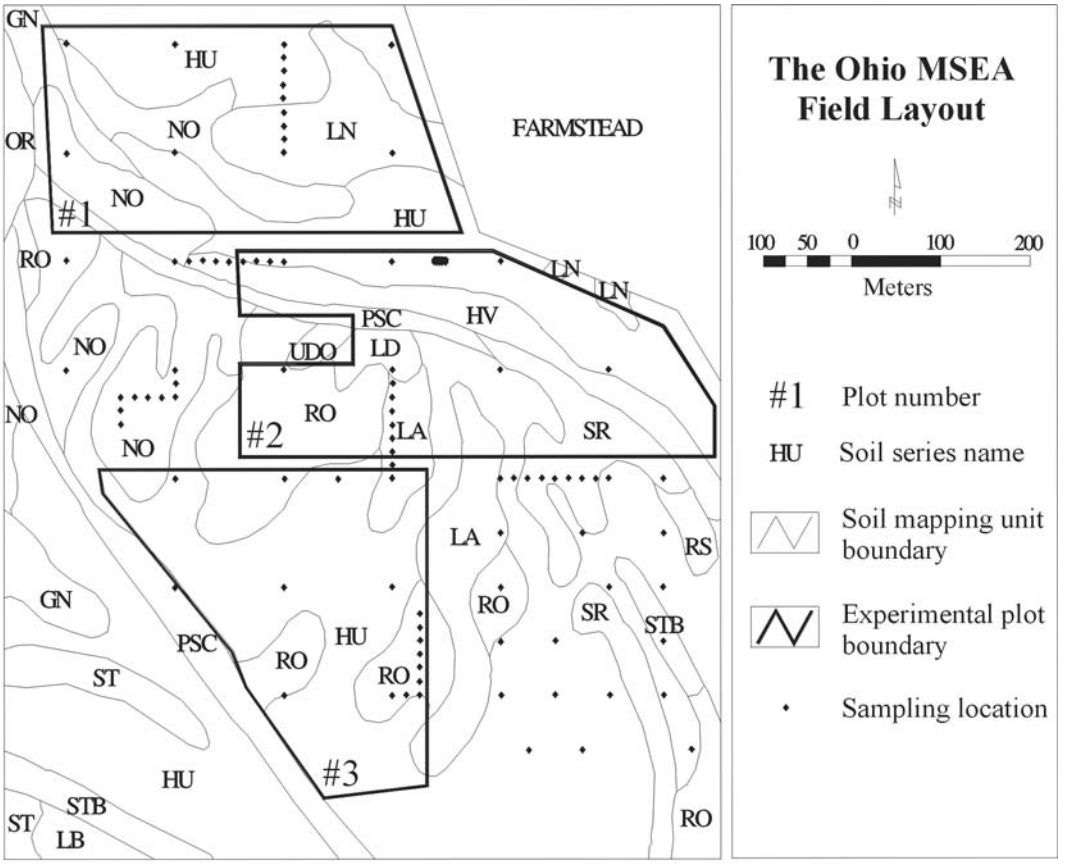

Figure 19.2. Ohio MSEA soil map (Wu et al., 1996). Source: US Department of Agriculture, Natural Resources Conservation Service, Columbus, Ohio.

early spring and preplanting, early planting and germination, mature crop, and senescent soybean, and early senescent corn crop growth periods, respectively. Ground data were collected close in time to the overflights, by a crew that measured the MSEA on a regular basis in support of a number of studies, and by personnel concerned specifically with the overflights.

Other remote sensor data were collected during 1994 and have been analyzed. These data included airborne radar data in X, C, and L-bands from a Lockheed P–3 Orion aircraft and sensor supplied by the Navy, and the hyperspectral sensor AVIRIS flown by a NASA U–2 aircraft.

The MSEA effort is ongoing, and is significant because of the extensive data collection effort in the field. In addition, products such as a Digital Elevation Model (DEM) were developed from a Differential Global Positioning System (GPS) experiment, on-the-go yield measurements were made from a combine with GPS capability, and a very extensive soil type map was developed for the site (as shown in Figure 19.2, Wu et al., 1996), and much of these data were processed for analysis using Geographic Information System (GIS) technologies (Senay et al., 1998).

Low Altitude, Small Film Format Data

The Van Wert County area was flown approximately six times before and during the growing season of 1997. A single engine, six place aircraft was supplied by the local airport flight service for these flights of approximately 45 minutes duration. One or two photographers collected photo-

graphs from approximately 1,000 feet of altitude above ground level (AGL). Each used a single lens reflex type 35 mm camera of general manufacture. The optimal lens was a zoom telephoto with a focal length of approximately 100–180 mm or similar sort of lens. The film types included: black and white film for interpretation and publication, color slide film for interpretation and presentation to audiences, color infrared film for interpretation, and color print film for interpretation and for quick processing and printing to support immediate analyses (Lyon, 1993). The color infrared film was taken at ASA 100 to 125, using a yellow (minus blue light) filter and processed by Rocky Mountain Films in Aurora, CO. The color print and slide films were approximately 100 ASA and were taken with a polarizing filter to reduce atmospheric haze.

In 1998, a study which focused on evaluating crop responses to spatial variability was conducted at the Ohio MSEA site. As part of this study digital infrared data was obtained in May, August, and September. This information has a resolution of about 0.3 m by 0.3 m and was obtained from commercial services which use cameras mounted on aircraft flying at low altitude. We also used an AgLeader yield monitor to obtain on-the-go yield information. Scouting was performed every 1–4 weeks and extensive crop and soil data were obtained on several occasions at 27 to 36 sites for each of the three farming systems which were located on 9 ha fields.

Field Data Collection

The methods to collect and analyze field data are described in a number of publications cited here. In general, the following variables can be measured in the field and related to remotely sensed measures of light. They include: wet and/or dry biomass, crop residue by field scouting method or by removal and weighing, leaf area index (LAI), number of plant stocks in rows, areal cover of crop canopy, concentration or quantity of chlorophyll, crop height, plant moisture content, soil moisture content, soil color or reflectance, yield after harvesting, on-the-go yield, soil organic matter content, soil texture, soil fertility, soil nitrogen, soil phosphorus, soil potassium, presence and location of weeds, presence or location of wet areas during the growing season, presence of sandy or rocky or salty or other low quality soils, and related measures.

RESULTS

Crop Characteristics

All three experiments have demonstrated the capabilities of remote sensor measurements to supply information about crops. Whether the sensor was deployed in space, or in an expensive aircraft or in a relatively low-cost aircraft the analyses yielded information.

Remote sensing methods were useful in measuring the presence of wet biomass and dry biomass. The results include very good relationships between wet biomass and satellite and aircraft measured light (Price, 1992, 1993; Thenkabail et al., 1992, 1994; Van Deventer et al., 1997; Seney et al., 2000a, 2000b), and with dry biomass (Thenkabail et al., 1992).

A particularly valuable analysis approach demonstrated by our work and the work of a number of researchers was the use of ratio indices of remote sensed variables as compared to ground measured variables (Eidenshenk and Haas, 1992; Qi et al., 1993; Hatfield and Pinter, 1993; Lyon et al., 1998; Lunetta and Elvidge, 1998; Lyon, 2000, 2001). The most famous and widely used examples are those that employ the division of the red portion of the spectrum with that of the near infrared (Thenkabail et al., 1992; Price, 1994; Lyon et al., 1998). The normalized difference vegetation index (NDVI) has yielded very good results in our work with wet biomass (Thenkabail et al., 1992, 1994) and other ground measures (Van Deventer et al., 1997).

Other ratio indices have been tested by us (Thenkabail et al., 1992, 1994; Van Deventer et al., 1997; Lyon et al., 1998; Senay et al., 2000a, 2000b) and by others. Using combinations of middle infrared (TM5), red (TM3), and near infrared (TM4) provided information on crop moisture conditions or "stress" [e.g., STVI, Landsat (TM5 x TM3)/TM4,Thenkabail et al. 1992]. However, the NDVI is the most commonly used index and has been found to be the optimal example in several studies (Thenkabail et al., 1992; Lyon et al., 1998).

Yield and Crop Stresses

The low-altitude and low relative cost method of flying 35 mm photographs has demonstrated very good detection of spring, perennial weed growths. The optimal method is to use color print film and a 35 mm camera with a local aircraft service (Figure 19.3), and results are available within 24 hours or less of the flight. This method allows for a timely flight when weed conditions are obvious as compared to newly emerged or newly germinated crop, and provides adequate time to develop a plan and execute spraying of weeds. A similar approach can be used with infrared film but processing usually takes several days or longer (Figure 19.4a). Alternatively, digital cameras can be used and the data downloaded directly to a personal computer for near real-time analyses.

Remote sensing has the potential to be used to determine yield variability. Our earlier studies with Landsat TM data often showed low correlation between multispectral data and yields (Thenkabail et al., 1992, 1994). However, in the recent experiment at the MSEA site there was a strong linear correlation between yields and the near-infrared bands (Senay et al., 1998). It is possible that this improved ability to use spectral data to determine crop yields is associated with the higher resolution (1 m compared to 30 m) and with the availability of on-the-go yield data for use in developing relationships between yields and the spectral data.

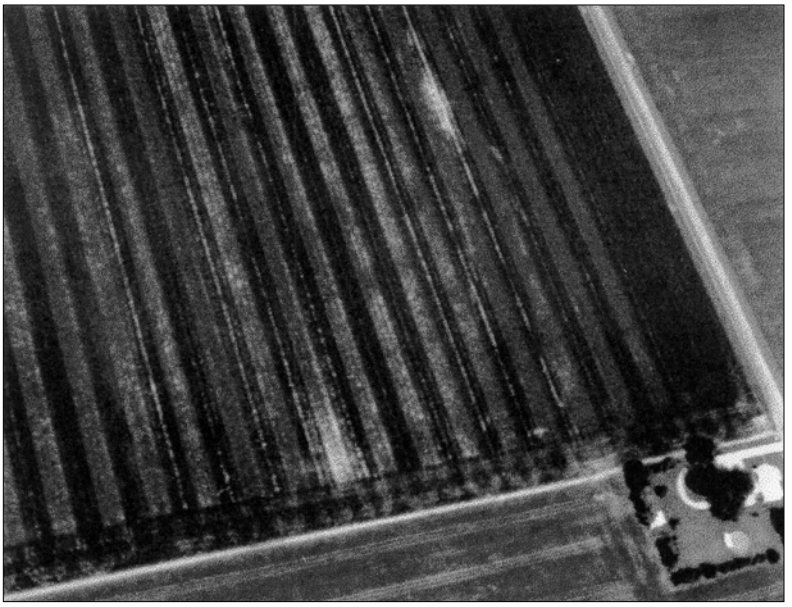
Whether these types of relationships can be used to accurately determine yields in fields where on-the-go yield data are not available remains to be seen. However, it appears that even low cost infrared data obtained from a camera mounted in an aircraft will provide useful information on relative yield and biomass differences within a field. Figure 19.4b shows reduced crops in areas with high weed pressures (Canada Thistle and Giant Ragweed) that are presented in Figure 19.4a.

Figures 19.5a,b,c and d, show yield data and infrared images of a cornfield at the MSEA site during different growth stages. A well is located in the largest bare area, which is connected to an access road, and a power pylon is located in the other bare area (lower corner). This set of figures illustrates both the usefulness and the difficulties in using remotely sensed data. The August image suggests that there is little spatial variability in the crop characteristics. This image was taken when mature plants had a high moisture content and were fairly green. In contrast, the September image depicts senescent plants and considerable spatial variability is evident. Unlike the information presented in Figures 19.4a and 19.4b the variable crop responses in this field are primarily due to soil differences. In particular the soils in the southern (lower) part of the field are coarser, have lower soil water retention characteristics, and are less fertile than soils in other parts of the field. In Figure 19.5b, the small green patches in the middle of the field and near the bottom right-hand corner are areas with low plant densities. They correspond well to the lowest yielding (dark green) patches in Figure 19.5d.

Residue

We have used satellite Landsat TM data and high resolution multispectral data to study residue. On a field basis, in the northern Ohio study, we were able to differentiate between contrasting soil plains, and conventional versus conservation tillage (Van Deventer et al., 1997). However, we re-

a.



b.

Figure 19.3. Low altitude aerial photographs of farm fields in Van Wert County showing weeds in a field, and poor management resulting in low seeding, germination, or fertilizer applications in some rows.

cently tested the same linear logistic regression model on the Maquoketa River Watershed in Iowa and there was poor agreement between remote sensed based estimates and those from field surveys (P. Gowda, personal communication).

Soil Characteristics

A valuable result of the use of remote sensor data is in the evaluation of soil moisture conditions. In particular, the middle infrared (approximately 1.5 and 2.2 μm) and to a certain extent the

near infrared (approximately 0.7 to 1.1 μm) supply good detail as to relative soil moisture conditions (Huete and Tucker, 1991; Van Deventer et al., 1997; Seney et al., 2000a, 2000b).

Soil fertility is an important issue in precision agriculture. Variables related to soil fertility are often not measured directly with a remote sensor, but are estimated from remote sensor variables using a related or surrogate variable (Lyon and McCarthy, 1995). Relative soil moisture and soil organic matter of bare soils can be measured directly. Relative soil phosphorus is measured in the field and compared to a surrogate variable measured remotely such as crop "greeness" or biomass, or leaf area index (Blackmer and Schepers, 1996).

Greater spectral resolution capabilities have allowed more detailed work on soil characteristics using indices similar to those previously published. Slightly modified indices that use the increased capabilities of Multispectral Scanner (MSS) aircraft data have proved useful. For example, the Simple Normalized Difference (SND) of the middle infrared (1.55–1.75 μm) divided by the near infrared (NIR, 0.92–1.10) which is similar to the Simple Vegetation Index (SVI) (Senay et al., 1998), and the Normalized Difference (ND) index using the equation (MIR-NIR)/(NIR + MIR) which is similar to NDVI in formulation (Seney et al. 2000a), have demonstrated increased capabilities. Both the SND and ND showed strong correlations with combined water in the soil (0.5 to 2.0 cm in depth) and in plants for corn (Senay et al., 2000a, 2000b).

Water in a Crop Environment

Most of our research has included an emphasis on water resource characteristics as they influence crops, soils, and water quality. These efforts have involved analyses of surface soil moisture, near surface drainage conditions, and vadose zone and groundwater conditions in support of watershed modeling (Ward and Elliot, 1995; Gowda et al., 1999). Remotely sensed measures have been valuable for a number of analyses. These include use of remote sensors or photography to document: wet soil conditions that may influence planting or germination; remote measurements of the impact of drought (Thenkabail et al., 1992); identification of land cover types in watersheds to help parameterize watershed models including GIS-based models (Moore et al., 1993; Gowda et al., 1999); calculation of watershed elevations for modeling (Garbrecht and Martz, 1993); remote measures of soil surface moisture (Van Deventer et al., 1997; Senay et al., 2000a, 2000b); use of remote sensing and GIS for nonpoint source modeling (Jakubauskas et al., 1992; Kang and Bartholic, 1994; Gowda et al., 1999); the accuracy of the remote sensor data or GIS products (Bolstad and Smith, 1995; Congalton and Green, 1998); and others.

Low altitude, 35 mm camera data can also identify drainage problems and the presence of subsurface drainage (Figure 19.6). During an early season overflight in Van Wert County, the weather and hydrology conditions were favorable for identification. Drainage systems were evident as light-toned areas which experienced better drainage than adjacent wet soil areas. The overflight occurred after a particularly wet spring, and about two days after the last rain. The drained areas were light toned because of the low relative moisture and hence increased reflectance as compared to adjacent, wetter soil areas (Figure 19.6).

General Characteristics of Fields

Statistical procedures and GIS technologies can be used to categorize spectral data into classes showing different crop characteristics, soils, topography and/or hydrological conditions. Figure 19.1 (see color section) shows more than 30 classes for the MSEA site which are based on the fine resolution visible, near infrared and middle infrared and elevation difference from the Digital Elevation Model (DEM). The classes themselves include measures of different levels (stalking, bio-

Figure 19.6. Low altitude aerial photographs of farm fields in Van Wert county showing wet areas, and the influence of subsurface drainage as lighter-toned linear features.

mass) of crop, differences in soils and elevation, and difference in plant and soil moisture conditions. The soybean crop is senescent and the corn is mature. The variety of spectrally distinct classes shows that a lot of detail can be sensed with the MSS sensor at one meter resolution and the additional discrimination power supplied by the data on relative elevation. Figure 19.7b is a false color composite of the fine resolution data and shows many of the same features that can be seen in Figure 19.1 (see color section). However, it provides less information on why these features occurred. These sorts of products can make a great amount of detail more obvious, and that same quantity of detail can be analyzed and evaluated as to accuracy (Lyon and McCarthy, 1995; Congalton and Green, 1998).

DISCUSSION AND CONCLUSIONS

The value of remotely sensed measurements lies in the utility of the data to identify normal and abnormal conditions in fields, and to do so rapidly over large areas. Producers know the characteristics of their fields, but things sometimes change rapidly and additional within-field data of a quantitative nature can only help the thoughtful management of crops and fields. The advent of Differential GPS positioning (Blackmer and Schepers, 1996) and on-the-go yield monitoring and more soil sampling allows the collection of powerful data sets. Combining these measurements with remotely sensed data and processing it all with GIS maps and modeling bodes well for detailed field management at low relative costs. Remotely sensed data can take the form of very low cost data either from shared satellite data collection and analysis efforts, or from low cost and rapid aerial photography from available local aircraft or commercial services (Lyon et al., 1986, 1995).

The best way to get started using precision agriculture technologies is to use some of the tech-

nologies to solve a specific field problem. The problem may be weeds, or variable fertility of soils, or poor germination. Use the technologies available to identify the locations of problems within the field and devise a solution and apply the solution. It is best to conduct the effort over several years to be sure that the result is not a chance situation with weather or some practice conducted in one certain year.

Infrared, color, or multispectral data acquired a few weeks after germination should provide information on weeds, soil spatial variability, and crop responses to this variability. Remote sensing data acquired during senescence is useful in identifying variability in crop densities and biomass. Data acquired during these two times and at other times during the growing season is also helpful in determining what caused the variability in crop responses.

Many experiments to characterize the potential of a given technology tend to be relatively expensive (Falkner, 1995; Lyon et al., 1995). As the technology and its utility become known, the researcher and industry then seeks to deliver this knowledge or technology at a cost of a few dollars per hectare. If the solution improves the yield in absolute terms, or removes the year to year variability of field yields, costs of this magnitude are economically viable.

A variety of results reported here or elsewhere have demonstrated that available remote sensor and GIS technologies can supply good information for management of crops, soils and waters on a within-field basis. Precision agriculture approaches can be implemented using a suite of these technologies, over time, to potentially improve yields and maintain soil and water quality.

ACKNOWLEDGMENTS

The authors wish to thank a number of people and sponsors for assisting in the development of these results.

The U.S. Environmental Protection Agency has helped to supply funding and aircraft remote sensor data through the National Exposure Research Laboratory Division at Research Triangle Park, NC and Las Vegas, NV, and through the assistance of EPA scientists Ross Lunetta and Clay Lake.

Some of the analysis of aerial photographs and farm conditions was conducted as a student Service Learning project at OSU, as part of a larger national effort called Learn and Serve America by the Ohio Campus Compact via the national Campus Compact at Brown University, as funded by the Corporation for National and Community Service.

Our thanks also go to our Departments at Ohio State University, OSU Extension, Van Wert County air service, Larry Lotz, Nathan Watermeier, Prasanna Gowda, and Jay Johnson.
